Torsional Response and Dissipationless Viscosity in Topological Insulators

Department of Physics, University of Illinois, 1110 West Green St, Urbana IL 61801

We consider the visco-elastic response of the electronic degrees of freedom in 2D and 3D topological insulators (TI). Our primary focus is on the 2D Chern insulator which exhibits a bulk dissipationless viscosity analogous to the quantum Hall viscosity predicted in integer and fractional quantum Hall states. We show that the dissipationless viscosity is the response of a TI to torsional deformations of the underlying lattice geometry. The visco-elastic response also indicates that crystal dislocations in Chern insulators will carry momentum density. We briefly discuss generalizations to 3D which imply that time-reversal invariant TI’s will exhibit a quantum Hall viscosity on their surfaces.

A striking feature of a topological insulator (TI) is its time-topological response. The paradigmatic example is the time-reversal breaking integer quantum Hall effect (IQHE) in 2D which exhibits a Hall conductance that is an integer multiple of $e^2/h$. More recently it was shown that there exist related states in 3D which are time-reversal invariant and exhibit a topological magneto-electric effect (TME). While the electro-magnetic response of topological insulators is the most well-known, in this Letter we consider the visco-elastic response of the electronic degrees of freedom in TIs. Namely, we want to consider the stress response

$$\langle T^{ij} \rangle = \Lambda^{ijk\ell} u_{k\ell} + \eta^{ijk\ell} u_{k\ell}$$

where $T^{ij}$ is the stress-tensor, $\Lambda, \eta$ are the elasticity and viscosity tensors respectively and $u_{ij}$ is the strain tensor. Here we show there is a dissipationless viscosity response in the topological Chern insulator (CI) state analogous to that found in the IQHE and fractional QHE states. While viscosities are normally associated with frictional dissipation, this viscosity, present only when time-reversal symmetry is broken, implies a force perpendicular to the fluid motion similar to the Lorentz force.

In a condensed matter system the electronic stress response can be calculated by coupling the electronic Hamiltonian to perturbations of the background lattice geometry. The topological responses due to geometric curvature have been studied in the language of quantum field theory anomalies. Alternatively, we consider the response of topological insulators to an external torsion field. A heuristic understanding of the difference between curvature and torsion is that when an object traverses a small loop in real space it is rotated if there is non-zero curvature, and translated if there is non-zero torsion. A familiar manifestation of torsion is a crystal dislocation. These line-defects are singular sources of torsion, analogous to a localized magnetic flux line. For example, while dragging an electron around a magnetic flux line its wavefunction is multiplied by a $U(1)$ phase, while for a dislocation line it is multiplied by a translation operator along the Burgers vector. The visco-elastic response is derived as a linear response to torsional perturbations of the underlying material geometry. We find that this response also leads to momentum density localized on crystal dislocations and mention the visco-elastic response of 3D time-reversal invariant topological insulators (3DTI).

To understand the torsion response we will often draw comparisons to the well-known electromagnetic responses of topological insulators which we briefly review now. The responses of the CI and 3DTI to external electromagnetic fields are encapsulated in topological effective actions i.e. free-energy functionals derived from calculating a partition function in the presence of external fields. The QHE and TME are encoded in the effective actions

$$S_{\text{eff}}^{(\text{QHE})}[A_\mu] = \frac{n e^2}{2h} \int d^3 x \epsilon^{\mu\nu\rho} A_\nu \partial_\rho A_\mu$$

$$S_{\text{eff}}^{(\text{TME})}[A_\mu] = \frac{e^2}{4h} \int d^4 x \theta \epsilon^{\mu\nu\sigma\tau} \partial_\mu A_\nu \partial_\sigma A_\tau$$

respectively which are derived from the responses of the topological insulators to an external field $A_\mu$, and in 3D an inhomogeneous scalar ‘axion’ field $\theta$ (note that $n$ is an integer). The nominal current response is $\langle j^\mu \rangle = \delta S_{\text{eff}} / \delta A_\mu$, which gives the QHE and TME when acting on Eq. (2) and (3) respectively. All known topological electro-magnetic responses in various dimensions can be described by similar topological effective actions.

