(Dated: April 10, 2017)

A recent rejuvenation of experimental and theoretical interest in the physics of few-body systems has provided deep, fundamental insights into a broad range of problems. Few-body physics is a cross-cutting discipline not restricted to conventional subject areas such as nuclear physics or atomic or molecular physics. To a large degree, the recent explosion of interest in this subject has been sparked by dramatic enhancements of experimental capabilities in ultracold atomic systems over the past decade, which now permit atoms and molecules to be explored deep in the quantum mechanical limit with controllable two-body interactions. This control, typically enabled by magnetic or electromagnetically-dressed Fano-Feshbach resonances, allows in particular access to the range of universal few-body physics, where two-body scattering lengths far exceed all other length scales in the problem. The Efimov effect, where 3 particles experiencing short-range interactions can counterintuitively exhibit an infinite number of bound or quasi-bound energy levels, is the most famous example of universality. Tremendous progress in the field of universal Efimov physics has taken off, driven particularly by a combination of experimental and theoretical studies in the past decade, and prior to the first observation in 2006, by an extensive set of theoretical studies dating back to 1970. Because experimental observations of Efimov physics have usually relied on resonances or interference phenomena in three-body recombination, this connects naturally with the processes of molecule formation in a low temperature gas of atoms or nucleons, and more generally with N-body recombination processes. Some other topics not closely related to the Efimov effect are also reviewed in this article, including confinement-induced resonances for explorations of lower-dimensionality systems, and some chemically interesting systems with longer-range forces such as the ion-atom-atom recombination problem.

I. INTRODUCTION AND OVERVIEW

Spectacular recent breakthroughs for the three-body problem with near-resonant two-body interaction, in both experiments and theories, have spawned this review of universal few-body physics, which concentrates on systems with finite-range interactions. Vitaly Efimov’s 1970 prediction (Efimov, 1970) that an infinite family of universal three-body states should emerge when two or more two-body scattering lengths are sufficiently large in magnitude first received partial experimental confirmation in 2006 by Rudi Grimm’s group in Innsbruck (Kraemer et al., 2006). That development was quickly followed in 2006 by Rudi Grimm’s group in Innsbruck (Kraemer

A. Systems with finite range interactions

It is reasonable to ask why finding a new family of resonances has generated such excitement in few-body physics, excitement that has translated into an exponentially growing rate of citations for the 1970 Efimov paper during the past 15 years. In fact these resonances are unique and counterintuitive. For every previously known example of a system where infinitely many bound states or resonances exist that converge to a breakup threshold, the forces were infinite in their extent. The best known example of this is of course the asymptotically attractive Coulomb potential \( V(r) \rightarrow -1/r \) which has an energy level formula \( E_n \propto -1/n^2 \), and a second example is the charge-dipole two-body potential \( V(r) \rightarrow -(s^2 + 1/4)/2r^2 \) at \( r > r_0 \) which has (for a system of units with reduced mass \( \mu = 1 \)) an energy level formula \( E_n = E_0 \exp(-2\pi n/s) \). The presence of a finite versus infinite number of quantized levels below a threshold hinges on the convergence or non-convergence of the zero-energy JWKB phase integral with Langer correction included. (Vol.II of (Morse and Feshbach, 1953) presents a pedagogical derivation of the Langer correction needed for accurate semiclassical calculations, e.g. when the independent coordinate domain is semi-infinite or finite as is true for the radial coordinate in three-dimensional problems.) That is, one can deduce the energy level formula relevant to a given two-body potential energy function \( V(r) \) by evaluating the zero energy total phase \( \phi = \int_{r_0}^{\infty} \sqrt{-2\mu V(r)/\hbar^2 - \frac{1}{2m}} \, dr \). If this \( \phi \) is infinite, then the number of converging energy levels will also be infinite, whereas if \( \phi \) is finite then their number is also finite. This type of analysis also applies to the recently predicted “super-Efimov effect” (Gao et al., 2015; Gridnev, 2014; Moroz, 2014; Nishida et al., 2013; Volosniev et al., 2014) which is likewise predicted to yield an infinite sequence of bound (or resonant) levels for a system of three fermions in 2 dimensions, (see also (Efremov et al., 2013)) with a density of states far smaller than in the original Efimov effect.

A common thread running through this story is the fact that hyperspherical coordinate techniques played a key role in the early theoretical predictions of the Thomas and Efimov effects in pre-1980 studies, and they have
played an equally crucial role in showing later that ultracold quantum gases should provide a powerful way to observe universal Efimov physics, by linking the Efimov effect quantitatively to the loss process of three-body recombination. Hyperspherical studies have shown unusual flexibility, as they have been used on the one hand with zero-range regularized pseudopotential interactions to obtain closed-form analytical results (Efimov, 1970, 1971, 1973a, 1979; Kartavtsev and Macek, 2002; Macek, 1986, 2002; Macek et al., 2005; Mehta et al., 2008; Nielsen et al., 2001; Nielsen and Macek, 1999; Watanabe and Komine, 1989) and on the other hand as the basis for quantitative numerical solutions using finite-range analytical or numerical three-body Hamiltonians (D’Incao and Esry, 2005; Esry and Greene, 2006; Esry et al., 1999, 1996a; Suno et al., 2002; Wang et al., 2012a, d). This flexibility has led to a tremendous deepening of our understanding of three-body recombination and atom-dimer elastic and inelastic scattering over the past two decades, both the quantitative understanding and, equally important, qualitative and semi-quantitative ways to understand the main reaction pathways which govern the corresponding physical mechanisms. Despite this headway, there has not been a comprehensive review or monograph that has presented the full hyperspherical methodology, nor has there been one that covered much of the connections with diverse areas of physics from nuclear systems to cold atoms to exotic species and atomic electron states, and one of the goals of the present review is to bridge this gap in the existing literature.

The concepts of the hyperspherical approach are of course far from being a new innovation in few-body theoretical physics. They go back at least as far as the pioneering work of Llewellyn Hilleth Thomas,(Thomas, 1935) who realized that three nucleons whose ratio of potential range to scattering length becomes arbitrarily small, \( r_0/|a| \to 0 \), must have a ground state energy that “collapses” to \( E \to -\infty \). The triton model considered by Thomas is depicted in Fig.2. This was demonstrated by showing that the effective potential energy of such a system, as a function of the hyperradius \( R \) (Thomas denoted this variable as \( s \)), has the form \(-1/R^2\), a potential that exhibits the well-known “fall to the center” collapse of its ground state energy, as is discussed in quantum mechanics textbooks (Landau and Lifshitz, 1997). Another early application of hyperspherical coordinates framework was developed by Julian Schwinger’s student at Harvard, R. E. Clapp, in his PhD thesis work on the triton binding energy (Clapp, 1949). Fock’s 1958 study of the analytical nature of the electronic helium atom wavefunction at small hyperradii also utilized hyperspherical coordinates in a fundamental way (Fock, 1958).

Some of the deepest insights into the nature of the three-body problem have emerged from Macek’s adiabatic hyperspherical methodology (Macek, 1968). The latter consists of a comprehensive theoretical framework in which the Hamiltonian of the system is initially diagonalized at fixed values of the hyperradius \( R \), yielding adi-
abatic curves which represent the energies of the system as functions of $R$. These give an immediate, dynamics-based representation of the available reaction pathways for any given system, and highlight the emerged structure of the bound and quasi-bound states of the system as well as their excitation and decay mechanisms (Fano, 1976, 1983; Lin, 1986, 1995). Coupling matrix elements can also be computed which permit, as is shown in this review article, a systematic solution of the full three-body Schrödinger equation to the accuracy desired for arbitrary bound state problems as well as two-body inelastic and rearrangement collisions (A+BC), three-body collisions (A+B+C), and photon-assisted collision processes (Fink and Zoller, 1985).

**B. Coulomb Systems**

The three-body problem in quantum mechanics with Coulomb interactions has generated intense effort throughout the past century. Early in the days of the “old quantum theory”, it was a major problem to understand the ground and excited states of the helium atom. With Schrödinger’s wave mechanics, in combination with other tools such as the Ritz variational method, it became possible by the 1930s to calculate properties of such low-lying states in the three-body Coulomb problem to high precision. For higher excited states lying in the two-body or three-body continua, however, progress was much slower. The ability to nonperturbatively calculate the simple process of electron impact ionization of hydrogen at low energies ($< 1$ eV) above the double escape threshold, for instance, did not emerge until the 1990s (Bartlett et al., 2003; Kadyrov et al., 2009; Kato and Watanabe, 1995; McCurdy et al., 1997; Robicheaux et al., 1997), although important theoretical work prior to that had identified the unusual threshold behavior for two-electron escape (Fano, 1983; Greene and Rau, 1982, 1983; Klar and Schlecht, 1976; Peterskop, 1971; Rau, 1984; Read, 1984; Selles et al., 1987; Wannier, 1953; Watanabe, 1991). Analogous theoretical headway occurred over that same period for other three-body observables, such as double photoionization of He and H$^+$ (Meyer and Greene, 1994; Meyer et al., 1997; Robicheaux et al., 1997). Of course long before the quantal version of the three-body problem became topical, the Newtonian version with inverse square forces had acquired paramount importance and was singled out by researchers such as Poincaré and Hilbert as a crucial bottleneck that had to be solved.

Early efforts on systems with Coulomb interactions by Macek, Lin, and Fano demonstrated that significant insights into the qualitative and semiquantitative nature of doubly-excited states of He and H$^+$ emerge when an adiabatic hyperspherical approximation is implemented (Fano, 1976; Lin, 1986; Lin and Morishita, 2000; Macek, 1968). Surprisingly high doubly-excited states of two-electron atoms can be treated in the adiabatic scheme, as seen for calculations of high states which yielded a simple interpretation of regularities seen in photoabsorption (Donke et al., 1991; RAU, 1992; Sadeghpour and Greene, 1990; Tang et al., 1992). Extensions to other atomic systems such as the alkaline earth atoms (Greene, 1981) and the negative ion of helium (Watanabe, 1982) were also developed, which showed that nonadiabatic couplings often need to be incorporated in order for the results to be even qualitatively useful (Christensen-Dalsgaard, 1984). The exploration of near-separability of the two-electron wavefunction in alternative choices of coordinates, which yields nontrivial insights in some cases, was reviewed by (Tanner et al., 2000).

Another arena where three-body Coulombic interactions have been subjected to intensive study has been in the context of muon-catalyzed fusion (Hino and Macek, 1996). Interesting studies of the $^3$He$^+$ reaction of importance for muon-catalyzed fusion were carried out, for instance, using hyperspheroidal coordinates (Fukuda et al., 1990; Hara et al., 1988). Another hyperspheroidal coordinate application was to HD$^+$ by Macek and Jerjian (Macek and Jerjian, 1986) and by Hara et al. (Hara et al., 1989) Some of the most suitable systems for an adiabatic representation in hyperspherical coordinates are those with two or more equal mass particles, such as the ion formed from two electrons and one positron, i.e. the positronium negative ion (Botero and Greene, 1985, 1986; Fabre de la Ripelle, 1993). Also, not to be overlooked is the fact that this approach can be made quantitatively accurate, in some cases with direct solution of the coupled hyperradial equations in the adiabatic representation (Kadomtsev et al., 1987).

In fact the adiabatic representation has challenges as the system grows in complexity and in the number of relevant coupled hyperradial equations, and for such systems the clever recasting as a set of diabatic equations, called the “slow-variable discretization” (SVD) method proposed by Tolstikhin et al. (Tolstikhin et al., 1996), improves the efficiency enormously. When propagation to very large hyperradii is required in order to obtain accurate scattering information, a hybrid method (Wang et al., 2011a) has proven to be quite efficient and accurate, which uses SVD at small to intermediate hyperradii but solves the direct coupled adiabatic equations at very large hyperradii. One of the most recent applications of the SVD hyperspherical treatment is an investigation of the famous Hoyle triple-$\alpha$ resonance by (Suno et al., 2015).

Other exotic examples of three-body Coulombic systems that have been studied include the antiproton+hydrogen atom system, explored by (Esry and Sadeghpour, 2003), which gives an idea of the prototypical hyperspherical potential curves that emerge from applying the adiabatic hyperspherical method to the $\bar{p}pe$
system, as is shown in Fig. 3. A huge number of interacting channels are evident, which might initially seem hopelessly daunting in complexity. Closer inspection shows, however, that most of the curve crossings are highly diabatic, and the diabatic potential curves are remarkably simple, suggesting approximately conserved quantum numbers. Further examples of such simplicity emerging for a seemingly complex system will be demonstrated throughout the present review. Some exciting headway in treating four-body Coulomb systems has also occurred during the last few decades, notably by Morishita and Lin, 1998, 1999; Morishita et al., 1997) in a robust improvement over primitive early studies (Clark and Greene, 1980; Greene and Clark, 1984). A small number of treatments have extended adiabatic hyperspherical ideas to more than four particles, although they are still at a relatively primitive state at this time (Blume and Greene, 2000; Bohn et al., 1998; Daily and Greene, 2014; Kim and Zubarev, 2000; Kushihe et al., 2004; Morishita and Lin, 2005; Rittenhouse et al., 2006; Rittenhouse and Greene, 2008; Sogo et al., 2005). Fig. 4 shows an example of the lowest potential energy curves obtained by (Daily and Greene, 2014) for a system of 3 electrons and 2 positrons. These potentials contain bound states of the different symmetries of this 5-body system, and they also describe the lowest energy scattering processes.

Early interest in three-body continuum states in Coulombic systems was mainly triggered by a desire to understand electron impact ionization of atoms, especially in the low energy range, through phenomena such as the Wannier-Rau-Peterkop threshold law for that process derived initially through entirely classical arguments (Wannier, 1953) and later confirmed through quantum mechanical and semiclassical arguments by (Peterkop, 1971, 1983; Rau, 1971). Experimental confirmations of this unusual irrational threshold law for a process with both electrons escaping from a residual particle of positive charge \( Z_e \), namely \( \sigma \propto E^\gamma \) where \( \gamma = \frac{1}{2} \left( \frac{100Z^2 - 9}{4Z^2 + 1} \right)^{1/2} - 1 \), were measured for electron impact ionization of atomic helium by (Cvejanovic and Read, 1974) and for two-electron photodetachment of \( \text{H}^- \) (Donahue et al., 1982)(both for \( z = 1, \gamma = 1.127... \)). Going beyond the double escape threshold law proved to be highly challenging, with some of the first credible absolute cross sections from a theoretical calculation, for the fundamental \( e + H \rightarrow e + e + p \) process, emerging first in the numerical “convergent close-coupling” studies by (Bartlett et al., 2003; Bray and Stelbovics, 1993; Kadyrov et al., 2009), performed in ordinary independent electron coordinates. One of the first studies that obtained competitively accurate results within a hyperspherical coordinate framework was that of (Kato and Watanabe, 1995, 1997), and it was followed by a subse-

![Figure 3](image-url) Figure 3 Hyperspherical potential energy curves for the even-parity, zero angular momentum states of the \( \pi^+ e^- \) system, showing the rich variety of collision channel pathways that exist in this system. The states shown in the energy range displayed here are mostly of the type “anti-hydrogen plus electron”. Note that the energy and hyperradius are displayed respectively here on an “effective quantum number scale” \( \nu \equiv (-mU(R))^{-1/2} \) with \( m \) the proton mass, and square root hyperradial scale \( R^{1/2} \), reflecting the usual scaling in a Coulomb potential. For instance \( \nu = 1 \) corresponds to the energy of the ground 1s state of the hydrogenic \( \pi^+ e^- \) state on this scale. Adopted from (Esry and Sadeghpour, 2003).

![Figure 4](image-url) Figure 4 (Color online) The lowest several potential energy curves for zero angular momentum and even total parity are shown versus hyperradius for a 5-body Coulomb system, consisting of three electrons and two positrons. Denoting \((S_+, S_-)\) the separate spin quantum numbers of the positrons and the electrons, these potentials shown as dashed, dash-dotted, dash-dot-dotted, and dotted lines correspond to \((S_+, S_-) = (1, \frac{1}{2}), (0, \frac{1}{2}), (1, \frac{3}{2}), (0, \frac{3}{2})\), respectively. The horizontal solid lines ordered from lowest to highest indicate the asymptotic fragmentation threshold energies of \( \text{Ps}_2 + e^- \), \( \text{Ps} + \text{Ps}^- \), and \( 2\text{Ps} + e^- \). Adopted from (Daily and Greene, 2014).
quent detailed study by (Kazansky et al., 2003; Malegat, 2003, 2004; Selles et al., 2004). Highly quantitative results are also now obtained for this two-electron escape process by direct solution of the time-independent (McCurdy et al., 2004) or time-dependent (Pindzola and Robicheaux, 1998; Pindzola et al., 2007) Schrödinger equation. Recent years have seen extensive interest in the time-reversed process: three-body recombination. For a low-temperature plasma consisting of electrons and protons, this is the reaction $e + e + p \rightarrow H(nl) + e$ (Pohl et al., 2008; Robicheaux, 2007; Robicheaux et al., 2010) or its antimatter analog with positrons and antiprotons; this mechanism underpins recent exciting progress in the formation of antihydrogen (Andresen et al., 2010, 2011).

