(Received 6 December 2017; revised manuscript received 7 February 2018; published 14 May 2018)

When a beam of light is laterally confined, its field distribution can exhibit points where the local magnetic and electric field vectors spin in a plane containing the propagation direction of the electromagnetic wave. The phenomenon indicates the presence of a nonzero transverse spin density. Here, we experimentally investigate this transverse spin density of both magnetic and electric fields, occurring in highly confined structured fields of light. Our scheme relies on the utilization of a high-refractive-index nanoparticle as a local field probe, exhibiting magnetic and electric dipole resonances in the visible spectral range. Because of the directional emission of dipole moments that spin around an axis parallel to a nearby dielectric interface, such a probe particle is capable of locally sensing the magnetic and electric transverse spin density of a tightly focused beam impinging under normal incidence with respect to said interface. We exploit the achieved experimental results to emphasize the difference between magnetic and electric transverse spin densities.

Subject Areas: Optics

I. INTRODUCTION

The transverse spin density (TSD) of light describes field vectors, which spin transversely with respect to the local propagation direction of the electromagnetic wave [1–3]. In nature, such polarization states occur when electromagnetic waves experience strong lateral confinement since the appearance of transverse spin is intimately linked to the presence of longitudinal field components [1–3]. Typical optical systems exhibiting a TSD are waveguide modes [4–7], surface plasmon polaritons [8–10], near fields of nanostructures [11], whispering gallery modes [12], interfering plane waves [13], and tightly focused beams [14–16].

In recent years, a wide variety of applications have led to a continuously increasing interest in the TSD (see, for instance, Refs. [1–3,7] and references therein), particularly because of a related directional emission and coupling effect [17]. The phenomenon, which is often referred to as spin-momentum locking [18,19], can be used to implement spin-dependent signal routing [17,20,21] and single-atom optical devices such as isolators and circulators [22,23]. Thus, the TSD constitutes the foundation for novel quantum information processing concepts at the nanoscale [5,7]. Further potential applications of the TSD can be found in particle manipulation experiments in optical tweezers [10,13,14] and sensing, for example, of magnetically induced circular dichroism [24,25]. This interest in the TSD also led to the development of highly sensitive techniques, capable of measuring the TSD in propagating and evanescent waves [15,26].

Although the experimental techniques introduced in Refs. [15,26] are mainly concerned with the TSD of the electric field, from a theoretical point of view, both magnetic and electric components contribute equally to the total spin density $s$ [1–3]:

$$s = \frac{\text{Im}[\mu_0 \mathbf{H} \times \mathbf{H} + \epsilon_0 \mathbf{E} \times \mathbf{E}]}{4\omega} \equiv s_H + s_E.$$  \hspace{1cm} (1)

where $\omega$ refers to the angular frequency of the time-harmonic wave, $\mathbf{H}$ and $\mathbf{E}$ denote the magnetic and the electric fields, and $\mu_0$ and $\epsilon_0$ represent the permeability and the permittivity in vacuum. This equally weighted split into $s_E$ and $s_H$ is often referred to as dual symmetry [27] or electromagnetic democracy [28]. While in the highly symmetric case of a single circularly polarized plane wave the spin density is purely longitudinal and the magnetic and electric components are equal, $s_H^2 = s_E^2$  [1,2,28,29], in
more general fields of light, this equivalence of $s_H$ and $s_E$ does not hold.

Here, we explore, both theoretically and experimentally, the fundamental difference between the TSD of the magnetic and the electric field. At first, we theoretically elaborate on the distribution and composition of the TSD in the simplified exemplary scenario of a linearly polarized Gaussian beam. Then, we experimentally investigate the TSD of the magnetic and the electric field in tightly focused beams of light. While for the electric TSD a suitable measurement technique has been presented in Ref. [15], the magnetic component of the TSD has, to the best of our knowledge, not been experimentally studied so far. On these grounds, we detail, for the first time, a versatile experimental approach for reconstructing the TSD of the magnetic field at the nanoscale, which, at the same time, allows us to access the TSD of the electric field. Finally, we apply the technique to three different tightly focused polarization tailored beams of light and compare the reconstructed components of the respective TSD.