Our primary interest is the 2D CI for which we will use a continuum massive Dirac Hamiltonian as a model. To calculate the visco-elastic response we couple the massive Dirac Hamiltonian to geometric perturbations. Because of its spinor nature, the Dirac Hamiltonian does not couple to geometry through the metric tensor, but instead via the orthonormal triad $e^a$ and its inverse $e_a$ (frame field) and the spin connection $\omega^a_b$. The latin index $a$ labels the particular vector of the frame which, when expanded in terms of a local coordinate basis $\partial / \partial x^\mu = (\partial_1, \partial_2, \partial_3)$, has components $e^a_\mu$. In a lattice version of the theory, the frame is defined by the local orbital orientation. The stress response can be thought of as a functional of $e^a$ and $\omega^a_b$, but we should not take them to be related to each other as they would be in Riemannian geometry. In particular, we will find that the dissipationless viscosity response of the Dirac model is related to torsion.
is convenient, in fact, to set the spin connection to zero such that the torsion is contained in the properties of the triad alone.

The action and Hamiltonian for continuum 2D massive Dirac fermions coupled to a frame field are

\[ S = \int d^3 x \det(e) \psi^\dagger \gamma^0 (p_\mu e^\mu_\alpha \gamma^\alpha - m) \psi \]

\[ H = p_\mu e^\mu_\alpha \Gamma^\alpha + p_\mu e^\mu_\alpha \Gamma^\alpha + m \Gamma^0 \]

(4)

with \( a = 0, 1, 2 \), \( \gamma^a = (\sigma^z, i\sigma^y, -i\sigma^x) \) and \( \Gamma^\alpha = (\sigma^z, \sigma^x, \sigma^y) \). If the frame field is position independent the energy spectrum is simply \( E_\pm = \pm \sqrt{p_1^2 + p_2^2 + m^2} \) with \( p_a = e^\alpha_a p_\alpha \). This is a gapped insulator when \( m \neq 0 \).

Now we will calculate the off-diagonal response of the stress-energy current (analogous to \( \sigma_{xy} \)) due to a perturbation of the triad \( e^p_\alpha(x) = \delta^p_\alpha + \delta e^p_\alpha(x) \) around the trivial background. We will see later that the triad has a simple interpretation in terms of elasticity theory and provides a natural geometric deformation. The stress-energy current (analogous to \( \sigma \))

\[ \psi_p = \frac{e^2}{2\hbar} \sum_{i=0}^N C_i \text{sgn}(M_i) \zeta_{reg} = \frac{1}{16\pi} \sum_{i=0}^N C_i I_T(M_i) \]

(8)

respectively. We can rewrite

\[ I_T(M) = -\frac{M}{\sqrt{\pi}} \int_0^\infty dt t^{1/2} \int_0^\infty dy ye^{-t(y+M^2)} \]

(9)

which yields \( I_T(M) = -2M/\sqrt{\pi} + 2|M|^2 \text{sgn}M + O(\sqrt{\epsilon}) \). We have three physical constraints that will give proper renormalization conditions (i) \( \sigma_{xy} = e^2/\hbar \), \( n \in \mathbb{Z} \) (ii) \( \zeta_{reg} \) is finite and (iii) if \( \sigma_{xy} = 0 \) then \( \zeta_{reg} = 0 \). We know that when the Dirac mass switches sign we go through a phase transition between a trivial insulator and a topological insulator. The sign of \( m \) that gives the topological insulator is regularization dependent, and without loss of generality we pick \( m > 0 \) to be the non-trivial insulator. This means that for \( m < 0 \) we require both \( \sigma_{xy} = \zeta_{reg} = 0 \), which is the origin of the third condition. A solution for \( M_i, C_i \) under the constraints above is always possible. In all cases, one finds that in the non-trivial phase we have

\[ \sigma_{xy} = \frac{e^2}{\hbar} \quad \zeta_{reg} = \frac{h}{8\pi} \left( \frac{|m|}{\hbar^2} \right)^2 \equiv \frac{h}{8\pi \tau^2} \]

(10)

If we had chosen \( m < 0 \) to be the topological phase then the signs of both coefficients would be flipped. Note that we have restored the units in the viscosity response. The dimensions of this coefficient are angular momentum density, which is equivalent to momentum per unit length, and the units of dynamic viscosity (force/velocity). Comparing to the value of the Hall viscosity for the IQHE[5, 6] \( \zeta_{IQHE} = \frac{h}{8\pi \epsilon B} \), we see a similar structure coming from the length scale endowed by the time-reversal breaking field. Also, the viscosity is continuous in the limit \( m \to 0 \) analogous to the \( B \to 0 \) (\( \ell_B \to \infty \)) limit of the IQHE.