C. Chemical Physics

Another class of studies that has utilized a 3-body hyperspherical solution to solve a challenging problem in chemical physics is the dissociative recombination (DR) of $H_2^+$ (Kokoouline and Greene, 2003; Kokoouline et al., 2001; Pettrignani et al., 2011). To describe the DR process where an electron collides with $H_2^+$ and the final state dissociates into $H_2 + H$ or $H + H + H$, the use of hyperspherical coordinates has both a practical computational advantage and a qualitative conceptual advantage. For instance, the theory of DR is much better understood for a diatomic target than for a polyatomic target, so the use of an adiabatic hyperspherical representation of the nuclear positions ultimately maps polyatomic DR theory back in terms of more familiar diatomic DR theory. Those studies also showed that a nontrivial rearrangement collision can be controlled by conical intersection dynamics, more specifically in this case the Jahn-Teller effect. Part of that solution was a description of the incident electron channels as well as the energetically-closed Rydberg channel pathways using multichannel quantum defect techniques, which will not be discussed in detail here but are summarized elsewhere in the literature (Kokoouline et al., 2011).

In chemical physics, some of the most impressive theoretical studies of few-atom reactive scattering have been carried out using a hyperspherical coordinate framework. See for instance an early treatment by (Kuppermann and Hipes, 1986) of H+H$_2$ scattering. In 1985, experimentalists Neumark and coworkers perform a groundbreaking study (Neumark et al., 1985) of the famous F+H$_2$ $\rightarrow$ FH + H reaction, which required several years before a converged theoretical treatment using hyperspherical coordinates in a variant of Macek’s adiabatic representation - the diabatic-by-sector method - was developed by Launay and coworkers (Launay and Dourneuf, 1990). Other studies of importance in hyperspherical treatments of reactive scattering were developed by (Pack and Parker, 1987, 1989). However, other studies of important rearrangement reactions were carried out using Jacobi or other coordinates, such as the calculation by (Neuhauser et al., 1991), but our focus in this article is primarily on methodologies that ultimately boil down to solving one or a coupled set of one-dimensional hyperradial Schrödinger equations. A simple and popular method for solving such coupled 1D differential equations is the logarithmic derivative method (Johnson, 1973; Manolopoulos et al., 1993), while a more advanced technique frequently utilized when there are many close avoided crossings in the potential curves has been developed by (Tolstikhin et al., 1996) and implemented in various studies such as (Wang et al., 2011a).

A handful of studies have even gone beyond three-atom processes and computed scattering cross sections for reactions involving four-atoms using hyperspherical (Clary, 1991) or other methods (Bohr et al., 2014). These studies can be viewed as solutions to the few-body Schrödinger equation, starting from the Born-Oppenheimer potential energy surface as a function of the internuclear coordinates. Of course a number of important reactive systems have two or more fundamentally coupled potential surfaces, with or without conical intersections, and these require further sophistication even in formulating the basic Born-Oppenheimer Hamiltonian governing the coupled electronic and nuclear degrees of freedom.

D. Fragmentation, recombination, and molecule formation

The general theory of nuclear reactions was formulated in hyperspherical coordinates in a useful set of papers by (Delves, 1959, 1960), who showed that the usual unitary scattering matrix can be defined in general by inspecting the asymptotic form of the flux-conserving solution at large hyperradii. Hyperspherical coordinates were picked up by Smirnov and others in the Soviet school of nuclear physics, and that work is reviewed in an extremely practical and general article by (Smirnov and Shitikova, 1977). The work of that school concentrated on the development of non-interacting solutions in the hyperangular degrees of freedom, the so-called hyperspherical harmonics, including a graphical way to construct the solutions, and the analog of fractional parentage coefficients to achieve their antisymmetrization when applied to several fermionic particles such as nucleons (Smirnov and Shitikova, 1977). This has been developed further in nuclear collision theory by (Barnea, 1999; Barnea and Novoselsky, 1997) and by (Nielsen et al., 2001) More recently, a model treatment of elastic nucleon scattering of the type $A + A_2$ has shown that there is a significant benefit from adopting adiabatic hyperspherical ideas in the calculation, particularly if the theory is implemented using integral relations for the scattering amplitudes that are developed by (Barletta and Kievsky, 2008, 2009; Barletta et al., 2009).
The variant of the three-body problem involving short-range forces, particularly relevant in nuclear physics, has served as an independent but equally important testing ground for theory. Whereas in ultracold atomic physics it is a recombination process such as \( A + B + C \rightarrow AB + C \), that is of greatest interest, which can form a diatomic molecule in a gas of free atoms, in nuclear physics it is more typically the time reverse of recombination, i.e. \( AB + C \rightarrow A + B + C \) whose reaction rates and scattering amplitudes are of interest in laboratory experiments and in astrophysical contexts. An early study by (Thomas, 1935) showed that the range \( r_0 \) of two-body nuclear forces cannot be made arbitrarily smaller than the nucleon-nucleon scattering lengths \( a_{nn}(S = 0) = -18.9 \text{ fm} \), \( a_{np}(S = 0) = -23.7 \text{ fm} \), \( a_{np}(S = 1) = 5.43 \text{ fm} \), because the three-nucleon ground state would become \textit{arbitrarily deep} and plummet all the way to \(-\infty\) in the limit \( r_0 \rightarrow 0 \), a behavior never observed experimentally, of course, but which is now referred to as the “Thomas collapse” effect. Interestingly, however, one sees that the scattering lengths are generally much larger in magnitude than the known range \( r_0 \sim 1 - 2 \text{ fm} \) of the nucleon-nucleon strong force. Another intriguing foray into the behavior of three particles interacting via short range forces came decades later from Efimov, who predicted an effect that bears some connection with the Thomas collapse effect: Efimov predicted that for a system of three particles having infinite two-body scattering lengths, there must be an infinite number of 3-body bound levels that become \textit{arbitrarily weak} in their binding. Efimov’s work went on to predict that in the limit where three equal mass particles have common interparticle scattering lengths \( a \), the number of such universal bound levels becomes finite and is truncated to the approximate value \( N \approx \frac{1}{2} \ln(|a|/r_0) \). These levels are called universal because they depend only on the dimensionless ratio between the scattering length and the distance \( r_0 \) beyond which the two-body interactions are negligible, and in some cases an additional parameter is needed, such as the “three-body parameter” discussed below in Sec. III.

The recombination process that occurs when three ultracold atoms collide, e.g. \( A + A + A \rightarrow A_2 + A \) in a Bose-Einstein condensate, became a particularly important topic in the field of degenerate quantum gases in the mid-1990s, when it was increasingly realized that this was the dominant loss process in most experiments. The reason was that most of the experimental ingenuity had been directed towards turning off inelastic two-body losses by cleverly designing the quantum states of the trapped atoms. This left little possibility to further turn off inelastic three-body losses, although the gases in real experiments were usually sufficiently dilute that the quantum gas produced could be studied for reasonable periods of time, usually from 0.1 - 100 s. The process of three-body recombination was studied in a perturbative treatment by Verhaar and collaborators for the case of spin-polarized atomic hydrogen (de Goey et al., 1986); the rate coefficient for the process is only of order \( 10^{-38} \text{ cm}^6/\text{s} \), i.e. of extremely low probability because it requires a spin flip via magnetic interactions. For more typical systems such as alkali atoms that recombine in an ultracold gas, an application of the Verhaar approach (Moerdijk et al., 1996; Moerdijk and Verhaar, 1996) predicted that the recombination rate should scale overall as \( a^2 \), i.e. as the square of the atom-atom scattering length \( a \).

In fact the growth of the recombination rate coefficient \( K_3 \) with \( a \) was eventually shown to be much faster than quadratic. The first promising step towards a deeper understanding of three-body recombination emerged from a study by (Fedichev et al., 1996a) that predicted that the true scaling of \( K_3 \) should vary much more strongly with scattering length, as \( a^4 \). Sparked by growing interest throughout the ultracold science community in the need for a deeper understanding of three-body recombination, two nonperturbative treatments of this process at large two-body scattering lengths were published in 1999, one by Nielsen and Macek (Nielsen and Macek, 1999) and the other by Esry et al. (Esry et al., 1999). While these 1999 Letters confirmed the (Fedichev et al., 1996b) prediction of an overall \( a^4 \) scaling of the three-body recombination rate coefficient \( K_3 \), they both found an additional Stueckelberg interference modulation with the encouraging potential to cause destructive interference at some very large values of \( a \), potentially beneficial for experiments where loss needs to be minimized. In addition, (Esry et al., 1999) predicted that an infinite number of resonances should periodically enhance the recombination rate at large negative \( a \), and that these resonances are Efimov states that have become unbound and merged into the three-body continuum. In the case of homonuclear three-body recombination, those “zero-energy” resonances are predicted to have an approximate geometric scaling in the scattering length, with each successive Efimov resonance occurring at a two-body scattering length that is approximately \( e^{\pi/\kappa_0} \approx 22.7 \) times larger than the preceding one.

Following these initial predictions, subsequent theoretical studies extended and amplified them, e.g. as reviewed with a focus on the hyperspherical coordinate point of view by several articles (Greene, 2010; Nielsen et al., 2001; Rittenhouse et al., 2011b; Wang et al., 2013, 2015a,a). Importantly, alternative treatments found largely similar conclusions using methods such as effective field theory (Bedaque et al., 2000; Braaten and Hammer, 2001, 2003, 2006), a separable interaction application of effective field theory (Shepard, 2007), two exactly solvable models (Gogolin et al., 2008; Macek et al., 2006; Mora et al., 2011) and the treatment by (Köhler, 2002; Lee et al., 2007) that adopted the early theoretical nuclear physics treatment of (Alt et al., 1967). All of these explorations added tremendously to confidence in the
theory community that the Efimov effect should be observable, despite the dearth of experimental confirmation prior to 2006.

Then, however, this field received a tremendous injection of excitement in 2006 when recombination rate measurements for a Cs gas by Grimm’s Innsbruck group (Kraemer et al., 2006) observed the aforementioned Efimov resonance in the three-body rate coefficient $K_3$ at a large negative scattering length, in agreement with the 1999 prediction (Esry et al., 1999). That study provided the first experimental confirmation of the Efimov effect. The scattering length dependence of measured recombination rates in that 2006 experiment closely resembled the predicted shape (Esry et al., 1999) for a three-body Efimov resonance, but a skeptic might argue that observation of one resonance alone might not be convincing evidence of its Efimov character. However, subsequent observations of three-body recombination in numerous systems have solidified, confirmed, and extended that interpretation beyond any doubt. The most dramatic signature has been observing multiple resonances, separated by the predicted Efimov factor of 22.7 in the scattering length, and multiple predicted interference minima, separated by that same universal factor (Braaten and Hammer, 2006; Esry et al., 1999; Greene, 2010; Nielsen and Macek, 1999).

A further unexpected level of universality emerged from experimental studies with three-atom recombination. The three-body parameter had been thought by virtually all theorists to occur “randomly”, and to vary widely from system to system. The three-body parameter can be viewed as setting the energy $E_0$ of the lowest Efimov state at $a = \infty$ (unitarity), or alternatively, as the smallest scattering length $a^{(1)}$ at which a zero-energy Efimov resonance occurs and thus sets the location of all subsequent resonances through the universal scaling formula, $a^{(n)} = a^{(1)} e^{(n-1)\pi/s_0}$. The remarkable surprise was experimental evidence from the Grimm group (Berninger et al., 2011) and several others (Dyke et al., 2013; Gross et al., 2009, 2010, 2011; Roy et al., 2013; Wild et al., 2012) which showed that for homonuclear three-body systems dominated by van der Waals (vdW) $-C_6 r^{-6}$ two-body interactions at long range, an approximate van der Waals universality fixes $a^{(1)} \approx -10\ell_{vdW}$ in terms of the characteristic length $\ell_{vdW} \equiv [mC_6/(16\hbar^2)]^{1/4}$. As Fig. 5 shows, the three-body parameter is fixed to within approximately 15% by this simple relation. Shortly after this experimental evidence was published, a theoretical interpretation emerged from (Wang et al., 2012a) which showed that a classical suppression of the two-body probability density whenever two-particles approach to within $r < \ell_{vdW}$ produces an effective hyperradial barrier that restricts three-body motion at $R < 2\ell_{vdW}$ and sets the three-body parameter. To clarify, there is a classical suppression because the probability of a classical particle having local velocity $v(r)$ to exist in a region of width $\Delta r$ is proportional to $\Delta r/v(r)$, the time spent by the particle in that region in each traversal. In the presence of an attractive van der Waals force, the velocity increases suddenly and dramatically when the interparticle distance $r$ decreases to less than the van der Waals length, causing this probability density to plummet in such regions. The existence of the hyperradial barrier was subsequently confirmed and extended in further studies by (Naidon et al., 2014a,b, 2012) which stressed particularly that a key element of this van der Waals universality is a change from a very floppy equilateral to a roughly linear geometry that occurs near $R \approx 2\ell_{vdW}$; the geometry change then triggers strong non-Born-Oppenheimer repulsion and suppresses the three-body solution at all smaller hyperradii in the relevant potential curve. An alternative toy model addressing the implications of two-body van der Waals forces on the three-body approximate universality has also been published as a preprint by (Chin, 2011). Other treatments aimed at this issue of three-body parameter universality that start from a two-channel or narrow two-body resonance point of view are presented in (Schmidt et al., 2012; Sørensen et al., 2012; Wang and Julienne, 2014).

![Figure 5](Color online) Three-body parameter scaled by $\ell_{vdW}$ for three equal mass particles. Specifically, this quantity is the value of the (negative) atom-atom scattering length at which the first universal Efimov resonance is observable in a zero energy three-body recombination process. The error bars have been calculated as the weighted mean of the experimental results reported in Sec.III.

The case of heteronuclear universal Efimov physics appears to be significantly more complicated, e.g. for the particularly interesting case of heavy-heavy-light (HHL) systems that exhibit more favorable Efimov scaling than for the homonuclear three-body systems. But a degree of van der Waals universality has been predicted in (Wang et al., 2012d) to still be relevant for the “Efimov favored” HHL case. The complexity grows for these heteronuclear systems because more parameters control the universality, namely two van der Waals lengths and a mass ratio, and the universal energy spectrum now depends on two.

\[
\begin{align*}
\ell_{vdW} & \equiv [mC_6/(16\hbar^2)]^{1/4} \\
& \approx -10\ell_{vdW} \\
& \equiv (\ell_{vdW})^{1/4} \end{align*}
\]
scattering lengths that are uncorrelated in general. Nevertheless, early experimental evidence from two different experimental groups (Pires et al., 2014b; Tung et al., 2014; Ulmanis et al., 2016a) suggests that this generalized van der Waals universality for HHL systems is at least approximately valid, but still deserves careful study in the future. A very recent experimental preprint (Johansen et al., 2016) suggests that for Efimov physics near a narrow two-body Fano-Feshbach resonance in the $^6\text{Li}$-$^{133}\text{Cs}$ system, the universal van der Waals theoretical predictions developed for Efimov physics in the HHL system near a broad two-body resonance (Wang et al., 2012d) will require very substantial modifications, e.g., by implementing a multichannel model for the two-body interaction Hamiltonian as in (Kartavtsev and Maek, 2002; Mehta et al., 2008; Wang and Julienne, 2014). For light-light-heavy (LLH) three-body systems, Ref. (Wang et al., 2012d) stresses that these are “Efimov-unfavored”, and it is unlikely that a true Efimov state will be observable experimentally.

E. Recombination processes involving cluster resonances with more than three particles

A detailed discussion of universal four-boson and five-boson energy levels and recombination resonances is given below in subsection III.G, but here we point out some of the basic issues involved in describing cluster resonances in systems of $N > 3$ identical bosons having short-range interactions. Most of these systems have a pairwise attractive long-range interaction and a strong short-range repulsion, as in the case $N$ bosonic helium atoms. Simple counting then shows that in the relative-coordinate system the number of positive terms in the kinetic energy operator is proportional to $(N - 1)$ whereas the number of net attractive terms in the pairwise potential energy is equal to $N(N - 1)/2$. Thus, one expects that if one is in a negative region of the two-body scattering length $a$ where 3 particles are not quite attracted strongly enough to bind a universal trimer state, there could be a value of the negative scattering length $a = a_{\lambda B}$ where 4 or more particles are able to bind. Similarly, if one goes to a region where 4 particles are not quite strongly enough to be bound, there should be a negative value of $a = a_{\lambda B}^-$. One can explore this theoretically either by varying the two-body potential strength to modify the scattering length,(Gattobigio et al., 2012; Nicholson, 2012; von Stecher, 2010, 2011; Yamashita et al., 2010; Yan and Blume, 2015) or by artificially changing the particle mass in the calculations for a fixed two-body potential, which also modifies the repulsive/attractive balance in the Hamiltonian (Hanna and Blume, 2006). This concept has been studied in a number of studies, and some universal aspects have already emerged. In particular, the most recent careful discussion by (Yan and Blume, 2015) gives evidence that for general short-range two-body interactions, such as gaussians or other short-range potentials, the $N$-body cluster energies at unitarity $a \to \infty$ are not uniquely specified since they depend on the type of “three-body regulator” implemented. However, there does appear to be a quasi-universality that emerges in the case of van der Waals two-body interactions: the cluster bound state energies at unitarity are then approximately fixed in terms of the van der Waals length scale.

These and other developments will be addressed in the remainder of this review, including a detailed description of the techniques, while stressing methods of interpretive analysis that have been utilized to study these universal phenomena from a hyperspherical coordinate perspective. A very recent treatment of universal 5-body bound states in a mass-imbalanced fermionic system has been developed by (Bazak and Petrov, 2016) using alternative (integral equation) techniques (Pricoupenko, 2011).