II. MAGNETIC AND ELECTRIC TRANSVERSE SPIN

We begin the discussion by exemplarily considering a paraxial, linearly $x$-polarized, monochromatic Gaussian beam of light, whose electric field distribution can be approximated by [30]

$$
E(x, y, z) \approx E_0 \frac{z_0 e_x}{z_0 + iz} \exp \left[ i k z - \frac{k r^2}{2 z_0 + i 2 z} \right],
$$

(2)

where $z_0$ and $E_0$ represent the Rayleigh range and amplitude of the beam, with $r = (x^2 + y^2)^{1/2}$ as a radial coordinate. Evidently, such a field distribution does not fulfill the transverse constraint of Maxwell’s equations—Gauss’s law in vacuum [31]—$\nabla \cdot E = 0$. However, it is possible to revise Eq. (2) accordingly by introducing a longitudinal field component [32,33]. In the focal plane ($z = 0$), a suitably adapted field distribution can be written as [1,2]

$$
E(x, y) \approx E_0 \left( e_x + \frac{i x e_z}{z_0} \right) \exp \left[ -\frac{k r^2}{2 z_0} \right].
$$

(3)

Following this line of arguments, we can derive a similar expression for the focal distribution of the magnetic field of the described Gaussian beam. By starting with a $y$-polarized magnetic field—perpendicular to the $x$-polarized electric field—and by applying Gauss’s law of the magnetic field [31], $\nabla \cdot H = 0$, we obtain [1]

$$
H(x, y) \approx H_0 \left( e_y + \frac{y e_z}{z_0} \right) \exp \left[ -\frac{k r^2}{2 z_0} \right],
$$

(4)

with $H_0 = \sqrt{\varepsilon_0 / \mu_0 E_0}$. It is important to note that Eqs. (3) and (4) represent approximations and are only valid for paraxial or weakly focused Gaussian beams of light. However, the equations contain several important features, which illustrate the central message of this paper: a nonzero phase difference between longitudinal and transverse field components, and differing spatial distributions of the magnetic and the electric TSD.

At first, we elaborate on the relative phases of the individual field components. As indicated by the imaginary units in Eqs. (3) and (4), the longitudinal field components are $\pm \pi / 2$ out of phase with respect to the transverse field components, resulting in transversely spinning magnetic and electric field vectors wherever the corresponding field components $H_y$ and $H_z$ or $E_x$ and $E_z$ overlap [2]. For further investigation of the resulting transverse spin, we calculate the focal spin density distribution by inserting Eqs. (3) and (4) in Eq. (1), which yields [1]

$$
s \approx (\varepsilon_0 E_0^2 e_y - \mu_0 H_0^2 e_z) \exp \left( -\frac{k z^2}{2 z_0} \right).
$$

(5)

As we can see, $s$ is a purely transverse, azimuthally oriented vector field, since the longitudinal component $s^z$ is zero. For illustration, in Fig. 1(a), we depict the TSD, $s^\perp = s_H^\perp + s_E^\perp = (s_H^x + s_E^x) e_x + (s_H^y + s_E^y) e_y$ (see the yellow arrowheads), on top of the Gaussian distribution of the $x$ component of the electric field intensity ($|E_x|^2$), using $x$ and $y$ coordinates normalized to the beam waist $w_0 = (2 z_0 / k)^{1/2}$. The amplitude of the total TSD depends on the radial distance to the optical axis, but it is independent of the azimuth within the beam. However, despite the cylindrical symmetry of the total TSD, its type (electric or magnetic) changes depending on the azimuth.

To emphasize the spatially dependent composition of the TSD, we plot the individual contributions $s_H^x$, $s_E^x$, $s_H^y$, and $s_E^y$ in Fig. 1(b). The TSD of the electric field exhibits a two-lobe pattern along the $x$ axis for $s_H^x$ ($s_E^x = 0$), while the two lobes of the TSD of the magnetic field are arranged along the $y$ axis for $s_H^y$ ($s_E^y = 0$). Different color codes are used to highlight the differences between magnetic and electric TSDs. The two distributions of $s_H^x$ and $s_E^x$ are rotated by $90^\circ$ with respect to each other, which is a direct consequence of the orthogonality of the magnetic and electric transverse field components of the linearly polarized Gaussian beam exemplarily studied here.

In conclusion, the results we derived from this simplified model beam highlight the difference of the distributions of $s_H^x$ and $s_E^x$ in spatially confined light [1]. This notion is essential, for instance, in spin-momentum locking experiments based on silicon nanophotonics [21,34], where both electric and magnetic dipolar modes are supported [35–37]. The example also emphasizes the importance of distinguishing $s_H^x$ and $s_E^x$ experimentally [21]. While techniques...
for measuring $\mathbf{s}_H^E$ have been presented recently [15,26], in the following we discuss a measurement concept for $\mathbf{s}_H^E$, allowing for a direct comparison between $\mathbf{s}_H^E$ and $\mathbf{s}_E^H$ in complex and highly confined light fields.