To make contact with the literature on the IQH viscosity we will re-derive the Hall viscosity for the CI state using an adiabatic transport calculation. This can be carried out by putting the Dirac equation on a torus and calculating the adiabatic curvature due to shear deformations (equivalently deformations of the modular parameter \( \tau \)) of the torus[5]. Consider a square torus, made in \( \mathbb{R}^2 \)
by identifications \((x, y) \sim (x + a, y + b)\) with \(a, b \in \mathbb{Z}\), with fixed unit volume, and consider area preserving diffeomorphisms, corresponding to spatial metrics of the form

\[
g_{ij} = \frac{1}{\tau_2} \left( \begin{array}{cc} \tau_1 & \tau_1 \\ \tau_1 & |\tau_1|^2 \end{array} \right), \quad g^{ij} = \left( \begin{array}{cc} |\tau_2|^2 & -\tau_1 \\ -\tau_1 & 1/\tau_2 \end{array} \right)
\]

(11)

The basis vectors and the spatial part of the triad are

\[
e_1 = \sqrt{\tau_2} \partial_x, \quad e_2 = \frac{1}{\sqrt{\tau_2}} (-\tau_1 \partial_x + \partial_y)
\]

(12)

\[
e_1 = \frac{1}{\sqrt{\tau_2}} (dx - \tau_1 dy), \quad e_2 = \sqrt{\tau_2} dy
\]

(13)

respectively, and the Hamiltonian is

\[
H = \left( \begin{array}{cc} m & P \\ P & -m \end{array} \right)
\]

(14)

where \(P = \frac{1}{\sqrt{\tau_2}} (\tau p_1 - p_2)\). We define \(P\) as \(P = ||P||^2\).

We consider the ground state in which all of the negative energy states \(\psi_{-}(p_1, p_2; \tau)\) are occupied. The adiabatic connection can be calculated from the explicit form of the single-particle wavefunctions and we find

\[
A = i \sum_{m, n \in \mathbb{Z}} \psi^\dagger_{m, n}(m, n; \tau) d\psi_{-m, n}(m, n; \tau)
\]

(15)

\[
= -i \sum_{m, n \in \mathbb{Z}} f(||P||^2) \frac{1}{2} d\ln \left( \frac{P}{\mathcal{P}} \right)
\]

and where the sums are over the discrete quantized momenta on the torus. This gives the adiabatic curvature

\[
F = i \frac{d\tau \wedge d\bar{\tau}}{2\tau_2} \sum_{m, n} \rho_{m, n} f'(||P||^2).
\]

(17)

If we convert the sum into an integral we find

\[
F = i \frac{d\tau \wedge d\bar{\tau}}{\tau_2} \frac{1}{16\pi} \sum_{m, n} \rho_{m, n} f'(||P||^2).
\]

(18)

which yields the same (unregulated) viscosity as above.

We will now give a physical interpretation in terms of conventional elasticity fields[15]. Assuming we have an elastic medium, we can pick a reference un-displaced state and define a (spacetime) displacement field \(u^\alpha(x)\).

Then the triad can be written as \(e^\alpha_\mu = \delta^\alpha_\mu + w^\alpha_\mu\) where \(w^\alpha_\mu = \partial u^\alpha / \partial x_\mu\) is the distortion tensor[15]. To simplify we assume that \(u^\alpha = 0\) i.e. \(e^\alpha = dt\). Now \(w^\alpha_\mu\) contains the velocity field \(w^A_\mu = v^A\) and the spatial distortion tensor \(w^A_\mu\) where \(A = 1, 2\) and \(i = x, y\). This formulation of the triad in terms of the distortion tensor is consistent with the usual definition as can be seen by calculating the spatial metric

\[
g_{ij} = e^i_\alpha e^j_\beta \delta_{AB} = \delta_{ij} + w_{ij} + w^A_\mu w^B_\mu \delta_{AB}
\]

which matches the metric from elasticity theory[15]. The stress-energy response from Eq. (7) is

\[
\langle T^\mu_\alpha \rangle = \zeta_{\text{reg}} \eta_{\mu \nu \rho} \partial_\nu \partial_\rho e^b_\alpha.
\]