II. ADIABATIC HYPERSPHERICAL TREATMENT

A Schrödinger wave equation for $N$ interacting particles, with masses $m_i$ moving in 3 dimensions per particle, becomes in the absence of external fields, a $d = 3N - 3$ dimensional partial differential equation (PDE) in the relative coordinate system. When expressed in hyperspherical coordinates, a single scalar coordinate, the hyperradius $R$ defined below, is singled out for special treatment within an adiabatic formulation. It is possible in general to formally transform the $d$-dimensional PDE, specifically the time-independent Schrödinger equation $\hat{H}\Psi = E\Psi$ for any potential energy function dependent on the relative position coordinates only, into an infinite set of ordinary coupled differential equations in a single adiabatic coordinate $R$. Moreover, a conceptual advantage of hyperspherical coordinates is that every possible fragmentation mode for any system of particles occurs in the limit $R \to \infty$.

The basic equations of the adiabatic representation are simple to derive. First of all, write the full time-independent Hamiltonian in the form

$$\hat{H} = \hat{T}_R + H_{R=\text{const}}, \quad (1)$$

where the term $H_{R=\text{const}}$ depends on $R$ only as a parameter and is a Hermitian partial differential operator in all other (hyperangular) coordinates of the system plus spins, denoted collectively here as $\{\varpi\}$. Next, solve the eigenvalue equation at each value of $R$:

$$H_{R=\text{const}}\Phi_\nu(R; \varpi) = u_\nu(R)\Phi_\nu(R; \varpi). \quad (2)$$

The exact eigenfunctions of the full $\hat{H}$ can now be expanded into the complete, orthonormal set of eigenfunc-
tions \( \Phi_\nu(R; \varpi) \) with \( R \)-dependent coefficients \( F_{E\nu}(R) \), as

\[
\Psi_E(R; \varpi) = R^{-(d-1)/2} \sum_\nu \Phi_\nu(R; \varpi) F_{E\nu}(R),
\]

(3)
giving an infinite set of coupled differential equations for the hyperradial functions:

\[
\left( -\frac{\hbar^2}{2\mu} \frac{d^2}{dR^2} + U_\nu(R) - E \right) F_{E\nu}(R) = -\sum_{\nu'} \tilde{W}_{\nu\nu'} F_{E\nu'}(R),
\]

(4)
where \( \mu \) is the \( N \)-body reduced mass and its explicit form is given in Eq. (9). Observe that for a coordinate space with \( d \) dimensions, the hyperradial kinetic energy operator has the form \( \tilde{T}_R = -\hbar^2 \frac{1}{2\mu R^{d-1}} \frac{\partial^2}{\partial R^2} R^d \) and the rescaling of the radial function eliminates the first-order derivative of \( F_{E\nu}(R) \) on the left-hand side of Eq. (4). The rescaling also adds what Fano called a “mock-centrifugal term” to \( u_\nu(R) \), giving the full effective hyperradial Born-Oppenheimer potential as

\[
U_\nu(R) = u_\nu(R) + \frac{(d-1)(d-3)\hbar^2}{8\mu R^2}
\]

(5)
The coupling terms on the right-hand side of Eq. (4) which are responsible for nonadiabatic coupling are given by:

\[
\tilde{W}_{\nu\nu'} F_{E\nu'}(R) = -\frac{\hbar^2}{2\mu} Q_{\nu\nu'}(R) F_{E\nu'}(R) - \frac{\hbar^2}{\mu} P_{\nu\nu'}(R) \frac{dF_{E\nu'}(R)}{dR}
\]

(6)
Here the two nonadiabatic coupling matrices are given by \( Q_{\nu\nu'}(R) \equiv \left\langle \left( \Phi_\nu(R; \varpi) \right| \frac{\partial}{\partial \varpi} \Phi_\nu'(R; \varpi) \right\rangle \right|^{(R)} \) and \( P_{\nu\nu'}(R) \equiv \left\langle \left( \Phi_\nu(R; \varpi) \right| \frac{\partial}{\partial R} \Phi_\nu'(R; \varpi) \right\rangle \right|^{(R)} \) where the double bracket notation signifies an integral (and spin trace) only over the \( \varpi \) degrees of freedom. This set of coupled equations is sometimes treated in the hyperradial Born-Oppenheimer approximation which neglects the right-hand side of Eq. (4). In that approximation, the system moves along a single potential energy curve with no possibility of changing from one potential to another, and this approximation of course has no possibility of describing an inelastic collision. But in some cases it can give a reasonable description of energy levels and scattering phaseshifts, although in most cases a more accurate result is obtained by retaining (except near close avoided crossings) the diagonal terms of Eq. (4) which is usually referred to as the hyperspherical adiabatic approximation.

While the hyperradial Born-Oppenheimer approximation, which considers only a single term in the expansion for \( \Psi_E \) in Eq. (4), is often reasonable, a far richer set of phenomena emerges when nonadiabatic coupling effects are incorporated, either by direct solution of the coupled radial equations or else using semiclassical methods such as Landau-Zener-Stückelberg or their improvements along the lines of (Nikitin, 1970; Zhu et al., 2001). This in fact yields a quantitative description of phenomena such as three-body or four-body recombination, and inelastic atom-dimer or dimer-dimer scattering.

The following development sketches one explicit version of this recasting of the Schrödinger equation into hyperspherical coordinates for an \( N \)-particle system in 3 dimensions. Note that a similar development for \( N \) 2D particles is presented by (Daily et al., 2015b), in the context of the quantum Hall effect. One first transforms the \( N \) laboratory frame position vectors \( \{\vec{r}_i\} \) in terms of a suitable set of \( N - 1 \) mass-weighted relative Jacobi coordinate vectors \( \{\vec{\rho}_i\} \), plus the center of mass vector which is trivial and is therefore ignored throughout. Extensive arbitrariness and flexibility exists for the choice of the Jacobi coordinate vectors, but for definiteness, one simple choice is based on choosing the \( j \)-th Jacobi vector as the (reduced mass weighted) relative vector between particle \( (j+1) \) and the center of mass of the preceding group of particles 1 through \( j \), i.e.:

\[
\vec{\rho}_1 = \sqrt{\frac{\mu_{12}}{\mu}} (\vec{r}_2 - \vec{r}_1)
\]

\[
\vec{\rho}_2 = \sqrt{\frac{\mu_{12} \mu_{13}}{\mu}} (\vec{r}_3 - \vec{r}_1 - \vec{r}_2)
\]

... etc., where the \( N - 1 \) Jacobi reduced masses are

\[
\mu_{12} = \frac{m_1 m_2}{m_1 + m_2}, \quad \mu_{123} = \frac{(m_1 + m_2)m_3}{m_1 + m_2 + m_3}, \quad \text{etc.,}
\]

(8)
and where the \( N \)-body reduced mass is

\[
\mu = (\mu_{12}\mu_{123}, \ldots) \frac{1}{N-1}.
\]

(9)
Alternative choices for the overall reduced mass \( \mu \) are possible and are sometimes utilized, but this choice in Eq. (9) is particularly desirable in many contexts because it preserves the overall volume element. With these definitions, the nonrelativistic kinetic operator acquires a simple form, namely

\[
\hat{T} = -\frac{\hbar^2}{2\mu} \sum_{j=1}^{N-1} \nabla_{\vec{\rho}_j}^2 = -\frac{\hbar^2}{2\mu} \sum_{i=1}^d \frac{\partial^2}{\partial x_i^2}
\]

(10)
The Cartesian coordinates of all these Jacobi vectors can thus be collected into a single \( d \)-dimensional relative vector \( \vec{x} \equiv \{x_1, x_2, x_3, \ldots x_d\} \), and these can in turn be transformed into hyperspherical coordinates by defining the hyperradius \( R \) as the radius of the \( d \)-dimensional hypersphere:

\[
R = \sqrt{x_1^2 + x_2^2 + x_3^2 + \ldots x_d^2}.
\]

(11)
There are again many possible choices for the \( d - 1 \) hyperangles \( \alpha_k \), but one simple generalization of our usual spherical coordinates is implied by the chain(Avery,
perspherical coordinates can be conveniently written as

\[ x_d = R \cos \alpha_d - 1 \]
\[ x_{d-1} = R \sin \alpha_d - 1 \cos \alpha_{d-2} \]
\[ x_{d-2} = R \sin \alpha_{d-1} \sin \alpha_{d-2} \cos \alpha_{d-3} \]
\[ ... x_2 = R \prod_{j=1}^{d-1} \sin \alpha_j, \quad \text{and} \quad x_1 = R \prod_{j=2}^{d-1} \sin \alpha_j \cos \alpha_1. \]

This easily generalizable choice of the hyperangles is sometimes referred to as the canonical choice. The ranges spanned by these hyperangles are then

\[ 0 \leq \alpha_1 \leq 2\pi, 0 \leq \alpha_i \leq \pi, i = 2, \ldots, d-1. \quad (13) \]

Now, the nonrelativistic kinetic energy operator in hyperspherical coordinates can be conveniently written as

\[ \hat{T} = \hat{T}_R + \frac{\hbar^2 \hat{\Lambda}^2}{2\mu R^2}, \quad (14) \]
where \( \hat{T}_R = -\frac{\hbar^2}{2\mu} \frac{1}{R^d} \frac{\partial}{\partial R} \hat{R}^{d-1} \frac{\partial}{\partial R} \), and where \( \hat{\Lambda}^2 \) is the isotropic Casimir operator for the group O(d), (Cavagnero, 1984, 1986; Knirk, 1974; Smirnov and Shitikova, 1977) given explicitly by

\[ \hat{\Lambda}^2 = -\sum_{i \neq j} \Lambda^2_{ij}, \quad \Lambda_{ij} = x_i \frac{\partial}{\partial x_j} - x_j \frac{\partial}{\partial x_i}. \]

The operator \( \hat{\Lambda}^2 \) is often referred to as the square of the “grand angular momentum” operator of the system. These equations now show how the physics of this d-dimensional problem can be mapped exactly onto an adiabatic representation in the single coordinate \( R \), with potential energy curves \( U_v(R) \) and nonadiabatic coupling terms as in standard Born-Oppenheimer theory. As is particularly stressed by (Fano, 1981b, 1983; Macek, 1968), and as we document below, this approach yields tremendous insights in many physical systems.

Some examples of applying the adiabatic hyperspherical representation to systems with many particles are summarized below in Sec.(IV). But before turning to examples, we show how far greater symmetry and simplicity emerge from a clever choice of the hyperangles for three-particle systems, \( N = 3 \), by adopting a “body-fixed” coordinate system of the type suggested by (Whitten and Smith, 1968). The particular variant described here adopts the conventions specified by (Suno et al., 2002).

Usually we are interested in three-body systems that have exact separability in the relative and center of mass coordinates, whereby the relative degrees of freedom can be described by six coordinates, i.e. \( d = 6 \) is the full dimensionality of this space. Three of these coordinates are conveniently chosen to be Euler angles \( \{\alpha, \beta, \gamma\} \) that connect the body-fixed frame to the space-fixed frame. Three remaining coordinates in this system are the hyperradius \( R \) and two hyperangles \( \theta \) and \( \varphi \). Following Refs. (Johnson, 1983; Kendrick et al., 1999; Lepetit et al., 1990; Whitten and Smith, 1968) with only minor modifications described in (Suno et al., 2002), this begins from the mass-scaled Jacobi coordinates introduced above (Delves, 1960)

\[ \hat{\rho}_1 = (\tilde{r}_2 - \tilde{r}_1)/\Delta, \]
\[ \hat{\rho}_2 = \Delta \left[ R^3 - \frac{m_1 \tilde{r}_1 + m_2 \tilde{r}_2}{m_1 + m_2} \right], \quad (15) \]

with

\[ \Delta = \frac{1}{\mu} \frac{m_3 (m_1 + m_2)}{m_1 + m_2 + m_3}. \quad (16) \]

and \( \mu \) is the three-body reduced mass as was defined above, namely

\[ \mu^2 = \frac{m_1 m_2 m_3}{m_1 + m_2 + m_3}. \quad (17) \]

In this expression, particle \( i \) with mass \( m_i \) has position \( \tilde{r}_i \). When the three particles have identical mass \( m \), the parameters simplify to \( \Delta = (4/3)\frac{m}{\mu} \) and \( \mu = m/\sqrt{3} \). And specializing the above definition of the hyperradius \( R \), it is given here by:

\[ R^2 = \rho_1^2 + \rho_2^2, \quad 0 \leq R < \infty. \quad (19) \]

The hyperangles \( \theta \) and \( \varphi \) are determined by the four nonzero components of the two Jacobi vectors in the body frame \( x - y \) plane by

\[ \begin{align*}
(\hat{\rho}_1)_x &= R \cos(\theta/2 - \pi/4) \sin(\varphi/2 + \pi/6), \\
(\hat{\rho}_1)_y &= R \sin(\theta/2 - \pi/4) \cos(\varphi/2 + \pi/6), \\
(\hat{\rho}_2)_x &= R \cos(\theta/2 - \pi/4) \cos(\varphi/2 + \pi/6), \\
(\hat{\rho}_2)_y &= -R \sin(\theta/2 - \pi/4) \sin(\varphi/2 + \pi/6),
\end{align*} \quad (20) \]

where by definition \( \rho_1 = 0 = \rho_2 \). For definiteness, note that the \( x, y, \) and \( z \) right-hand coordinate system of the body-fixed frame is chosen such that the \( z \) axis is parallel to \( \hat{\rho}_1 \times \hat{\rho}_2 \), and the \( x \) axis is that with the smallest moment of inertia. The ranges of the hyperangles are \( 0 \leq \theta \leq \frac{\pi}{2} \) and \( 0 \leq \varphi < 2\pi \) (Kendrick et al., 1999). If the three equal mass particles are in fact truly identical, then the hyperangle \( \varphi \) can be further restricted to the range \( [0, 2\pi/3] \). Note that in this case, the interaction potential is symmetric under the operation \( \varphi \to \pi/3 - \varphi \). Then the bosonic or fermionic symmetry of the Schrödinger solutions under exchange of any two particles is particularly simple to impose as a boundary condition in these coordinates. The volume element for integrals over \( |\Psi|^2 \) is equal to \( dV = d\alpha d\beta d\gamma d\rho_1 d\rho_2 d\rho_3 d\theta d\varphi \sin \beta d\beta d\gamma R^3 dR d\Delta \), and the Euler angle ranges are \( 0 \leq \alpha < 2\pi, 0 \leq \beta < \pi, 0 \leq \gamma < \pi \). The full Schrödinger equation for the rescaled wavefunction \( \psi_E = R^{1/2} |\Psi| \) describing three identical particles now takes the form

\[ \left( -\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + \frac{15}{8\mu R^2} + \frac{\Lambda^2}{2\mu R^2} + V(R, \theta, \varphi) \right) \psi_E = E \psi_E, \quad (21) \]
In this expression, \( \mathbf{L}^2 \) is the squared “grand angular momentum operator” and is given by (Kendrick et al., 1999; Lepetit et al., 1990)

\[
\frac{\mathbf{L}^2}{2\mu R^2} = T_1 + T_2 + T_3, 
\]

where

\[
T_1 = -\frac{2}{\mu R^2 \sin \theta} \frac{\partial}{\partial \theta} \sin 2\theta \frac{\partial}{\partial \theta}, 
\]

\[
T_2 = \frac{1}{\mu R^2 \sin^2 \theta} \left( \frac{\partial}{\partial \varphi} - \cos \theta \frac{L_z}{2} \right)^2, 
\]

\[
T_3 = \frac{L_x^2}{\mu R^2 (1 - \sin \theta)} + \frac{L_y^2}{\mu R^2 (1 + \sin \theta)} + \frac{L_z^2}{2 \mu R^2}. 
\]

The total orbital angular momentum operator in the body frame is denoted here as \( \vec{L} = \{L_x, L_y, L_z\} \). For an interacting 3-body system, one frequently adopts a sum of two-body potential energy functions for \( V(R, \theta, \varphi) \), but some explorations are carried out with explicit non-pairwise additive terms as well. That is, most explorations of universal physics have used an approximate 3-particle \( V \) of the form:

\[
V(R, \theta, \varphi) = v(r_{12}) + v(r_{23}) + v(r_{31}), 
\]

where \( r_{ij} \) are the interparticle distances. For three equal mass particles, these distances are expressed in terms of the hyperspherical coordinates as

\[
r_{12} = 3^{-1/4} R [1 + \sin \theta \sin(\varphi - \pi/6)]^{1/2}, 
\]

\[
r_{23} = 3^{-1/4} R [1 + \sin \theta \sin(\varphi - 5\pi/6)]^{1/2}, 
\]

\[
r_{31} = 3^{-1/4} R [1 + \sin \theta \sin(\varphi + \pi/2)]^{1/2}. 
\]

As was indicated above, the first step in implementing the adiabatic representation is to solve the fixed-\( R \) adiabatic eigenvalue equation for a given symmetry \( L^I \) to obtain the fixed-\( R \) adiabatic eigenfunctions (\( \Phi_{\nu} \), sometimes referred to as channel functions) and eigenvalues (potential energy curves \( U_{\nu}(R) \)). Here we adopt an abbreviated notation with \( \Omega = (\theta, \varphi, \alpha, \beta, \gamma) \) and for some systems \( \Omega \) includes spin degrees of freedom as well. For the body-frame choice of hyperangles, it is simplest to expand the Euler angle dependence of the \( \Phi_{\nu} \) in terms of normalized Wigner D-functions, \( \tilde{D}_{MK}(\alpha\beta\gamma) \), i.e. as

\[
\Phi_{\nu}^{[L]}(R; \Omega) = \sum_K \phi_{K\nu}(R; \theta, \varphi) \tilde{D}_{MK}(\alpha\beta\gamma). 
\]

This representation guarantees that \( \Phi_{\nu}^{[L]} \) is automatically an eigenfunction of \( \vec{L}^2 \), and it is also an even (odd) eigenfunction of the parity operator \( \hat{\Pi} \) provided \( K \) is restricted to even (odd) values respectively. A few more details of this body frame representation are useful when using this representation to convert the 5-dimensional PDE Eq.(21) into a set of coupled 2D PDEs in \( \theta, \varphi \) only. In this body frame representation of angular momentum, the raising and lowering operators are defined (owing to the anomalous commutation relations of body-frame operators) as:

\[
L_{\pm} = L_x \mp iL_y, 
\]

where

\[
L_{\pm}\tilde{D}_{MK}^{L}(\alpha\beta\gamma) = \sqrt{(L \mp K)(L \pm K + 1)} \tilde{D}_{MK \pm 1}^{L}(\alpha\beta\gamma) 
\]

\[
L_z\tilde{D}_{MK}^{L}(\alpha\beta\gamma) = K \tilde{D}_{MK}^{L}(\alpha\beta\gamma). 
\]

After inserting the above expressions, one obtains for each value of \( \{L, M, \Pi\} \) a finite number of coupled 2D PDEs in \( \theta, \varphi \). The terms involving \( L_{\pm}^2 \) and \( L_{\mp}^2 \) cause couplings between components \( K \) and \( K \pm 2 \). While these PDEs are for complex solutions, as written here, it is possible to take linear combinations, e.g. \( \phi_{K}(R; \theta, \varphi) \pm \phi_{-K}(R; \theta, \varphi) \) and reformulate the PDEs in terms of real functions everywhere.