III. EXPERIMENTAL CONCEPT

Our experimental approach for simultaneously measuring $\mathbf{s}_H^E$ and $\mathbf{s}_E^H$ relies on a field probe that exhibits a magnetic as well as an electric dipole resonance. In this regard, suitable field probes, which support both types of modes, are high-refractive-index nanoparticles [35,38,39]. Here, we utilize a silicon (Si) nanosphere with core radius $r_{\text{Si}} = 79$ nm and an estimated silicon dioxide (SiO$_2$) shell of thickness $\delta = 8$ nm as a probe. The particle is sitting on a glass substrate [see sketch in Fig. 2(a)] attached to a 3D-piezo stage, enabling us to scan the field probe through the focal plane of a tightly focused beam. A scanning electron micrograph of the particle is shown in the inset. In order to understand the actual scattering behavior of our probe, we first analyze its scattering cross section [see Fig. 2(b)] using Mie theory [40]. For the calculation, we assumed a particle in free space, not considering the glass substrate. The black line indicates the total scattering cross section of the particle, with the red and blue lines representing the contributions of the magnetic and electric dipolar modes, respectively. Due to the spectral overlap between the electric and magnetic resonances, a generic input field excites a dipolar mode with simultaneously electric and magnetic contributions in the shown spectral range [35,38,41,42]. With the objective to induce electric and magnetic dipole moments with a comparatively high efficiency, we choose an excitation wavelength between the maxima of both resonances (here, $\lambda = 630$ nm) for the TSD sensing experiment. Using a point dipole approximation, the electric ($\mathbf{p}$) and magnetic ($\mathbf{m}$) dipole moments of the particle are thus both proportional to the local excitation fields, $\mathbf{p} \propto \mathbf{E}$ and $\mathbf{m} \propto \mathbf{H}$, while higher-order multipoles can be neglected.

The direct link between the excitation field and the induced dipole moments is the basis of our TSD reconstruction approach. When we can determine the magnetic and the electric transversely spinning dipole moments of our probe particle from the light that it scatters into the far field, we effectively measure the TSD of the
excitation field [15]. In order to achieve an unambiguous reconstruction of \( \mathbf{s}_{H}^2 \) and \( \mathbf{s}_{E}^2 \), a detailed analysis of the simultaneous emission of magnetic and electric dipoles close to a dielectric interface is required.

In comparison to a dipole in free space, the far-field emission pattern of a dipole above a dielectric substrate is strongly altered by the air-glass interface [32,43]. Because of the dominant emission of a dipole into the higher-index material [43], we are specifically interested in the light transmitted into the glass half-space. To calculate the directional emission, we use a plane-wave decomposition with the transverse electric (\( E_{x} \)) and transverse magnetic (\( E_{p} \)) polarization states as a basis. Following Ref. [32], the far field in the glass half-space, \( \mathbf{E}_{f} = E_{p}\mathbf{e}_{p} + E_{x}\mathbf{e}_{x} \), of an arbitrarily polarized electromagnetic dipole can be written in compact form as

\[
\mathbf{E}_{f}(k_{x},k_{y}) \propto \mathbf{C}\mathbf{T}(\mathbf{Mp} + \mathbf{R}\mathbf{Mm})/c_{0},
\]

with \( C = (k_{0}^{2}n^{2} - k_{d}^{2})^{1/2}/k_{z}\cdot \exp[ik_{d}d] \). The transverse wave number is defined as \( k_{\perp} = (k_{0}^{2} + k_{d}^{2})^{1/2} \), while the longitudinal wave number can be calculated by \( k_{z} = (k_{0}^{2} - k_{d}^{2})^{1/2} \). The parameter \( d \) represents the distance between the dipole and the interface, and \( c_{0} \) refers to the vacuum speed of light. The matrix \( \mathbf{T} \) consists of the Fresnel transmission coefficients \( t_{x} \) and \( t_{p} \) [32],

\[
\mathbf{T} = \begin{pmatrix} t_{p} & 0 \\ 0 & t_{x} \end{pmatrix},
\]

while \( \mathbf{M} \) is a rotation matrix, representing the overlap of the electric and the magnetic dipole moments with the field vectors of the plane waves of the angular spectrum [44],

\[
\mathbf{M} = \begin{pmatrix} k_{x}k_{0} & k_{y}k_{0} & -k_{z}k_{0} \\ k_{x}k_{0} & k_{y}k_{0} & -k_{z}k_{0} \\ -k_{x}k_{0} & -k_{y}k_{0} & k_{z}k_{0} \end{pmatrix}.
\]