(19)

Since \(e^b_\alpha\) does not enter, this simplifies to a momentum-density \(\langle T^\mu_\alpha \rangle = \zeta_{\text{reg}} \eta_{\mu \nu} \partial_\nu e^b_\alpha\) and a momentum-current \(\langle \eta e^b_\alpha \rangle = \zeta_{\text{reg}} \eta_{\mu \nu \rho} \partial_\nu \partial_\rho e^b_\alpha\). These satisfy the continuity equations \(\partial_\mu \langle T^\mu_\alpha \rangle = -\partial_\alpha \langle \eta e^b_\alpha \rangle\). Restricting ourselves to linear elasticity theory we can freely switch between frame (a) and local coordinate (\(\mu\)) indices in the response equations. Thus \(\langle T^\mu_\alpha \rangle = \langle \eta e^b_\alpha \rangle\). Also, spacetime indices are raised/lowered using the unperturbed metric.

For \(\langle T^\mu_\alpha \rangle \neq 0\), \(u^A\) cannot be single-valued: it is a dislocation with Burgers vector \(b^A\) at \(x_0\), for which \(e^i_\mu \partial_\mu w^A_\mu = \zeta_{\text{reg}} \eta_{\mu \nu \rho} \partial_\nu \partial_\rho e^b_\alpha\) (where \(x_0\) is the locations of dislocations and \(b^m\) is the Burgers vector of the \(m\)-th dislocation). For a lattice system, the dislocation is the fundamental quantized unit of torsion since transporting an electron around a defect translates the wavefunction by a multiple of a lattice constant. An edge dislocation with \(b = a\) (where \(a\) is the lattice constant) contains a momentum density of \(b/a^2\) along the direction of \(b\). To think about smooth torsion deformations we need to take the continuum limit and deformations are a continuous distribution of dislocations. As illustrated in Fig. 1(a), this response is a momentum density bound to a torsion ‘flux’ analogous to charge density bound to an electromagnetic flux in the bulk of a CI. Note that Fig. 1 is heuristic, since a realistic...
edge dislocation is not simply a cut into the material.

The physical interpretation of the momentum current response \( T_{\mu \nu} \) is not as simple because it is more difficult to picture a torsion electric field. In the 2D plane, a moving dislocation (torsion flux) will generate a torsion electric field via the analog Faraday effect. Since we have seen that dislocations naturally carry a momentum density, moving it will generate a momentum-current density as per the response equation. In fact, the momentum-current due to the moving dislocation is being carried perpendicular to the induced torsion electric field.

Another realization of the momentum current response is obtained by using another instance of the Faraday effect: roll the CI into a cylinder and then insert a torsion flux into the cylindrical hole. This can be thought of as threading a dislocation into the hole of the cylinder so that any particles traveling around the hole will be translated by the Burgers vector \( b_{\alpha} \) of the threaded dislocation. Changing \( b_{\alpha} \) as a function of time creates a torsion electric field the same way that a changing magnetic flux causes a circulating electric field. There is one key difference with the electromagnetic case: in order to preserve area the threaded torsion flux cannot be uniform and the translation must average to zero over the length of the cylinder as illustrated in Fig. 1(b). Thus, the natural experiment is a torque experiment where a cylinder of CI is twisted. This is equivalent to threading a dislocation with a position dependent Burgers vector.

The formalism developed here is a natural generalization of classical elasticity. If \( u_{\alpha} = 0 \) on the boundary, we can rewrite the effective Lagrangian (Eq. (7)) as

\[
\mathcal{L}_{\text{eff}} = \frac{\zeta_{\text{reg}}}{2} \epsilon_{\mu \nu \rho \sigma} \eta_{a b} u_{\mu}^{a} \partial_{\nu} u_{\rho}^{b} = \frac{\zeta_{\text{reg}}}{2} \epsilon_{\mu \nu \rho \sigma} \eta_{a b} (u_{\mu} \partial_{\nu} u_{\rho} + M_{\mu \rho} \partial_{\nu} M_{\rho \lambda} + 2 M_{\mu \sigma} \partial_{\nu} u_{\rho \lambda})
\]