### A. Recombination cross sections and rate coefficients

It was proven by Delves that the hyperspherical representation preserves the usual desired properties of continuum scattering solutions, such as flux conservation when the Hamiltonian is Hermitian which ensures unitarity of the scattering matrix \( S \) and symmetry of the \( S \)-matrix when the Hamiltonian is time-reversal invariant. One simple conceptual aspect of Macek’s adiabatic hyperspherical representation involving potential energy curves and nonadiabatic couplings is that the computation of the unitary \( S \)-matrix can utilize any of the powerful techniques already developed for treating two-body inelastic scattering processes. In other words, just as in standard multichannel scattering theory (Rodberg and Thaler, 1970) or multichannel quantum defect theory (Aymar et al., 1996; Burke et al., 1998; Fano, 1970; Gao, 2001; Greene and Junger, 1985; Mies, 1984; Mies and Raoult, 2000; Ruzic et al., 2013; Seaton, 1983), one simply propagates solutions of the coupled equations in Eq. (4) out to large distances, fits to linear combination of energy-normalized regular and irregular radial functions \( \{f_{E\nu}(R), g_{E\nu}(R)\} \) and in this manner obtain a real, symmetric reaction matrix \( K_{\nu\nu'}(E) \) characterizing solutions from some large matching radius \( R_0 \) out to infinity:

\[
\Psi_{E\nu}(R; \varpi) = \sum_{\nu'} \frac{\Phi_{\nu}(R; \varpi)}{\sqrt{d_{\nu\nu'}}} (f_{E\nu}(R)\delta_{\nu\nu'} - g_{E\nu}(R)K_{\nu\nu'}) 
\]
outgoing-wave or incoming-wave boundary conditions. (See, e.g. Sec.II of (Aymar et al., 1996).) Of particular interest in the context of ultracold quantum gases is the three-body recombination rate coefficient which was derived in (Esry et al., 1999). The relevant formula for three identical bosonic particles which are in a thermal gas rather than a BEC, after correcting for a factor of 6 in the formulas reported in that paper, is:

\[ K_3(E) = \frac{\hbar k}{\mu} \frac{192\pi^2}{k^5} \sum_{\nu',\nu} |S_{\nu',\nu}|^2 \]  

(31)

Here \( k = \sqrt{2\mu E/\hbar^2} \) and the sum includes all entrance three-body continuum channels \((A+A+A, \nu)\) for the symmetry of interest, and over all final state two-body bound channels \((A_2+A, \nu')\). A few words are relevant to explain how this recombination rate coefficient is to be used in rate equations used to model this reaction in a cold gas. This quantity \( K_3(E) \) is the fundamental coefficient relevant to a single triad of particles in the gas. The coefficient in the rate equations for disappearance of atoms or appearance of dimers is another rate coefficient, \( L_3 \), which is determined by the following points. If one imagines that there are \( N \) atoms in a thermal gas volume \( V \), then there are \( g_N = N(N-1)(N-2)/3! \approx N^3/6 \) distinct triads of the type \( A+A+A \) in the system. If we define a density as \( n = N/V \), then the rate equation for disappearance of atoms from a cold trapped gas is

\[ \frac{dn}{dt} = -L_3 n^3, \]  

(32)

where for a thermal trapped gas, \( L_3 = 3K_3 g_N \approx K_3 \). This last equation, the leading factor of 3 in the middle is the number of atoms lost in each recombination event, and the value 3 reflects the fact that for a typical trapped gas of atoms, a recombination event releases so much kinetic energy that both the final dimer and the final atom following recombination will be ejected, i.e. all three of the initially free atoms. If an unusually deep trap is implemented, or if the binding energy of the dimer produced is far less than the trap depth, then that factor of 3 would of course be changed to 2 since only the dimer would escape the atom trap, though one should then also keep track of the energy deposited into the cloud by the remaining hot atom. As is also well known, (Burt et al., 1997; Kagan et al., 1985; Söding et al., 1999) if the initial atom cloud is in a pure BEC rather than a thermal gas, then the preceding \( K_3 \) needs to be reduced by a factor of \( 3! \).

Some of the simplest and most important early predictions of the low energy recombination rate behavior include an expected \( a^4 \) scaling (Fedichkov et al., 1996b), which was later seen to be modified in a nontrivial way that differs depending on whether the atom-atom scattering length \( a \) is positive (Esry et al., 1999; Nielsen and Macek, 1999) or negative (Esry et al., 1999). If \( a \) is large and positive, then there exists a strongly-bound dimer state whose energy is approximately \( -\hbar^2/a \), and the recombination rate into that universal dimer should have St"uckelberg interference minima at scattering lengths \( a^{(i)} \) whose spacings should scale geometrically with the Efimov scaling parameter \( a^{(i+1)}_+ / a^{(i)}_+ = e^{\pi/a_0} \approx 22.7 \). If instead, \( a \) is negative, then this implies that there is no weakly-bound universal dimer, and recombination can occur only into deeper nonuniversal dimer channels. On this side, even though the attraction is not strong enough to bind two atoms together into an universal dimer, the Efimov effect can bind trimers at certain values of \( a^{(i)} < 0 \). Moreover, the successive values of \( a \) where a trimer can form at zero energy also obey the Efimov scaling, \( a^{(i+1)}_- / a^{(i)}_- \sim 22.7 \). While the first experiments (Berninger et al., 2011, 2013; Dyke et al., 2013; Ferlaino et al., 2009a, 2008, 2011; Gross et al., 2009, 2010, 2011; Knoop et al., 2010, 2009; Machtet et al., 2012a,b; Pollack et al., 2009; Zaccanti et al., 2009; Zenesini et al., 2013) were only able to observe a single Efimov resonance (\( i = 1 \)) for homonuclear systems, a recent impressive experiment by (Huang et al., 2014b) has observed the \( i = 1, 2 \) resonances and confirmed their approximate ratio to be close to Efimov’s predicted value.

Much subsequent theory has treated the physics of recombination, and developed compact analytical formulas within the framework of zero-range models and/or effective field theory, which are particularly convenient for analyzing experimental data. See for instance the following references (Braaten and Hammer, 2006; Gogolin et al., 2008; Macek et al., 2006; Mora et al., 2011). A different direction of extending and generalizing recombination theory has been the treatment of recombination processes for \( N > 3 \) particles. A generalization of Eq.(31) presented above for recombination of \( N \) identical bosons into any number of bound fragments is derived in (Mehta et al., 2009):

\[ K_N(E) = N! \frac{\hbar k}{\mu} \left( \frac{2\pi}{k^d} \right)^{d-1} \frac{\Gamma(d/2)}{2^{d/2}} \sum_{\mu\nu} |S_{\mu\nu}|^2. \]  

(33)

Here \( d \) is the number of dimensions in the relative coordinate space after eliminating the trivial center-of-mass motion, i.e. for \( N \) particles in 3 dimensions, \( d = 3N - 3 \). This last formula of course reduces to the above expression for \( K_3 \) when \( N = 3 \).

III. THE BIRTH OF FEW-BODY PHYSICS: THE EFFECTS OF THOMAS AND EFIMOV

A. The Thomas collapse

In the early days of nuclear physics, in 1935, a mere three years following the Chadwick discovery of the neutron, L. H. Thomas published a seminal work about the structure of the triton, \(^3\)H (Thomas, 1935). In particular,
Thomas studied the existence of the triton ground state obtained with different assumptions for the neutron-proton interaction, but neglecting neutron-neutron interactions as it is depicted in Fig. 2. As a result, (Thomas, 1935) found that the neutron-neutron potential energy should have a repulsive character at short range, and that the neutron-proton interaction cannot be confined to a distance very small compared with 1 fm. These findings constitute the very first exploration of few-body physics with finite range forces, and they sparked the interest of many physicists in different fields of physics, especially atomic physics and molecular physics in addition to nuclear physics.

The key point of (Thomas, 1935) is that it is possible to account for nucleon-nucleon (or atom-atom) interactions having an arbitrary scattering length \( a \) with many different two-body interaction models. For a two-body model with arbitrarily short range \( r_0 \) there must be a corresponding potential depth of order \( \hbar^2 / 2mr_0^2 \) in order to yield a value of \( a \) that is independent of potential range and fixed at an experimentally measured value. For instance, in a spherical square well model having depth \( V_0 \) and range \( r_0 \), the zero-energy two-body scattering length for two equal mass particles of mass \( m \) and reduced mass \( m/2 \) is equal to \( a = r_0 - \tan qr_0/q \), where \( q = \sqrt{mV_0}/\hbar^2 \). As \( r_0 \) is decreased to smaller and smaller values, \( q \) must increase approximately in proportion to \( 1/r_0 \) in order to maintain any given fixed scattering length. Thomas then examined the nature of the three-body ground state energy in this limit of decreasing potential range \( r_0 \) but fixed two-body scattering length. The qualitative argument is rather simple, namely that when a third particle is brought into the system having equal scattering lengths \( a \), this adds two new potential energy terms to the Hamiltonian of the same depth and range, while only adding one new kinetic energy term. As a result, the three-body system is shown by Thomas to have a ground state energy that must be of order \( -\hbar^2 / 2m r_0^2 \), which becomes arbitrarily large and negative as \( r_0 \to 0 \).

**B. Efimov physics and universality in ultracold gases**

Efimov considered an analogous three-body problem which also involved two-body scattering lengths \( a \) much larger in magnitude than the potential range, i.e. \( |a|/r_0 >> 1 \), except that Efimov visualized the two-body interaction range \( r_0 \) to be fixed, and \( |a| \to \infty \).

Three identical particles with resonant two-body interaction will show an infinite series of three-body bound states as predicted by Efimov (Efimov, 1970, 1971, 1973b) more than 40 years ago. This infinity of trimer states follows a discrete symmetry scaling, i.e., the energy of the \( n \)-th and \( n + 1 \)-th states are related through \( E_{n+1} = \lambda^2 E_n \), where for the particular case of three identical bosons \( \lambda = e^{\pi / s_0} \) with \( s_0 = 1.0062 \) (Braaten and Hammer, 2006; Efimov, 1970; Ferlaino et al., 2011; Greene, 2010; Wang et al., 2013), and hence \( \lambda \approx 22.7 \). Efimov introduced the universal theory of three-body collisions thinking in nuclear systems as the preferable scenario for the quest of his predictions. However, the first experimental evidence of the prediction of V. Efimov came from ultracold gases (Kraemer et al., 2006), and this early evidence has triggered an explosive growth in research into few-body ultracold physics.

In ultracold systems the exciting capability to tune two-body atomic scattering length, using magnetic, optical or RF-induced Fano-Feshbach resonances (Chin et al., 2010; Hanna et al., 2010; Inouye et al., 1998; Köhler et al., 2006; Owens et al., 2016; Tscherbul et al., 2010). This tunability of ultracold system Hamiltonians makes them perfect candidates to study few-body universality. However, the formation of universal trimers must be detected and characterized in such systems. The most usual route to such detection is to measure the three-body loss coefficient \( L_3 \) as a function of the two-body scattering length \( a \), as is schematically shown in Fig.1. Specifically, the universal Efimov trimers cause an enhancement of \( L_3 \) at a given two-body negative scattering length \( a^{(n)} \), and the Efimov physics exhibits interference minima at values of the positive two-body scattering length \( a^{(n)}_+ \), as shown in Fig.1. Efimov states can also be studied by radiative or oscillatory field association, as has been achieved in \( ^6\text{Li} \) by (Lompe et al., 2010b; Nakajima et al., 2011b) and in \( ^7\text{Li} \) by (Machetey et al., 2012b).

**C. Faddeev equations for three identical bosons: bound states**

1. Hamiltonian and Faddeev operator equations

In the following three spinless and equal mass particles of bosonic character are considered which interact via short range fields. Note that the notation introduced below for deriving the Faddeev equations follows (Glöckle, 2012). Then the total Hamiltonian for three \( s \)-wave interacting bosons obeys the following form:

\[
H = H_0 + \hat{V}_{23} + \hat{V}_{31} + \hat{V}_{12},
\]

where \( H_0 \) is the three-body kinetic operator, \( \hat{V}_{ij} \) indicates the short range potential between the \( i \)-th and \( j \)-th particle. For simplicity the following notation is introduced \( V_i \equiv V_{jk} \) with cyclic permutation of \( (i, j, k) \). The three-body Schrödinger equation reads:

\[
(H_0 + \sum_i \hat{V}_i)\Psi = E\Psi
\]

where \( \Psi \) indicates the three-body wave function. Employing now the three-body non-interaction Green’s function, i.e. \( G_0 \equiv \{E - H_0\}^{-1} \), Eq. (35) can be recast to the
following form:
\[ \Psi = \hat{G}_0 \sum_{i} \hat{V}_i \Psi = \hat{G}_0 \hat{V}_1 \Psi + \hat{G}_0 \hat{V}_2 \Psi + \hat{G}_0 \hat{V}_3 \Psi. \]  \tag{36}

where this holds as long as the Green’s function is free of poles. In our case this is valid since we focus on the description of three-body bound states, i.e. the energy of any bound state is negative while the zeroth-order Hamiltonian has only kinetic energy and is positive definite. As Eq. (36) illustrates the total three-body wavefunction \( \Psi \) can be decomposed in three components, namely \( \Psi = \sum_{i} \psi^{(i)} \) with \( i = 1 \ldots 3 \) where each \( \psi^{(i)} \) indicates the \( i \)-th Faddeev component of the total three-body wavefunction. Physically, the \( i \)-th Faddeev component, i.e. \( \psi^{(i)} \) implies that the \( i \)-th particle is a spectator particle with respect to the interacting pair \((j, k)\). Employing this decomposition ansatz in Eq. (36) yields a system of three coupled Faddeev equations which describe the bound state properties of the three-body system.

\[
\begin{pmatrix}
\psi^{(1)} \\
\psi^{(2)} \\
\psi^{(3)}
\end{pmatrix} = \hat{G}_0 \begin{pmatrix}
0 & \hat{t}_1 & \hat{t}_1 \\
\hat{t}_2 & 0 & \hat{t}_2 \\
\hat{t}_3 & \hat{t}_3 & 0
\end{pmatrix} \begin{pmatrix}
\psi^{(1)} \\
\psi^{(2)} \\
\psi^{(3)}
\end{pmatrix} \tag{37}
\]

where the term \( \hat{t}_i \) represents the two-body transition operator. More specifically, \( \hat{t}_i \) obeys the following Lippmann-Schwinger equation:
\[
\hat{t}_i = \hat{V}_i + \hat{V}_i \hat{G}_0 \hat{t}_i, \quad \text{for } i = 1, 2, 3
\]  \tag{38}

where the term \( \hat{G}_0 \) denotes the Green’s function of three non-interacting bosons. This implies that the transition operator \( \hat{t}_i \) is considered as a two-body operator embedded in a three-body Hilbert space.

The Faddeev equations in Eq. (37) can be decoupled by taking into account the exchange symmetry between the three particles. Formally the exchange symmetry can be addressed by a permutation operator \( \hat{P}_{ij} \) which permutes the \( i \)-th with the \( j \)-th particle. In addition, the considered system consists of three identical bosons therefore the total wavefunction \( \Psi \) is symmetric. Due to this the exchange operator only permutes the particles in the Faddeev components. By using the permutation operator, a pair of Faddeev components \( \psi^{(j)}, \psi^{(k)} \) can be expressed in terms of \( \psi^{(i)} \) and vice versa. The \( \psi^{(i)} \) component of the Faddeev equations in Eq. (37) then takes the following form:
\[
\psi^{(i)} = \hat{G}_0 \hat{t}_i (P_{ij} P_{jk} + P_{ik} P_{jk}) \psi^{(i)}, \quad \text{for } (i, j, k = 1, 2, 3),
\]  \tag{39}

where the indices \((i, j, k)\) form a cyclic permutation.

Eq. (39) represents the operator form of the Faddeev equations and in the following Eq. (39) is expressed in momentum space. For completeness reasons in the following the Jacobi coordinates and the corresponding momenta are briefly reviewed.