To calculate the far field of the magnetic components of the dipole emitter, a second rotation matrix \( \mathbf{R} \) is introduced, which is required because of interchanging electric and magnetic field vectors [31,32]:

\[
\mathbf{R} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.
\]

We utilize Eq. (6) to exemplarily calculate the far-field emission pattern \( (I = I_{p} + I_{s} \propto |E_{p}|^{2} + |E_{s}|^{2}) \) of a magnetic dipole spinning around an axis parallel to the air-glass interface. For \( \mathbf{m} = (0,1,i) \), we obtain the emission pattern depicted as the side-view plot in Fig. 2(c), where, for the sake of completeness, we show the emission into the air half-space as well. For the distance between the dipole and the interface in the calculations, we use the radius of the particle, \( r_{0} = r_{Si} + \delta = 87 \) nm. We see that, similar to a transversely spinning electric dipole moment (see, for example, Refs. [20,45]), the transversely spinning magnetic dipole moment results in a directional far-field emission into the angular region above the critical angle \( [k_{\perp} > k_{0}, k_{z} = (k_{0}^{2} - k_{d}^{2})^{1/2}] \). By assuming \( \mathbf{m} \propto \mathbf{H} \), this links the TSD of the magnetic field to the far-field directionality.

In this context, the objective of the following theoretical discussion is the derivation of a quantitative connection between the TSD (magnetic and electric) and the directional emission pattern of the probe particle above the critical angle. For that purpose, we need to calculate the difference of the light scattered into opposite transverse directions for a general electromagnetic dipole [15]. First, we consider the directionality along the \( x \) direction, \( k_{x} = \pm k_{\perp} \) and \( k_{y} = 0 \), and above the critical angle, \( k_{1} > k_{0} \). Calculating the difference between the light scattered in the positive and negative \( x \) directions for both polarization states, \( \Delta I_{x}^{\pm} = I_{x}(k_{0},+k_{x}) - I_{x}(k_{0},-k_{x}) \), results in

\[
\Delta I_{x}^{\pm} = D|t_{x}|^{2} \left[ \frac{|k_{z}|}{k_{0}} \frac{\text{Im}(m_{1}^{*}p_{1})}{c_{0}} - \frac{\text{Re}(m_{1}^{*}p_{1})}{c_{0}} \right],
\]

with \( D = 4C^{2}k_{\perp}/k_{0} \). By performing a similar calculation for the \( y \) direction, \( \Delta I_{y}^{\pm} = I_{y}(0,+k_{y}) - I_{y}(0,-k_{y}) \) and \( \Delta I_{y}^{\pm} = I_{y}(0,-k_{y}) - I_{y}(0, k_{y}) \), we obtain

\[
\Delta I_{y}^{\mp} = D|t_{y}|^{2} \left[ \frac{|k_{z}|}{k_{0}} \frac{\text{Im}(m_{2}^{*}m_{2})}{c_{0}} + \frac{\text{Re}(m_{2}^{*}m_{2})}{c_{0}} \right].
\]

For each of Eqs. (10)–(13), we can discern two different terms. The first terms include only electric or magnetic dipole components, while the second terms consist of a mixture of both electric and magnetic dipole components. A comparison of the purely magnetic and purely electric terms with the magnetic and electric components of the TSD—\( s_{E}^{H}, s_{E}^{H} \propto \text{Im}(H_{x}^{2}H_{x}^{2}), s_{E}^{H} \propto \text{Im}(E_{x}^{2}E_{x}^{2}), s_{E}^{H} \propto \text{Im}(E_{z}^{2}E_{z}^{2}) \)—reveals a strong similarity. Considering the aforementioned dipole approximation of the scattering response of the particle, \( \mathbf{p} \propto \mathbf{E} \) and \( \mathbf{m} \propto \mathbf{H} \), we see that the first terms in Eqs. (10)–(13) are proportional to the individual components of the TSD. However, the four equations contain additional terms, which represent the interference of electric and magnetic dipole components. A simple difference measurement of the scattered light—as discussed in Ref. [15]—would therefore not be sufficient to
reconstruct the TSD. Nonetheless, it is possible to unambiguously distinguish between the terms representing the TSD and the nonrelevant electromagnetic interference terms by measuring the directional emission for two different transverse wave numbers, \( k_{1,1} \) and \( k_{1,2} \), since only the terms corresponding to the TSD exhibit factors depending on \( k_x \). For example, by measuring \( \Delta s_{1,1}^{x,p} I_{s} \) and \( \Delta s_{1,2}^{x,p} I_{s} \), we obtain two linearly independent equations, which can be solved for the term representing \( s_{y}^{x} \). The same approach can be utilized for the three other components of the transverse spin density—\( s_{y}^{y} \), \( s_{x}^{x} \), and \( s_{x}^{y} \).