\[
u_{\mu \nu} = \frac{1}{2} \left( \frac{\partial u_{\mu}}{\partial x_{\nu}} + \frac{\partial u_{\nu}}{\partial x_{\mu}} \right), \quad M_{\mu \nu} = \frac{1}{2} \left( \frac{\partial u_{\mu}}{\partial x_{\nu}} - \frac{\partial u_{\nu}}{\partial x_{\mu}} \right)
\]

within linear elasticity theory: \( u_{\mu \nu} \) and \( M_{\mu \nu} \) are the strain and rotation tensors respectively. The first term is the torsional viscosity which is the Lorentz invariant version of the QH viscosity[5]. The stress-energy tensor response \( T_{\mu \nu} \) is not necessarily symmetric and thus does not fit in classical elasticity (independent of \( M_{\mu \nu} \)). It is natural to interpret the stress-response within micropolar (Cosserat) elasticity theory which takes the local rotational degrees of freedom of the medium into account[16, 17]. The distinction here is clear since Dirac fermions couple directly to the triad and not the metric, and the spinor nature of the Dirac equation gives local rotational degrees of freedom to which the triad couples.

Finally, we briefly mention two interesting 3D generalizations, the details of which will be presented elsewhere. The first is an anisotropic extension to 3D with the form

\[
S_{\text{eff}}^{[e_{\mu}]} = \frac{\zeta_{\mu}}{2} \int d^{4}x \epsilon_{\mu \nu \rho \sigma} e_{\nu}^{a} \partial_{\rho} e_{\sigma}^{b} \eta_{a b} \tag{20}
\]

where \( \zeta_{\mu} \) is a vector of viscosity coefficients which is analogous to the 3D IQHE[18]. IQHE or QAHE states which are ‘stacked’ along a direction perpendicular to the vector \( \zeta_{\mu} \) exhibit the viscosity response in Eq. (20). This action is basically equivalent to the 3D viscosity response of Ref. [9]. For a 3D strong TI we find

\[
S_{\text{eff}}^{[e_{\mu}]} = \frac{1}{2} \int d^{4}x \zeta^{(3)}_{\mu \nu \rho \sigma} \partial_{\nu} e_{\rho}^{a} \partial_{\sigma} e_{\rho}^{b} \eta_{a b} \tag{21}
\]

which is a total derivative unless \( \zeta^{(3)} \) is not a constant. Hence, on the surface of a 3DTI (where \( \zeta^{(3)} \) has a domain-wall) there will be a dissipationless visco-elastic response. This is expected since the surface also contains a QHE. In gravity theories with torsion the isotropic term is known as the Nieh-Yan term[19] and the anisotropic term is the (anisotropic) extension of the triad CS term.

We leave open the question on how to experimentally measure this response in 2DEGs or TIs. First, unlike electric charge, momentum is not conserved when translation symmetry is broken, as it is in any realistic material. Additionally, our result seems to be generically non-quantized and somewhat regularization dependent.

The reason these issues do not appear in the quantum Hall calculations is because the kinetic energy is quenched and each single-particle state contributes the same amount to the viscosity. We strongly believe this would be modified if one considers a lattice with a uniform magnetic field (Hofstadter problem) instead of a continuum Hamiltonian. Because the Hall viscosity is a mix of a geometric response with some topological flavor, it will have some non-universal features in any realistic system. With translation and rotation symmetry the viscosity was shown to be quantized[9], but the only physical response that has been linked to viscosity, and is insensitive to translational invariance is the edge-dipole moment[8] However, the latter result only applies to un-reconstructed edges and is sure to be modified with real edge theories. The connection between the quantitative value of the viscosity and real experiments, as well as the bulk-edge correspondence for generic edge theories is not well-understood and remains an open question that needs to be carefully considered.

We thank J. D. Bjorken, K. Fang, L. Freidel, C. Hoyos-Badajoz, X.-L. Qi, A. Randono, S. Ryu, and D.T. Son for discussions. This work was supported in part by NSF grant DMR 0758462 (TLH,EF), ICMT (TLH), and the U.S. Department of Energy contract DE-FG02-91-ER40709 (RGL). We thank the Galileo Galilei Institute.