2. Faddeev equations in momentum representation

Consider that the motion of three bosonic particles with masses \( m_i \) with \( i = 1 \ldots 3 \) are described by the lab coordinates \( x_i \) whereas the corresponding momentum is \( \mathbf{k}_i \) with \( i = 1 \ldots 3 \). Then in order to describe the relative motion of three particles the following three sets of Jacobi coordinates are introduced:
\[
\mathbf{r}_i = x_i - \frac{m_j x_j + m_k x_k}{m_j + m_k} \quad \text{and} \quad \mathbf{p}_i = \frac{(m_j + m_k) \mathbf{k}_i - m_i (\mathbf{k}_j + \mathbf{k}_k)}{M},
\]  \tag{40}

where \((i, j, k = 1, 2, 3)\) form a cyclic permutation and the Jacobi vector \( \mathbf{r}_i \) denotes the relative distance between the \( j \)-th and \( k \)-th particles whereas the vectors \( \mathbf{p}_i \) indicate the distance of the \( i \)-th particle, i.e. the spectator particle, from the center of mass of the \((j, k)\) pair of atoms. Note that the coordinate of the center of mass of three particles obeys the simple relation \( \mathbf{R} = \sum_{i=1}^{3} m_i x_i / M \) where \( M = \sum_{i=1}^{3} m_i \) denotes the total mass of the system.

Similarly, for the Jacobi momenta we obtain the following relations:
\[
\mathbf{q}_i = \frac{m_k \mathbf{k}_j - m_j \mathbf{k}_k}{m_j + m_k} \quad \text{and} \quad \mathbf{p}_i = \frac{(m_j + m_k) \mathbf{k}_i - m_i (\mathbf{k}_j + \mathbf{k}_k)}{M},
\]  \tag{41}

where \((i, j, k = 1, 2, 3)\) form a cyclic permutation, the \( \mathbf{q}_i \) denotes the relative momentum of \((j, k)\) pair and the \( \mathbf{p}_i \) indicates the momentum of the spectator particle relative to the center of mass of \((j, k)\) pair. The total momentum is given by the relation \( \mathbf{P} = \sum_{i=1}^{3} \mathbf{k}_i \).

According to these definitions the kinetic operator \( \hat{H}_0 \) in the momentum space takes the following form:
\[
\hat{H}_0 = \frac{\mathbf{P}^2}{2M} + \frac{\mathbf{q}_i^2}{2\mu_i} + \frac{\mathbf{p}_i^2}{2\mu_i},
\]  \tag{42}

where \( \mu_i = (m_i m_k)/(m_j + m_k) \) is the reduced mass of the \((j, k)\) pair particles and \( \mu_i = m_i (m_j + m_k) / M \) denotes the reduced mass of the spectator particle and the center of mass of the \((j, k)\) pair.

In the following is assumed that the collisions occur in the frame of the total center of mass, this means \( \mathbf{P} = 0 \). Therefore, the term \( \mathbf{P}^2/(2M) \) can be removed from the total Hamiltonian which then takes the form:
\[
\hat{H}' = \frac{\mathbf{P}^2}{2\mu_i} + \frac{\mathbf{q}_i^2}{2\mu_i} + \mathbf{V}_i(\mathbf{p}_i) + \mathbf{V}_j(\mathbf{r}_i + \frac{m_j}{m_j + m_k} \mathbf{p}_i)
+ \mathbf{V}_k(\mathbf{r}_i + \frac{m_k}{m_j + m_k} \mathbf{p}_i).
\]  \tag{43}

Since the Jacobi coordinates and momenta are introduced, the reduced Faddeev equation (see Eq. (39)) can be transformed into the momentum space. For this purpose a certain set of Jacobi momenta is chosen, i.e. \((\mathbf{p}_1, \mathbf{q}_1)\). This means that in this particular set of Jacobi coordinates the particle 1 is the spectator of the pair
(2,3). Upon introducing a complete set of states $|q_1,p_1\rangle$, Eq. (39) becomes

$$
\langle q_1,p_1|\psi^{(1)}\rangle = G_0(q_1,p_1) \int \frac{dq'_1}{(2\pi)^3} \frac{dp'_1}{(2\pi)^3} \langle q_1,p_1|q'_1,p'_1\rangle \times \langle q'_1,p'_1|P_{12}P_{23} + P_{13}P_{23}|\psi^{(1)}\rangle,
$$

where the three-body Green’s function in momentum space is given by the relation $G_0(q_1,p_1) = |E - \frac{q_1^2}{2m} - \frac{p_1^2}{2m} - \frac{\text{m}^2}{4m}|^{-1}$. Note that for the bound trimer spectrum the total energy $E$ is negative; thus in this case the $G_0$ Green’s function is free of poles.

The matrix elements of the transition operator $\hat{t}_1$ in Eq. (44) can be evaluated with the help of the corresponding Lippmann-Schwinger equation Eq. (38):

$$
\langle q_1|\hat{t}(\varepsilon)|q_1\rangle = \delta(p_1 - p_1') \langle q_1|t(E - \frac{p_1^2}{2m_1})|q_1'\rangle,
$$

where the term $t(E - \frac{p_1^2}{2m_1})$ is the two-body transition amplitude embedded in the two-body Hilbert space. This means that the transition amplitude obeys a two-body Lippmann-Schwinger equation of the following form:

$$
\langle q_1|t(\varepsilon)|q_1\rangle = \langle q_1|V_1|q_1\rangle + \int \frac{dq''_1}{(2\pi)^3} \langle q_1|V_1|q''_1\rangle \times \left[ \varepsilon - \frac{q''_1^2}{2m_1} \right]^{-1} \langle q''_1|t(\varepsilon)|q_1\rangle.
$$

(45)

In addition the exchange operators in Eq. (44) for equal masses namely $m_1 = m_2 = m_3 = m$ obey the following relation:

$$
\langle q'_1,p'_1|P_{12}P_{23} + P_{13}P_{23}|q''_1,p''_1\rangle =
\delta(q'_1 + \frac{3}{4}p''_1 + \frac{q''_1}{2})\delta(p'_1 - q''_1 + \frac{p''_1}{2})
+ \delta(q'_1 - \frac{3}{4}p''_1 + \frac{q''_1}{2})\delta(p'_1 + q''_1 + \frac{p''_1}{2}).
$$

(46)

By substituting the Eqs. (45,46) and (47) in the reduced Faddeev equation, namely Eq. (44) we get the following expression:

$$
\langle q_1,p_1|\psi^{(1)}\rangle = \left( E - \frac{q_1^2}{m} - \frac{3p_1^2}{4m} \right)^{-1} \times
\int \frac{dp'_1}{(2\pi)^3} \left[ \langle q_1|t(E - \frac{3p_1^2}{4m})|p'_1 - \frac{p_1}{2}\rangle \langle p_1 + \frac{p_1}{2},p'_1|\psi^{(1)}\rangle + \langle q_1|t(E - \frac{3p_1^2}{4m})|p'_1 + \frac{p_1}{2}\rangle \langle -p_1 - \frac{p_1}{2},p'_1|\psi^{(1)}\rangle \right].
$$

(48)

3. Separable potential approximation: two-body transition elements and the reduced Faddeev equation

In the following is considered that the two-body interactions can be modeled by a separable potential, such as the Yamaguchi potential (Yamaguchi, 1954). This particular type of potentials simplifies the Faddeev equations [see Eq (48)] into one-dimensional integral equation. Assume that the two particles interact via $s$-wave interactions only through the following non-local potential:

$$
\langle q_1|\hat{V}_1|q_1'\rangle = -\frac{\lambda}{m} \chi(q_1)\chi(q_1'),
$$

(49)

where $\lambda$ denotes the strength of the two-body interactions, $m$ indicates the mass of the particles and the $\chi(\cdot)$ functions are the so called form factors. Typically, the $\chi$-form factors are chosen such that the potential $V$ yields the same scattering length and effective range correction as the real two body interactions. Note that since we are interested in three-body bosonic collisions of neutral atoms in the following subsection we provide the form factors $\chi$ which are derived from a van der Waals potential. This particular choice of form factor incorporates in a transparent way the pairwise two-body interactions of the three neutral atoms.

After insertion of Eq. (46), the two-body transition matrix elements for the separable potential in Eq. (49) obey

$$
\langle q_1|t(\varepsilon)|q_1\rangle = -\frac{\lambda}{m} \chi(q_1)\tau(\varepsilon)\chi(q_1'),
$$

with $\tau^{-1}(\varepsilon) = 1 + \frac{\lambda}{m} \int \frac{dq_1}{(2\pi)^3} \frac{\chi(q_1)^2}{\varepsilon - \frac{q_1^2}{m}}.
$$

(50)

After specializing to states where the three particles have total angular momentum $L = 0$ and using the separable potential from Eq. (49), as well as the two-body transition matrix elements from Eq. (50), the reduced Faddeev equation in Eq. (48) reads

$$
\langle q_1,p_1|\psi^{(1)}\rangle = -2\frac{\lambda}{m} \left( E - \frac{q_1^2}{m} - \frac{3p_1^2}{4m} \right)^{-1} \tau(E - \frac{3p_1^2}{4m}) \times \chi(q_1) \int \frac{dp'_1}{(2\pi)^3} \chi(p_1 + \frac{p_1}{2}) \langle p_1 + \frac{p_1}{2},p'_1|\psi^{(1)}\rangle.
$$

(51)

This integral equation can be further simplified by employing the following ansatz for the Faddeev component $|\psi^{(1)}\rangle$:

$$
\langle q_1,p_1|\psi^{(1)}\rangle = \left( E - \frac{q_1^2}{m} - \frac{3p_1^2}{4m} \right)^{-1} \chi(q_1)F(p_1).
$$

(52)

Substituting the ansatz of Eq. (52) in the reduced Faddeev equation, namely Eq. (50) an integral equation for the amplitudes $F$ is obtained where its arguments depend only on the magnitude of the $p_1$ vector states due to the $s$-wave character of the two-body interactions. Under these considerations the integral equation of the ampli-
tudes $\mathcal{F}$ reads

$$
\mathcal{F}(p_1) = -\frac{\lambda}{m} \left( E - \frac{3p_1^4}{4m} \right) \times \int \frac{dp'_1}{(2\pi)^3} \frac{\chi(p'_1 + p_1)}{E - \frac{p_1^2}{m} - \frac{p'_1^2}{m} - \frac{p_1 p'_1}{m}} \mathcal{F}(p'_1),
$$

where for a particular choice of $\chi$-form factors the preceding equation is transformed into a matrix equation. For a given $s$-wave scattering length and effective range parameters, numerically the energy is varied in searching for roots of the corresponding determinantal equation of Eq. (53).

Finally, it should be noted that replacement of the $\chi$-form factor by $\chi(q_1) \rightarrow 1$ in the reduced Faddeev equation in Eq. (51) one obtains the Skorniakov-Ter-Martirosian equation (Skorniakov and Ter-Martirosian, 1957) for three bosons colliding with zero-range $s$-wave interactions. The following subsection focuses on deriving a separable potential which is suitable for the two-body interactions of neutral atoms, i.e. van der Waals forces.

**D. Separable potentials for van der Waals pairwise interactions**

In order to study the universal aspects of the three body spectrum of bosonic gases it is necessary to focus on the two-body interactions which govern the collisional behavior of ultracold gaseous matter. More specifically, it is well known that neutral bosonic atoms at large separation distances experience an attractive van der Waals interaction due to retardation (Casimir and Polder, 1948) which modifies this at very long range but is largely irrelevant to the energy scale of interest here. This particular type of interaction potential imprints universal features onto the corresponding wavefunction (Flambaum et al., 1999; Gao, 1998) which becomes manifested in the spectra of three interacting bosons.

However, as was shown in the previous subsection, the Faddeev equations are best simplified by using the separable potential approach. Thus it is of major interest to construct a separable potential which encapsulates the main features of the van der Waals force. (Naidon et al., 2014a,b) show that such a potential can be derived simply by using the analytically known zero-energy wavefunction of two particles in the presence of van der Waals potential (Flambaum et al., 1999). Namely, the zero-energy two-body wavefunction for van der Waals interaction is given by the following relation:

$$
\phi(r) = \Gamma \left( \frac{5}{4} \right) \frac{r}{\ell_{vdW}} J_{\frac{3}{4}} \left( \frac{2r_{vdW}^2}{r^2} \right),
$$

where $a_s$ is the $s$-wave scattering length, $\ell_{vdW} = \frac{1}{4}(mC_6/h^2)^{1/4}$ is the van der Waals length scale with $C_6$ being the dispersion coefficient. The quantities $\Gamma(\cdot)$ and $J_{\frac{3}{4}}(\cdot)$ represent the Gamma and Bessel functions respectively.

Fig. 6 depicts the wavefunction in Eq. (54) for an $s$-wave scattering length $a_s = 50\ell_{vdW}$. At short distances the two-body wavefunction oscillates fast enough which in essence reflects the fact that the van der Waals potential contains many two-body bound states. At large distances the wave function of Eq. (54) obtains the form $\phi(r) \rightarrow 1 - r/a_s$. It is evident that a separable potential based on the above mentioned two-body wavefunction contains the correct behavior of the two-body wavefunction as well as effective-range effects due to the short-range oscillatory part of $\phi(r)$. The latter is of particular importance since (Naidon et al., 2014a,b) demonstrate that the universality of the three body parameter of the Efimov states relies exactly on the short-range oscillatory part of the two-body wavefunction. The Yamaguchi potential from Eq. (49) is adopted, where the $\chi$-function in the momentum space is defined by:

$$
\chi(q_1) = 1 - q_1 \int_0^\infty dr \left[ 1 - \frac{r}{a_s} - \phi(r) \right] \sin(q_1 r),
$$

where $\phi(r)$ is the zero-energy two-body rescaled radial wavefunction (see Eq. (54)). Note that the argument of the $\chi$-form factor depends only on the magnitude of
the vector \( \mathbf{q}_1 \) due to the \( s \)-wave character of the wavefunction. The strength \( \lambda \) of the Yamaguchi potential is determined by the following expression:

\[
\lambda = \left[ -\frac{1}{4\pi a_s} + \frac{1}{2\pi^2} \int_0^\infty dq_1 |\chi(q_1)|^2 \right]^{-1}. \tag{56}
\]

As an example, Fig. 7 illustrates the binding energies versus the \( s \)-wave scattering length, \( a_s \). The two-body dimer energies within the separable potential approximation, see Eq. (57), (red dotted line) are compared with the effective range theory of van der Waals interactions given by (Flambaum et al., 1999) (blue solid line). The yellow solid line indicates the universal dimer energies. Evidently, Fig. 7 depicts that the separable potential introduced in Eq. (57) captures the essential two-body physics beyond the effective range approximation.

### E. The Efimov spectrum and its universal aspects

This subsection focuses on the impact of van der Waals forces on the Efimov spectrum of three identical \( s \)-wave-interacting bosons, the typical situation for three ultracold atoms but irrelevant for the few-nucleon problem. In particular, the reduced Faddeev equation in Eq. (44) is numerically solved within the separable potential approximation. The separable potential is constructed according to the prescription given in the previous subsection. Specifically, use of the potential in Eq. (57) ensures that it contains all the relevant zero-energy information about the van der Waals potential. Under these considerations, Fig. 8 depicts the Efimov spectrum of three neutral atoms as a function of the \( s \)-wave scattering length. In particular, the blue curve and dots indicate the ground Efimov trimer state. The orange dots and curve denote the first excited state. The black dashed curve refers to the universal dimer threshold, \( E = -\frac{k^2}{m\pi^2} \), whereas the green dotted curve corresponds to the two-body binding energies given for the potential in Eq. (57). Deeply in the regime of unitarity, namely \( |a_s| \to \infty \), the trimer energies for the ground and first excited state are \( E_1 = 0.035338 \ell_{vdW}^2 \) and \( E_2 = 6.6806 \times 10^{-5} \ell_{vdW}^2 \) respectively, or in wave vectors we have that \( \kappa_1 = 0.1879 \ell_{vdW}^{-1} \) and \( \kappa_2 = 0.00817 \ell_{vdW}^{-1} \). For the first two \( \kappa \) wave vectors a scaling factor is obtained which is equal to \( \kappa_1/\kappa_2 = 22.9988 \). The latter deviates from the universal scaling law obtained within the zero-range approximation which is given by the relation \( \kappa_1^{\text{ZR}}/\kappa_2^{\text{ZR}} = 22.6944 \). This discrepancy between the van der Waals approach and the zero-range approximation can be attributed to the fact that the latter method completely neglects effective range corrections. Specifically, the ground Efimov state is strongly influenced by finite range effects in the two-body interaction potentials (Ji et al., 2015). Note that the value obtained for \( \kappa_0 \) is in reasonable agreement within 16% with the corresponding calculation in (Wang et al., 2012a), which was based on a local position space.
van der Waals interaction. More specifically, for a hard-core van der Waals potential tail (Wang et al., 2012a) obtains the value $\kappa_0 = 0.226(2) \ell_{vdW}^{-1}$ at unitarity for the ground Efimov state.