With this theoretical consideration in mind, we can finally design an experimental procedure, capable of measuring the magnetic and electric TSDs of an incoming tightly focused beam. Figure 2(d) shows a sketch of our setup. A polarization tailored beam is tightly focused by a microscope objective with NA = 0.9. The resulting focal field is probed by the Si particle immobilized on a glass substrate. The probe can be scanned through the focal plane by a 3D-piezo stage. Below the substrate, an oil-substrate. The polarization, to be observed in the back focal plane (BFP) of the detection path. In particular, imaging the BFP after passing through the WP can be identified as one of the main sources of error since the two partial beams are impinging with respect to each other. The experimental results are in very good agreement with the theoretical distributions (see insets) calculated with vectorial diffraction theory [32,46]. Minor deviations are caused by imperfections of the incoming beam, the probe particle, and the elements in the detection path. In particular, imaging the BFP after passing through the WP can be identified as one of the main sources of error since the two partial beams are impinging...
features of our approach is sensitive and allows for demonstrating the main limitations. Nonetheless, it can be seen that our measurement in insets on top of the central and right columns of Fig. 4, we see a strong magnetic TSD and a very weak (theoretical predictions and the experimentally measured distributions of \( s_H \) and \( s_E \) are shown in Figs. 4(e)–4(h). We see a good overlap of theory and experiment, effectively verifying the aforementioned considerations. In particular, we see a strong magnetic TSD and a very weak (theoretically zero-valued) electric TSD.

When comparing these results with the distributions of the tightly focused radially polarized beam plotted in Figs. 4(i)–4(l), we see that, as expected, \( s_H \) and \( s_E \) are essentially interchanged. This time, we obtain a strong electric TSD accompanied by a weak (ideally zero-valued) magnetic TSD. The apparent minor rotations of the experimental distributions of \( s_E \) with respect to the theoretical prediction are caused by aberrations of the incoming beam and deviations in the response of the probe particle in combination with the aforementioned imperfections of the detection path.

**V. CONCLUSION**

In conclusion, we presented a probe-based scanning technique, which allows for the simultaneous reconstruction and distinction of the TSD of the magnetic and the electric field. This was achieved by analyzing the far-field directionality of the light scattered off the nanoprobe. We utilized the technique to emphasize the importance of
distinguishing the magnetic and the electric components of the TSD in the case of highly confined light. In the process, we demonstrated the difference between the distributions of \( s_H^⊥ \) and \( s_E^⊥ \) in a tightly focused linearly polarized beam. In particular, we showed their 90° rotation with respect to each other. Additionally, we investigated \( s_H^⊥ \) and \( s_E^⊥ \) in tightly focused azimuthally and radially polarized beams. Thereby, we emphasized that the radially polarized beam exhibits purely electric TSD, while the azimuthally polarized beam exhibits purely magnetic TSD.

These beams can be used, for instance, to distinguish whether an observed effect is dependent on \( s_H^⊥ \), \( s_E^⊥ \), or their interplay. A possible application can be found in the optical manipulation of particles exhibiting magnetic and electric dipole resonances. There, azimuthally and radially polarized beams could be used to investigate light-matter spin-angular-momentum transfer for magnetic and electric fields individually [13,48]. On the other hand, the interplay between \( s_H^⊥ \) and \( s_E^⊥ \) can be an important factor in magnetolectric coupling [48,49].

From a general and more conceptional point of view, although the interaction of light and matter is, in many scenarios, mainly governed by the electric field and the corresponding spin density, our results demonstrate the relevance of the dual symmetry (electromagnetic democracy) representation of the spin angular momentum of light. In this regard, our work takes its place alongside recent experimental efforts to distinguish the different and more elusive components of linear and angular momenta of light [50].

Most importantly, by being able to influence and tailor the magnetic and electric parts of the TSD separately, we anticipate that the spin-momentum locking of transversely spinning magnetic dipoles, an effect that has recently been investigated in Refs. [51,52], will gain relevance in upcoming experimental and theoretical studies, similar to those [35–37], the spin-momentum locking of combined electric and magnetic dipoles represents a promising route towards signal routing and polarization multiplexing at the nanoscale.