Away from unitarity and for negative values of the scattering length, Fig. 8 shows that the trimer states cross the three body threshold and become resonances in the 3 particle scattering continuum. In particular, the ground state crosses the threshold at $a_{-}^{(1)} = -10.849 \ell_{vdW}$, whereas the first excited Efimov trimer merges with the three-body continuum at $a_{-}^{(2)} = -169.199 \ell_{vdW}$. Note that the $a_{-}^{(1)}$ for the ground Efimov state is in good agreement with the hyperspherical approach employed by Wang et al. (Wang et al., 2012a). More specifically, (Wang et al., 2012a) for a hard-core van der Waals potential tail obtains the value $\ell_{vdW}^{-1} = -9.73(3) \ell_{vdW}$ for the ground Efimov state. In addition, the Naidon et al. model result agrees well with the corresponding experimental values, i.e. $a_{-}^{(1)} = -9.1 \ell_{vdW}$ (Ferlaino et al., 2011). Remarkably, the separable potential model presented by (Naidon et al., 2014a,b) reproduces the universal features of the Efimov spectrum without utilizing any auxiliary parameter of the type that is needed within the zero-range approximation. Recall that the three-body spectrum for the Efimov effect is not bounded from below in the zero-range approximation; thus an additional parameter (three-body parameter) is employed in order to define properly the “ground Efimov state”. In the van der Waals separable potential model the auxiliary parameter becomes unnecessary due to the fact that the potential itself describes not only the asymptotic behavior of the two-body wavefunction but also its behavior at short distances which oscillates rapidly. Indeed, the fast oscillations of the two-body wavefunction in regions of the three-body configuration space where two particles approach each other translates into an effective repulsive hyperradial barrier, which in return suppresses the probability to find three bosons at distances less than $R \sim 2 \ell_{vdW}$. This suppression effect was initially understood by (Wang et al., 2012a) using the hyperspherical approach where the steep attraction of the van der Waals forces leads to an effective three-body potential barrier at this somewhat surprisingly large hyperradius.

In order to illustrate this point from the reduced Faddeev equation in Eq. (49) the three-body wavefunction is first obtained in the momentum representation at $a_{-}^{(1)}$. Then following a Fourier transformation the corresponding configuration space three-body wavefunction is expressed in hyperspherical coordinates. After integrating the density over all the hyperangles $\alpha$, taking the square root and applying the hyperradius kinetic operator to the resulting hyperradial wavefunction, an effective potential is obtained as a function of the hyperradius $R$. This effective potential is compared with the corresponding adiabatic potential curve which contains the diagonal correction from the diagonal nonadiabatic coupling term $Q_{00}$. Fig. 9 compares the resulting implied hyperradial potential curve from (Naidon et al., 2014b) with the direct adiabatic hyperspherical solution from (Wang et al., 2012a), showing good general agreement. The gray dotted line illustrates the asymptotic $-R^{-2}$ Efimov potential curve at unitarity for comparison. While the effective potential curve possesses some additional structure, (Naidon et al., 2014b) states that this structure is an artifact which mainly arises from the oscillatory behavior of the Faddeev three-body wavefunction.

F. Efimov states in homonuclear systems

1. $^6$Li

Ultracold gases of fermionic $^6$Li have been the object of different studies about Efimov physics and universality in three-body physics, e.g. by (Huckans et al., 2009; Lompe et al., 2010a; Nakajima et al., 2010, 2011a; Ottenstein et al., 2008; Wenz et al., 2009; Williams et al., 2009). It should be pointed out that it is a bit of a stretch to include the $^6$Li system in our discussion of the Efimov effect for three identical bosonic atoms. Owing to the fermionic nature of $^6$Li there is no s-wave scattering between atoms in identical spin substates, but atoms in different substates do have an s-wave scattering length. The studies just quoted have in fact considered atoms in three distinguishable substates, but unlike the case of three identical bosons, the three interparticle scattering lengths are in
general different in the $^6\text{Li}$ system. However, they are all large and negative and therefore the system can be approximately mapped onto and compared with an Efimov system with three identical bosons in identical spin substates. In the following discussion, it should be kept in mind that this mapping is an approximation. It is argued by (Wenz et al., 2009) that one conjectured mapping, a definition of an effective “homonuclear” scattering length $a_{\text{ave}}$ that applies when all three interspecies scattering lengths are large and negative is:

$$
a_{\text{ave}}^4 = \frac{1}{3} (a_{12}^2 a_{23}^2 + a_{13}^2 a_{23}^2 + a_{12} a_{13}^2). \quad (58)$$

Nevertheless, quantities in Efimov physics such as the loss to deeply bound dimers and the three body parameter should more rigorously be understood to depend in general on all three separate scattering lengths for a fermionic atom such as $^6\text{Li}$, i.e. on $a_{12}, a_{23}, a_{13}$. In general, many of the experimental investigations have relied upon radio-frequency (RF) techniques for the identification of Efimov trimers. These methods employ RF pulses to form different Efimov states, which are detected as atom loss, thus leading to the characterization of their binding energies (Lompe et al., 2010a; Nakajima et al., 2010, 2011a; Wenz et al., 2009). The measured trimer energies show a clear dependence on the applied magnetic field close to the two-body Feshbach resonances, which has been viewed as evidence for deviations from Efimov’s universal three-body physics scenario. In particular, the geometric scaling factor $\lambda = 22.7$ is not observed between successive resonances, and this has been interpreted as a magnetic field dependence of the three-body parameter.

The apparent non-universality of $^6\text{Li}$ has been an open question in the last decade, leading two different non-universal models beyond non-universal two-body interactions (Nakajima et al., 2010). However, (Huang et al., 2014a) have shown that accounting for a realistic two-body energy dependent scattering length and taking into account finite temperature effects the three-body parameter for $^6\text{Li}$ turns out to be $a_+^{(1)}/\ell_{\text{vdW}} = -7.11 \pm 0.6$ which is very similar to the results obtained for identical bosons Table I and Table II. Moreover, the geometric scaling factor shows a 10% deviation with respect to $\lambda = 22.7$; the universal expected value.

2. $^7\text{Li}$

The Efimov physics in bosonic $^7\text{Li}$ has been extensively studied through characterizations of maxima and minima of the three-body loss coefficient (Dyke et al., 2013; Gross et al., 2009, 2010, 2011; Machtet et al., 2012a; Pollack et al., 2009), as well as using radio-frequency fields to measure the binding energies of weakly bound trimers (Machtet et al., 2012b). In particular, the Rice group identified the ground Efimov state for $^7\text{Li}$ in the $|m_F = 1\rangle$ hyperfine state as a resonance in the three-body loss coefficient for $a < 0$. An initial suggestion in (Pollack et al., 2009) that they had also observed the first excited Efimov resonance $a_+^{(2)}$ was later attributed to a calibration error. The recalibration, published in (Dyke et al., 2013), also corrected the position of the first Efimov resonance to $a_+^{(1)} = -252 \pm 10$. Efimov physics was also observed on the $a > 0$ branch of the spectrum as the expected minima in the three-body loss coefficient (Pollack et al., 2009), yielding $a_+^{(1)} = 89 \pm 4$ and $a_+^{(2)} = 1420 \pm 100$ when the recalibration of (Dyke et al., 2013) was applied. The ratio $a_+^{(2)}/a_+^{(1)} = 16 \pm 2$ deviates appreciably from the expected universal ratio of 22.7, (Essky et al., 1999; Nielsen and Macek, 1999) but this level of deviation for the first two Efimov features is not unexpected, based on theoretical calculations.

| $m_F$ | $a_+^{(1)} (a_0) - a_+^{(2)} (a_0) | a_+^{(1)}/\ell_{\text{vdW}}$ |
|-------|---------------------------------|------------------|
| 0     | 243 \pm 35                     | 264 \pm 11       |
| +1    | 247 \pm 12                     | 268 \pm 12       |

Table I Fitting parameters to an universal theory obtained by measuring the three-body loss coefficient in $^7\text{Li}$. Results taken from (Gross et al., 2010).

Similar results for the maxima of the three-body loss rate were obtained by Gross et al. (Gross et al., 2009, 2010, 2011) for two different hyperfine states: $|m_F = 1\rangle$ and $|m_F = 0\rangle$ as shown in Table I. However different results for $a_+^{(1)}$ in comparison with (Pollack et al., 2009) were obtained as displayed in Table I. This discrepancy for $a_+^{(1)}$ has been explained as a distinct magnetic field-scattering length conversion through a different characterization of the same Feshbach resonance (Gross et al., 2010). In Table I it is also observed the universal character of the three-body parameter $a_+^{(1)}$ in terms of the van der Waals length $\ell_{\text{vdW}}$ for $^7\text{Li}$. In particular, the values obtained for $a_+^{(1)}/\ell_{\text{vdW}}$ are very similar to the values observed in cesium (Berninger et al., 2011), rubidium (Wild et al., 2012) and potassium (Roy et al., 2013).

3. $^{39}\text{K}$

The study of Efimov states in bosonic $^{39}\text{K}$ at ultracold temperatures has been developed mainly by the LENS group (Roy et al., 2013; Zaccanti et al., 2009). In particular, the study of (Roy et al., 2013) is a remarkable exploration of the $a_+^{(1)}$ three-body parameter universality, even including narrow Feshbach resonances. This study was carried out by employing different spin states $m_F$, as well as different Feshbach resonances in an ultracold gas of $^{39}\text{K}$, some showing open-channel dominance while others are narrower closed-channel-dominated resonances.

Resonances with a small resonance strength $s_{\text{res}}$, (Chin
by varying the two-body scattering length in a sweep of as well as the three-body recombination rate constant, the two-body and three-body contact were determined, has been realized by (Wild et al., 2006), obtaining $a_{-}^{(1)} = -759 \pm 6 a_0$. The utilized fitting function is only valid at $T = 0$, and hence the fitting was realized for $a < 1/k_{\text{thermal}}$, where $k_{\text{thermal}} = \sqrt{2mk_BT}/\hbar$. The ratio between the measured three-body parameter and the van der Waals length is $a_{-}^{(1)}/\ell_{\text{vdW}} = -9.24 \pm 0.7$ (Wild et al., 2012). This value is very similar to the reported values for $^{133}$Cs (Berninger et al., 2011; Kraemer et al., 2006) and $^7$Li (Gross et al., 2009, 2010, 2011).

5. $^{133}$Cs

The first experimental evidence of the Efimov effect was observed in an ultracold gas of $^{133}$Cs (Kraemer et al., 2006) by tuning the Cs-Cs scattering length of through a Feshbach resonance, and measuring the enhancement and decreases of the three-body loss coefficient for negative and positive scattering lengths, respectively. At the same time, this pioneering work readily showed the possibility of using ultracold physics in order to explore universal physics in few-body physics. (Esry and Greene, 2006)

$$B_{\text{res}}(G) \quad |a_{-}^{(1)}/\ell_{\text{vdW}}| \quad \eta_-$$

- $7.56 \pm 0.17 \quad 8.63 \pm 0.22 \quad 0.10 \pm 0.03$
- $553.30 \pm 0.4 \quad 10.19 \pm 0.57 \quad 0.12 \pm 0.01$
- $554.71 \pm 0.80 \quad 9.48 \pm 0.79 \quad 0.19 \pm 0.02$
- $853.07 \pm 0.56 \quad 9.45 \pm 0.28 \quad 0.08 \pm 0.01$

Table III Exponentially determined three-body parameter $a_-$ for different Feshbach taken from (Berninger et al., 2011). The position of the Feshbach resonances employed are denoted by $B_{\text{res}}$, the three-body parameter as a function of the van der Waals length ($\ell_{\text{vdW}} = 101 a_0$) is reported, and finally $\eta_-$ is a nonuniversal quantity that reflects decay into deeply bound diatomic states (Wenz et al., 2009).

4. $^{85}$Rb

The study of Tan’s contact in an ultracold gas of $^{85}$Rb has been realized by (Wild et al., 2012). In particular the two-body and three-body contact were determined, as well as the three-body recombination rate constant, by varying the two-body scattering length in a sweep of the magnetic field through a Feshbach resonance. The two-body contact is an extensive thermodynamic magnitude proportional to the derivative of the internal energy of the ultracold gas with respect to the scattering length (Combescot et al., 2009; Schakel, 2010; Tan, 2008a,b,c; Werner et al., 2009), i.e, $C_2 \propto dE/da$. The three-body contact $C_3$ is defined in terms of the derivative of the internal energy with respect to the three-body parameter $C_3 \propto dE/da_-$. (Braaten et al., 2011; Castin and Werner, 2011).

The measurements of the three-body recombination rate were performed in dilute, ultracold, non-condensed clouds containing $1.5 \times 10^5$ atoms of $^{85}$Rb at a temperature $T=80 \text{nK}$. Then the magnetic field was varied through a Feshbach resonance in order to explore the region of negative scattering lengths. The obtained three-body recombination rate was fitted to the expected form for the Efimov three-body rate (Braaten and Hammer, 2006), obtaining $a_{-}^{(1)} = -759 \pm 6 a_0$. The utilized fitting function is only valid at $T = 0$, and hence the fitting was realized for $a < 1/k_{\text{thermal}}$, where $k_{\text{thermal}} = \sqrt{2mk_BT}/\hbar$. The ratio between the measured three-body parameter and the van der Waals length is $a_{-}^{(1)}/\ell_{\text{vdW}} = -9.24 \pm 0.7$ (Wild et al., 2012). This value is very similar to the reported values for $^{133}$Cs (Berninger et al., 2011; Kraemer et al., 2006) and $^7$Li (Gross et al., 2009, 2010, 2011).

$$\begin{array}{c|c|c|c}
 m_F & R^*(a_0) & s_{res} - a_{-}^{(1)}(a_0)/\ell_{\text{vdW}} & T (\text{nK}) \\
\hline
 0 & 22 & 2.8 & 640 \pm 100 & 10.0 \pm 1.6 & 50 \pm 5 \\
 0 & 456 & 0.14 & 950 \pm 250 & 14.7 \pm 3.9 & 330 \pm 30 \\
 0 & 556 & 0.11 & 950 \pm 150 & 14.7 \pm 2.3 & 400 \pm 80 \\
 +1 & 22 & 2.8 & 690 \pm 40 & 10.7 \pm 0.6 & 90 \pm 6 \\
 -1 & 24 & 2.6 & 830 \pm 140 & 12.9 \pm 2.2 & 120 \pm 10 \\
 -1 & 24 & 2.5 & 640 \pm 90 & 10.0 \pm 1.4 & 20 \pm 7 \\
 -1 & 59 & 1.1 & 730 \pm 120 & 11.3 \pm 1.9 & 40 \pm 5 \\
\end{array}$$

Table II Experimentally determined three-body parameter $a_-$ for different Feshbach resonances and spin states $m_F$ in $^{39}$K taken from (Roy et al., 2013). $R^*$ represents the intrinsic length scale and associated with it, the resonance strength $s_{res}$. The value for the three-body parameter as a function of the van der Waals length $\ell_{\text{vdW}} = 64.9 a_0$ is also reported, as well as the initial temperature $T$, which implies a saturation limit of the three-body recombination rate because the $S$-matrix is unitary.

\footnote{Usually $C_3$ is defined in terms of the so-called three-body interaction parameter $k_\epsilon$ (Braaten et al., 2011; Castin and Werner, 2011), which is related to the three-body parameter by the equation: $a_{-}^{(1)} = (-1.56 \pm 5)/k_\epsilon$. (Braaten and Hammer, 2006).}
sample of $^{133}$Cs. For these four observed Efimov resonances shown in Table III, the ratio of the three-body parameter $a^{(1)}_{\text{B}}$ to the van der Waals length $\ell_{\text{vdW}}$ is approximately equal for all the Feshbach resonances analyzed in the experiment, to within only about $\%15$ variations. More recently, Huang et al. (Huang et al., 2014a) have realized an exhaustive experimental work on the negative scattering length branch of the two-body interaction in Cs, confirming the universality of the Efimov scaling by seeing for the first time two successive Efimov resonances in a homonuclear system. Note, however, that more than one previous experiment has observed the expected Efimov scaling between two successive destructive interference St¨ uckelberg minima $a^{(m)}_{\text{B}}$; it should be remembered that this behavior of three-body recombination at positive scattering lengths is a non-resonant manifestation of universal Efimov physics.

G. Four-body and five-body bound states and recombination resonances

Normally one views 3-body recombination as a comparatively rare process in a dilute, ultracold gas. Typical Bose-Einstein condensates, for instance, can have lifetimes of the order of many seconds. Thus it may come as a surprise that higher order processes involving even more than 3 atoms simultaneously colliding in 3D can have even higher inelastic collision rates in some regimes of scattering length and density. There are theoretical predictions of this resonant $N$-body recombination in (Blume, 2012b; Blume and Yan, 2014; Mehta et al., 2009; Rittenhouse et al., 2011a; von Stecher et al., 2009; Wang and Esry, 2009; Wang et al., 2012c; Yan and Blume, 2015), and a few experimental observations (Dyke et al., 2013; Ferlaino et al., 2009b; Pollack et al., 2009; Ulmanis et al., 2016a; Zenesini et al., 2013). While these usually cause difficulty for applications of interest with quantum degenerate gases or optical lattices, they can be especially interesting and informative to study in their own right, especially from a few-body point of view.

The 4-body problem has challenged theorists for many years (Lazauskas and Carbonell, 2006) and is still of fundamental importance and interest. Extensive attention has been devoted to the question of whether there is an Efimov effect for four or more particles. For four or more identical particles, an early theoretical study by (Amado and Greenwood, 1973) concluded: “Hence the remarkable Efimov effect seems even more remarkably to be a property of the three-body system only.” Later, however, a treatment by (Kr¨ orger and Perne, 1980) based on a separable potential model concluded that in certain parameter ranges there is an Efimov effect for four bosons. To add to this apparent discrepancy between the preceding two references mentioned, the possible existence of an Efimov effect in a 3D four-body system with three heavy particles and one light particle was treated theoretically by (Adhikari and Fonseca, 1981) and later by (Naus and Tjon, 1987), reaching opposite conclusions (no and yes, respectively). A subsequent study by (Adhikari et al., 1995) suggests that an additional short-range length (or high-momentum) scale is required for each successively larger number $N$ of particles, in order to pin down the energy even of low-lying states. Another treatment by (Yamashita et al., 2006) concluded that four-body bound states can exist in the universal regime of large atom scattering lengths, but they will normally not be fixed in energy by 2-body and 3-body physics alone, and will require an independent 4-body parameter. This conclusion was supported by a later study as well, namely (Hadizadeh et al., 2011).

Based on 4-identical boson bound state calculations using low-energy effective field theory, it was conjectured by (Hammer and Platter, 2007; Platter et al., 2004) that there should be two 4-boson bound states at unitarity lying at energies between each successive pair of Efimov trimer energies. These studies suggested, in apparent disagreement with (Yamashita et al., 2006), that the energies are largely fixed by the three-body parameter, and at least to a good approximation, this would mean that no additional 4-body parameter is needed. A 4-body hyperspherical calculation was carried out (von Stecher et al., 2009) that was based on the use of correlated Gaussian basis functions(Suzuki and Varga, 1998) adapted to the adiabatic hyperspherical representation(Daily and Greene, 2014; Mitroy et al., 2013; Rakshit and Blume, 2012; von Stecher and Greene, 2009). Using that method, (D’Incao et al., 2009; Mehta et al., 2009; von Stecher et al., 2009; Wang and Esry, 2009) gave supporting evidence to that conjecture, and advanced the theory to the point where detailed predictions could be made of 4-body recombination rate coefficients and resonance positions. In the universal limit, for instance, theory predicted (von Stecher et al., 2009) that the two-body scattering lengths where 4-boson resonances would be observable as zero energy recombination resonances, should be at the following values of the boson-boson scattering length: $a_{4B,1} \approx 0.43^{(1)}$ and $a_{4B,2} \approx 0.9a^{(1)}_{\text{B}}$. These have since been confirmed in experimental studies (Ferlaino et al., 2009a) of homonuclear recombination processes involving four or more free bosonic atoms, although (von Stecher et al., 2009) pointed out that there was already some evidence for a four body process in (Kraemer et al., 2006). Exciting theoretical progress in developing a highly quantitative theoretical treatment was subsequently reported for four-body resonances and recombination by (Deltuva, 2010, 2011, 2012), in a momentum-space treatment based on a separable two-body interaction, a treatment that does not utilize hyperspherical coordinates. One interesting aspect of those theoretical and experimental efforts is the suggested implication that no additional 4-body parameter is needed to fix the universal behavior.
of four interacting identical bosons, as it appears to be fixed once the 3-body parameter is known. The extent to which this remains true for interactions of much shorter range than van der Waals potentials remains an active topic of investigation.

These developments in turn spawn a fundamental question: Are the universal properties also fixed for 5, 6, 7, and even more bosonic particles once the three-body parameter is known? If the answer is yes, this is a crucial point that can greatly simplify the development of realistic many-body theories for interacting bosons. A number of studies (Blume and Greene, 2000; Gattobigio et al., 2012; von Stecher, 2010, 2011; Yamashita et al., 2010) bear directly on this question. In particular, (von Stecher, 2011) predicts that a universal resonance of 5 identical bosons should occur at zero energy when the two-body scattering length is equal to $a_{\text{B}} = (0.65 \pm 0.01)a_{4\text{B}}$. That prediction was tested and confirmed experimentally by the Innsbruck group (Zenesini et al., 2013); this study also compared a detailed theoretical and experimental estimate of the direct 5-body recombination rate, apparently the first time a direct (i.e. non-stepwise) recombination process could be observed experimentally and computed theoretically. While this is suggestive of a general universality for all N-boson systems, very recent work by (Yan and Blume, 2015) suggests that this may apply only to systems whose long-range two-body interaction is dominated by van der Waals interactions, as shorter range interacting systems apparently exhibit extensive variability in their N-boson binding energies at unitarity. (Yamashita et al., 2010)

Following the prediction in (von Stecher, 2010, 2011), the possible existence of a universal 5-body recombination resonance was tested and confirmed in (Zenesini et al., 2013). Fig.10 shows the comparison between theory and experiment, in a region that includes both a universal 4-body resonance and a universal 5-body resonance. These predictions of universal resonances observable in N-body recombination have been extended in some impressive recent calculations to even larger numbers of identical bosons by (Gattobigio et al., 2011, 2012).

**H. Efimov states in heteronuclear mass-imbalanced systems**

The existence of an infinite series of three-body bound states for resonant two-body interaction, as predicted by Efimov (Efimov, 1970), is not only present for homonuclear systems, as such universal three-body bound states should appear as well for heteronuclear systems (D’Incao and Esry, 2006a,b; Efimov, 1973a, 1979; Helfrich et al., 2010; Mikkelsen et al., 2015; Petrov and Werner, 2015; Wang et al., 2012d, 2015b). In particular, in heteronuclear systems the mass-imbalanced nature of the three-body system preserves but modifies in an interesting way the discrete symmetry scaling characteristic of Efimov states, i.e., $a^{(n)} = \lambda a^{(n-1)}$, and hence preserving the
universality of the three-body bound states. Most importantly, it influences the scaling factor $\lambda$, which depends on the masses of the three particles involved. In particular, $\lambda$ gets smaller as the mass imbalance of the HHL system increases, which has sparked the study of highly mass-imbalanced systems as the best possible scenario for studying multiple excited Efimov states, and hence exploring as deeply and unambiguously as possible the universal characteristics of such states. To date, heteronuclear Efimov states have been searched for in $^{41}$K-$^{87}$Rb-$^{87}$Rb (Barontini et al., 2009; Wacker et al., 2016), $^{39}$K-$^{87}$Rb-$^{87}$Rb (Wacker et al., 2016), $^{40}$K-$^{87}$Rb-$^{87}$Rb (Bloom et al., 2013), $^{7}$Li-$^{87}$Rb-$^{87}$Rb (Maier et al., 2015) and $^{6}$Li-$^{133}$Cs-$^{133}$Cs (Johansen et al., 2016; Tung et al., 2014; Ulmanis et al., 2016a, 2015, 2016b).

The study of three-body losses in an ultracold mixture $^{41}$K-$^{87}$Rb performed by the LENS group led to the first claimed observation of heteronuclear Efimov states, specifically for $^{41}$K-$^{87}$Rb-$^{87}$Rb and $^{41}$K-$^{133}$K-$^{87}$Rb (Barontini et al., 2009). In particular, a three-body parameter $a_{(1)}^{(1)} = -246 \pm 14 \,a_0$ was claimed to be observed for K-Rb-Rb. However, this claimed observation of an Efimov resonance has been questioned in the literature, in part because it is so far from the expected theoretical range for this system. Owing to the positive value of the Rb-Rb scattering length $a \sim 100 \,a_0$, the first Efimov resonance is expected to occur in K-Rb-Rb at around $a_{(1)}^{(1)}(K-Rb) \leq -30,000 \,a_0$. In a very recent follow-up by the Aarhus experimental group, they find that there is a two-body p-wave feature in the vicinity of the LENS group’s claimed Efimov resonance $^{41}$K-$^{87}$Rb-$^{87}$Rb, which adds to doubts about the classification of that loss feature which doesn’t fit universal expectations for the 3-body system. (Ulmanis et al., 2016a; Wang et al., 2012d) Similarly, the K-K-Rb system is “Efimov-unfavored (LLH)” since it has two lighter and one heavier atom, and its first Efimov resonance has been predicted to occur only for $a_{(1)}^{(1)}(K-Rb) \leq -10^6 \,a.u.$ Other experiments on potassium mixtures with $^{87}$Rb with either the fermionic isotope $^{40}$K (Bloom et al., 2013) or the bosonic isotope $^{39}$K (Wacker et al., 2016) have failed to observe Efimov resonances at a reasonable value of the K–Rb scattering length, results which are more consistent with theoretical expectations. In particular, the JILA group (Bloom et al., 2013) studied an ultracold Bose-Fermi mixture $^{40}$K-$^{87}$Rb, in which only $^{40}$K-$^{87}$Rb-$^{87}$Rb supports Efimov resonances because $^{40}$K-$^{40}$K-$^{87}$Rb is suppressed by spin statistics. The JILA group measured the three-body recombination rate with the aim of testing whether they could observe approximately the same Efimov resonant position as had been seen for $^{41}$K-$^{87}$Rb-$^{87}$Rb by (Barontini et al., 2009). This expectation was of course fueled by the assumption of universality of the three-body parameter (Wang et al., 2012d). However, no trace of any Efimov resonances was observed at the expected two-body scattering length (Bloom et al., 2013), consistent with our current theoretical understanding (Ulmanis et al., 2016a; Wang et al., 2012d).

Very recently an Efimov resonance for $^{7}$Li-$^{87}$Rb-$^{87}$Rb was reported, (Maier et al., 2015) as a consequence of a first exploration of the negative Li-Rb scattering length in an ultracold mixture of bosonic Li and $^{87}$Rb. The observed resonance is found at $a_{(1)}^{(1)} = -1870 \pm 121 \,a_0$ in at least approximate agreement with the universal Efimov expectation (Wang et al., 2012d), and it should be stressed that it is vital to include in the analysis the correct heavy-heavy scattering length (Maier et al., 2015). Note that with current experimental capabilities it is extremely difficult to reliably create and control atom-atom scattering lengths beyond about 10,000 $a_0$, in absolute magnitude. Only one experiment to date, a heroic effort by the Innsbruck group in a homonuclear Cs gas (Huang et al., 2014a), has been able to measure Efimov physics at a scattering length as large and negative as $-22,000 \,a_0$.

| $n$ | $a_{(n)}^{(1)} (a_0)$ | $\lambda$ | $a_{(n)}^{(2)} (a_0)$ | $\lambda$ |
|-----|----------------------|-----------|----------------------|-----------|
| 1   | -311 ± 3             |           | -323 ± 8             |           |
| 2   | -1710 ± 70           | 5.48 ± 0.28 | -1635 ± 60           | 5.1 ± 0.2 |
| 3   | -8540 ± 2700         | 5.00 ± 1.8 | -7850 ± 1100         | 4.8 ± 0.7 |

Table IV: Experimental Efimov resonances for $^{6}$Li-$^{133}$Cs-$^{133}$Cs, with the Li-Cs scattering lengths denoted here as $a_{(n)}^{(1)} (a_0)$. For the spin states utilized in these experiments, the background Cs-Cs scattering length in this region of magnetic field near 843G is approximately in the range $-1600a_0 < a_{CS-CS} < -1000a_0$. The maxima of the three-body loss rate occur at the indicated values $a_{(n)}^{(0)}$, where $n$ stand for the ordering of the different associated Efimov states. The three-body parameter is denoted here as $a_{(1)}^{(1)}$. The discrete symmetry scaling factor for two successive Efimov states is denoted by $\lambda$. The Heidelberg group results of (Ulmanis et al., 2015) are shown in the second and third columns, the results of Chicago group (Tung et al., 2014) in the fourth and fifth columns. Note that the Heidelberg group also suggests a re-calibration of the Chicago group’s data in Table 2 of (Ulmanis et al., 2015), but those results are not shown here.

The most convincing tests of universal Efimov scaling are for the highly mass imbalanced case of $^{6}$Li-$^{133}$Cs-$^{133}$Cs, studied independently by the Heidelberg (Häfner et al., 2017; Pires et al., 2014b; Ulmanis et al., 2016a, 2015, 2016b) and Chicago groups (Johansen et al., 2016; Tung et al., 2014). Theoretically, the universal Efimov scaling factor for this system should be $\lambda = 4.88$ (D’Incao and Esry, 2006a; Wang et al., 2012d), which enables experiments to observe and characterize multiple resonances in a single Efimov series for the first time. As in many other approaches to Efimov physics with ultracold atoms, Chicago and Heidelberg groups use a magnetic Fano–Feshbach resonance for Li-Cs to vary the two-body scattering length. The results for the observed Efimov resonances, characterized by analysis of the mass-
ina in the three-body loss coefficient, are shown in Table IV, where the three-body parameter reported by the Chicago and Heidelberg groups can be seen to agree approximately, to within the error bars. Another interesting difference probed in the experiments by (Ulmanis et al., 2016a) is the contrasting value of the first Efimov resonance depending on the sign of the Cs-Cs scattering length. For instance, when the Cs-Cs scattering length is large and negative as in the cases reported in Table IV, the first resonance occurs at a Li-Cs scattering length value equal to \( a_{(1)} \approx -320a.u. \). But for a different range of magnetic fields where the Cs-Cs scattering length is positive \( a(Cs - Cs) \approx 200a_0 \), the first resonance occurs at \( a_{(1)} \approx -2000a.u. \). As is argued in (Ulmanis et al., 2016a), this major difference can be understood qualitatively already in the zero-range theory, without invoking van der Waals interactions, although a full model including van der Waals finite-range interactions is needed to make the description quantitatively accurate. These experiments are of course extremely difficult, and we stress the importance of developing highly accurate two-body scattering models before undertaking the analysis of departures from expected universal behavior.

The prediction of Efimov and the universality of the three-body physics (Efimov, 1970, 1971) is strictly true in the case of two-body resonant interactions and assuming \( T = 0 \), since no consideration was given to the kinetic energy of the three-body system. A few studies have carried out the appropriate Boltzmann average needed to derive finite temperature predictions of the three-body recombination rate, as in (Petrov and Werner, 2015; Rem et al., 2013). Thus, in realistic systems one would expect some deviations from Efimov’s prediction. However, the experimental observations seem to indicate that most of the Efimov states are accurately universal.

### I. Efimov and universal bound states for fermionic systems

It is well known that there is no Efimov effect for homonuclear trimers composed of identical fermions in a single intrinsic spin substate. This is easy to understand because the requirement of antisymmetry adds nodes to the spatial wavefunction and this raises the kinetic energy of the trimer internal degrees of freedom substantially. For a system of two heavy fermions of mass \( M \) in the same spin state and a lighter distinguishable particle of mass \( m \), the nodal constraint of antisymmetry is weaker and some interesting predictions for this case have been presented by (Kartavtsev and Malykh, 2007, 2014). The Efimov effect emerges for this FFX system with divergent \( F+X \) scattering length, provided the mass ratio is sufficiently large, namely \( M/m > 13.607 \). For smaller mass ratios than this critical ratio just mentioned, one observes one or two universal states, usually denoted “Kartavtsev-Malykh universal trimers”, but there is no true Efimov effect and the number of energy levels remains finite. Some level perturbations that can affect these universal trimer states have been identified by (Safavi-Naini et al., 2013).

The possibility of a four-particle Efimov effect is another intriguing prediction by (Castin et al., 2010), with 3 heavier identical fermions of mass \( M \) and one lighter distinguishable particle of mass \( m \). Specifically, they predict that only in the tiny mass ratio range \( 13.384 < M/m < 13.607 \) should one be able to observe the infinite number of energy levels converging geometrically to zero binding that characterizes Efimov physics. A very recent preprint from (Bazak and Petrov, 2016) predicts a pure five-body Efimov effect, for a system of 4 heavy identical fermions and 1 distinguishable particle, again in a small range between \( 13.279 \pm .002 < M/m < 13.384 \), based on a stochastic solution of the generalized Skorniakov-Ter-Martirosian (STM) equation (Pricoupenko, 2011), based on techniques analogous to diffusion Monte Carlo methods. The study of (Bazak and Petrov, 2016) also predicts mass ratios where one expects universal five-body states in regimes where no true Efimov effect exists, and a conjecture that the 5+1 hexamer and higher particle numbers will be qualitatively different rather than simply continuing the trend, a conjecture certainly deserving to be explored. This study agrees and improves on the accuracy of a prediction by (Blume, 2012b) that a universal 3+1 tetramer should exist at a mass ratio around \( M/m > 9.5 \), with the new and improved computed ratio equal to \( M/m > 8.862 \pm 1 \).

### J. Naturally occurring Efimov physics in the helium trimer

The study of helium clusters– their aggregation, formation and collision dynamics – has been an active research topic in chemical physics, in particular in the field of molecular beams (Campargue, 2001). Molecular beam experiments rely on the supersonic expansion of a chosen gas in vacuum, which induces the cooling of the different molecular degrees of freedom as the gas expands in the chamber. This cooling mechanism is due to inelastic collisions involving electronic, rotational and vibrational degrees of freedom, and hence it strongly depends on the inelastic cross sections as well as the number of collisions through the density of the gas (Montero and Pérez-Ríos, 2014; Zhdanov, 2002; Zucrow and Hoffman, 1976). The diluteness of the gas as it moves away from the nozzle can be controlled by the initial conditions of the expansion: temperature, pressure and mass flow, through the conservation of enthalpy and mass flow of the fluid. Therefore, any property or process related with the dynamics of the gas, such as cluster formation, could be controlled to some degree in those experiments. Using such methods, Schöllkopf and Toennies (Schöllkopf and Toennies, 1994, 1996) experimentally observed the helium dimer
and the ground state of helium trimer.

Figure 11 (Color online) (a) Adiabatic $J^\pi = 0^+$ hyperspherical potential curves from the calculation of (Suno and Esry, 2008), with the two bound state energies predicted for this symmetry drawn into the potentials. The higher energy of the two, which has an energy so small that it appears to coincide with $E=0$, was predicted to be an observable Efimov state. (b) Experimentally measured pair distribution functions of the two helium trimer bound states, with a theory comparison for the more diffuse state that is concluded to be an Efimov state. This measurement used laser ionization followed by Coulomb explosion of the three resulting ions, with detection in a COLTRIMS apparatus. For more details see the combined theoretical and experimental paper published by (Kunitski et al., 2015).

Although the ground state $^4\text{He}_3$ was observed two decades ago, the first excited state of $^4\text{He}_3$, which has Efimov character, was not observed until very recently (Kunitski et al., 2015). Fig. 11 summarizes both the key theoretical and experimental results for the system. This remarkably challenging experiment was performed by joining the technology of molecular beam experiments, atom interferometry, and modern ionization and detection techniques. In particular, a very well controlled nozzle conditions led to a supersonic expansion of He, where He trimers were selected by means of matter-wave diffraction through a grating. Then, all three atoms of the trimer are ionized by means of a strong ultrashort pulse, leading to the subsequent Coulomb explosion of the trimer compounds. The momenta of the ions after the Coulomb explosion were detected by cold target recoil ion momentum spectroscopy (COLTRIMS) (Jagutzki, 2002; Ullrich, 2003), which allowed in an analysis the reconstruction of the initial probability distribution of the trimer atom positions, and thereby allowing a deduction of the trimer binding energy. In this way, Kunitski et al. (Kunitski et al., 2015) studied the formation of two different He trimer states as functions of the pressure in the nozzle, leading to the first observation of the excited state of $^4\text{He}_3$.

The findings of Kunitski et al. (Kunitski et al., 2015) revealed the geometry of the the ground state and first excited state of helium trimer. In particular, for the ground trimer state it was observed a unimodal radial distribution for the atom-atom distance in the trimer, in relation with the expected equilateral geometry. However, for the first excited trimer state the radial distribution function shows a bimodal character, thus resembling an isosceles triangular geometry. These results demonstrate the Efimov character of the first excited state of helium trimer. In particular, the obtained binding energy is $2.60 \pm 0.2 \text{ mK}$ in very good agreement with some of the most recent theoretical predictions (Hiyama and Kamimura, 2012; Kunitski et al., 2015), however the bimodal radial distribution clearly deviates from what it is expected from the universal Efimov predictions for resonant two-body interaction at unitarity, which is not surprising in view of the finite value of the He-He scattering length (Blume et al., 2000, 2014).

The most recent hyperspherical coordinate calculations of the helium trimer properties in the electronic ground state appear to be those of (Suno and Esry, 2008). Their $J^\pi = 0^+$ adiabatic potential energy curves obtained with an up to date potential surface, which includes three-body as well as realistic retarded two-body potential terms, are shown in Fig. 11. The energies drawn into the lowest potential curve are the two computed bound state energies, namely $-130.86 \text{ mK}$ and $-2.5882 \text{ mK}$. The more weakly bound of these is the one expected to have significant Efimov state character, and it is in fact so weakly bound that its energy is indistinguishable from $E = 0$ on the scale of Fig. 11.

IV. FEW-BODY PERSPECTIVES ON MANY-BODY SYSTEMS

There are multiple ways in which few-body physics is useful for understanding, interpreting, and predicting new many-body phenomena. The most obvious is through the development of detailed theoretical understanding of the microscopic processes involving two, three, four, or some cases even a handful more particles within a gas or lattice array of particles. The detailed studies described above, and other review articles (Chin et al., 2010; Köhler et al., 2006; Wang et al., 2013, 2015a) have focused largely on two-body phenom-
enae such as Fano-Feshbach resonances, and on the three-body phenomena that arise such as Efimov resonances in three-body recombination and related behavior such as Stückelberg interference minima. The initially surprising experimental result (Cubizolles et al., 2003; Regal et al., 2004a; Streck et al., 2003) that huge universal fermionic dimers have remarkably small losses despite their huge size was understood in an important theoretical treatment by (Petrov et al., 2005a,b). This played a key role in stimulating experiments in the BCS-BEC crossover problem and in triggering explorations of other phenomena in unitary Fermi gases. Fig. 12 shows a later theoretical treatment of the two-component four-fermion system in hyperspherical coordinates, including the computed dimer-dimer scattering information. For instance, it has now become possible to map out an extremely accurate equation of state for unitary Fermi gases (Chevy et al., 2011; Ku et al., 2012).

Another way few-body theories have provided some useful perspectives on Bose-Einstein condensates and degenerate Fermi gases has simply been through applying the few-body toolkit and ideas - such as adiabatic hyperspherical potential curves - to the many-particle system directly. In some cases this is done by treating only a modest number of particles accurately, while in other cases the many-particle limit is examined but at a relatively crude level of approximation to estimate the many-particle potential energy curves.

Few-body physics also produces insight into systems of trapped atoms through the use of the idea of an artificially strong trap. The premise here is that frequently in a trapped quantum gas with thousands or even millions of atoms, the physical trap frequency might only be of order 10 Hz and determines only a largely irrelevant energy scale for the system. More relevant by far are the typical scale of interparticle interactions and the average kinetic energy or temperature, reflected in the separation of atoms $\Delta r$. The physical content of this separation length scale is sometimes referred to as the “Fermi wavenumber” $k_F = 2\pi/\Delta r$ even when the gas consists of some or even all bosonic particles. Then one can gain insight by treating only 2, 3, or 4 particles in an unphysical artificially tight “theoretical trap” designed to have a high frequency with particle separation $\Delta r$ comparable to the $\Delta r$ in the actual many-particle system. An example where this strategy enables a simple interpretation (Borca et al., 2003). of a complicated many-body problem is the famous “atom-molecule” coherent oscillations or quantum beats observed in an $^{85}$Rb experiment (Donley et al., 2002), depicted in Fig. 13.

### A. Polaron physics attacked from a few-body viewpoint

When a slow electron moves inside a bulk material such as a polar crystal or helium liquid, it attracts other particles from the bulk and the entity behaves as a quasi-particle, as described in highly-cited early studies by (Feynman, 1955; Fröhlich, 1954). Such a quasi-particle was denoted a polaron, and this term has been generalized to describe a more general situation in which an interaction-dressed minority particle moves in the field of other particles in a medium. An active field of research to this day, polarons have attracted extensive attention from experimental (Michaud and Sanche, 1987) as well
Polarons have received attention in ultracold atom experiments and theory over the past decade or so by (Astrakhardchik and Pitaevskii, 2004; Bei-Bing and Shao-Long, 2009; Bruderer et al., 2008; Catani et al., 2012; Cucchietti and Timmermans, 2006; Grusdt et al., 2015; Kalas and Blume, 2006; Kohstall et al., 2012; Koschorreck et al., 2012; Levinsen et al., 2015; Li and Das Sarma, 2014; Rath and Schmidt, 2013; Scelle et al., 2013; Schirotzek et al., 2009; Spethmann et al., 2012; Tempere et al., 2009) and very recently, as in (Hu et al., 2016; Jørgensen et al., 2016). Some work has considered an impurity with internal degrees of freedom called an “an- gulan” which is a quasi-particle consisting of a rotating impurity dressed by the quantal many-body environment (Lemeshko, 2017; Schmidt and Lemeshko, 2016). To date the explorations have concentrated on the behavior of a single impurity in a BEC or DFG, but a future few-body topic that is still in its infancy will be the study of interactions among two or more impurities dressed by the many-body environment. An initial foray along those lines by (Naidon, 2016) treats two-body polaron-polaron interactions. We refer the reader to the excellent recent review of this subject in (Naidon and Endo, 2016) and references therein.

as theoretical studies (Basak and Cohen, 1979; Fano and Stephens, 1986; Stephens and Fano, 1988) in condensed-matter physics. In recent years polaron physics has become a topic of great interest in the ultracold atomic physics community, owing to the promise of great control and observability. The few-body side of polaron physics has two major areas of interest. One aspect is to discern the details of a single quasi-particle in the many-body environment and the more advanced topic of interactions among 2, 3, or 4 quasi-particles, i.e. the effect of a many-body bosonic or fermionic bath of particles on the interactions, energy levels, and recombination of the quasi-particles. (Bellotti et al., 2016) The second area that has received extensive attention is the behavior of few-body analogues of a polaronic system, with small numbers of minority and majority particles, such as the HHL and HHHL and related problems discussed elsewhere in this review.

Polarons have received attention in ultracold atom experiments and theory over the past decade or so by (Astrakhardchik and Pitaevskii, 2004; Bei-Bing and Shao-Long, 2009; Bruderer et al., 2008; Catani et al., 2012; Cucchietti and Timmermans, 2006; Grusdt et al., 2015; Kalas and Blume, 2006; Kohstall et al., 2012; Koschorreck et al., 2012; Levinsen et al., 2015; Li and Das Sarma, 2014; Rath and Schmidt, 2013; Scelle et al., 2013; Schirotzek et al., 2009; Spethmann et al., 2012; Tempere et al., 2009) and very recently, as in (Hu et al., 2016; Jørgensen et al., 2016). Some work has considered an impurity with internal degrees of freedom called an “an- gulan” which is a quasi-particle consisting of a rotating impurity dressed by the quantal many-body environment (Lemeshko, 2017; Schmidt and Lemeshko, 2016). To date the explorations have concentrated on the behavior of a single impurity in a BEC or DFG, but a future few-body topic that is still in its infancy will be the study of interactions among two or more impurities dressed by the many-body environment. An initial foray along those lines by (Naidon, 2016) treats two-body polaron-polaron interactions. We refer the reader to the excellent recent review of this subject in (Naidon and Endo, 2016) and references therein.

B. Bose-Einstein condensates viewed in hyperspherical coordinates

In the Russian nuclear physics literature, a technique evolved during the 1960s and 1970s to treat the many-nucleon problem, which was referred to as “K-harmonic” theory. This treatment was based on a particularly simple approximation formulated in hyperspherical coordinates. The basic idea was to find the lowest grand angular momentum state, the “K-harmonic” |KQ>. This eigenfunction of hyperangular kinetic energy and various symmetry operators is usually an appropriately antisymmetrized linear combination of hyperspherical harmonics; they are constrained to obey the symmetries of the system such as the Pauli exclusion principle, definite parity, and so on. This approximation then uses this single harmonic to describe the hyperangular wavefunction of the system. When this technique is applied to the description of a single component BEC, it is particularly simple because the K-harmonic for this system is simply the state of vanishing grand angular momentum, K = 0, which is a constant in the hyperangular space of any N-particle system. While the resulting wavefunction is not sufficiently realistic to describe the true short-range interactions that occur whenever any two particles approach each other, the use of the Fermi pseudopotential in the many-body Hamiltonian implies that the average energy of interaction can be approximately represented perturbatively.(Bohn et al., 1998) In our terminology today, we can view this as approximating the lowest adiabatic hyperangular eigenfunction as this K-harmonic, after which perturbation theory can be applied to the interparticle interaction term in the Hamiltonian to determine the approximate ground state potential energy curve for the
many particle system, namely, $U_0(R)$. See Fig. 14. This treatment does a reasonable job of predicting the approximate maximum number of atoms that can exist in a harmonic trap when the scattering length is negative, beyond which the system undergoes a macroscopic collapse often referred to as the “Bosenova” (Bradley et al., 1997; Donley et al., 2001).

These questions have long been of theoretical interest, e.g. (Cowell et al., 2002; Lee and Lee, 2010; Radzihovsky et al., 2008), and recently they have begun to receive experimental attention. One way to deal with the transient nature of any short-lived quantum gas is to perform the experiment as a “quench”, i.e. begin with a BEC at small positive scattering length and then suddenly ramp to the range of unitarity, $a \to \infty$. A recent experiment at JILA by (Makotyn et al., 2014) very quickly stimulated extensive theoretical work (Aucilotto et al., 2015; Corson and Bohn, 2016; Hudson et al., 2014; Jiang et al., 2014, 2016; Kira, 2015; Laurent et al., 2014; Piatecki and Krauth, 2014; Rancon and Levin, 2014; Sykes et al., 2014; Yin and Radzihovsky, 2016) to understand their main observations, which were the following. (i) The $a^6$ scaling of three-body loss is no longer applicable at very large scattering lengths, i.e. when $na^3 >> 1$ where $n$ is the density. To understand this, Ref. (Makotyn et al., 2014) defines a characteristic wavenumber of the system (analogous to the Fermi wavenumber) as $K \equiv (6\pi^2n)^{1/3}$, which is comparable to the inverse of the average interparticle spacing.

Figure 14 (a) Adiabatic hyperspherical potential curves for an attractive BEC, a noninteracting BEC, and a repulsively interacting BEC. (b) Excitation energy calculated for an attractive ($a < 0$ BEC) in the hyperspherical adiabatic theory, compared with the random phase approximation which is essentially identical to Bogoliubov theory. Taken from (Bohn et al., 1998).

Since that simple study of (Bohn et al., 1998), other studies have considered improvements of the hyperspherical BEC treatment, including generalizations to asymmetrical traps and attempts to better include the few-body correlation physics beyond the simplest mean-field approximations. (Kim and Zubarev, 2002; Kushihe et al., 2004; Sorensen et al., 2004; Watson and McKinney, 1999)

C. The unitary Bose gas

Based on what has been learned from studies of dilute Bose gas recombination theory and experiments, one expects it to be impossible to create a long-lived Bose-Einstein condensate in the unitary limit where $a \to \infty$. This conclusion is based on the fact that three-body losses are seen to scale with the scattering length overall as $a^4$, aside from quantum resonance and interference factors. Nevertheless this is a fascinating limit, in part because it can test whether the recombination loss rates continue to scale as $a^4$ all the way to $a \to \infty$ and in part because the many-body behavior implied by the Gross-Pitaevskii equation looks so qualitatively different for large negative (infinitely attractive and immediate collapse) versus large positive scattering lengths (infinitely strong repulsion).

One of the main items of interest in this system, from a few-body physics perspective, is the saturation of losses at a value far smaller than would be expected from the zero-temperature $a^6$ scaling. An estimate (Sykes et al., 2014) has been made of the three-body rate coefficient $L_3 \approx 3 \times 10^{-23}$ cm$^6$/sec is reasonably close (around half as large as) the measured value in the JILA experiment of (Makotyn et al., 2014). This theoretical estimate is made using the few-body “artificial trap model” which considers only 3 atoms but places them in an artificially tight trap such that the atom density approximately matches the experimental average density, which was $\langle n \rangle = 5.5(3) \times 10^{12}$ cm$^{-3}$. As is discussed in greater de-
to (Sykes et al., 2014), one obtains somewhat poorer quantitative agreement but still the correct order of magnitude for the loss rate at unitarity by replacing the value of $a$ in the universal 3-body loss rate formulas by $1/K$ as defined above in terms of the average density in the gas. Other experimental studies of the unitary Bose gas that have focused on the three-body loss rate include (Eismann et al., 2016; Fletcher et al., 2013; Rem et al., 2013). And another intriguing “universality limit” where the scattering length is no longer a relevant length scale is the opposite limit $a \approx 0$, recently explored experimentally with some phenomenological conjectures in (Shotan et al., 2014).

D. Two-component Fermi gases and the BCS-BEC crossover problem

One fascinating type of dilute quantum gas experiment consists of distinguishable fermions, either in two or more spin substates or else composed of two or more types of distinguishable particles. This system received extensive attention from many theory (e.g. (Hu et al., 2007, 2006; Hui et al., 2004; Yan and Blume, 2016; Yin and Blume, 2015)) and experimental groups,(DeMarco and Jin, 1999; Houbiers et al., 1997; Ketterle and Zwierlein, 2008; Ku et al., 2012; Schunck et al., 2005; Zwierlein et al., 2006, 2004) with particularly keen interest in the community around a decade ago. Conceptually, one typically starts the experiment by forming a two-component degenerate Fermi gas without interactions, i.e. with vanishing scattering length between the two component atoms. Interactions between like fermions can usually be ignored, unless one is close to a $p$-wave Fano-Feshbach resonance. Now one increases the attraction by making the scattering length $a$ between unlike atoms small and negative, i.e. $-1 << k_f a < 0$. This is the regime usually referred to as the Bardeen-Cooper-Schrieffer (BCS) region, because the weak attraction tends to cause pairing. These BCS-type pairs are sometimes referred to as “pre-formed pairs” because the pairing occurs before the attraction is strong enough to form true isolated dimer bound states. Of course true molecular bound states can be formed only after the attraction has increased beyond $k_f a < -1$, to infinite $a$ and then $a$ is large and positive which allows true universal dimers to form with binding energy $\frac{1}{2m a^2}$. At that point, when the gas has large and positive $a$, the quantum gas has experienced a “crossover” from a degenerate Fermi gas to a BEC of weakly-bound molecules (Sá de Melo et al., 1993). Remarkably, such a system allows an exploration of either Fermi or Bose quantum statistics depending on the range of scattering lengths chosen experimentally. An impressive series of experiments has observed precisely these phenomena (Greiner et al., 2003; Loftus et al., 2002; Regal et al., 2005, 2004b), and this crossover physics has been reviewed by (Regal and Jin, 2007).

Of course the single-component Fermi gas is also of interest, with all fermionic atoms in the same intrinsic spin state. Owing to the absence of $s$-wave collisions in such systems, the cross sections for two-body elastic collisions that are needed for thermalization of the gas are generally quite small at ultracold temperatures. Use of a $p$-wave Fano-Feshbach resonance can enhance the cross sections, although two-body losses also usually grow in the vicinity of such resonances (Regal et al., 2003). A two-component Fermi gas has its three-body recombination losses suppressed since the low temperature behavior of the rate coefficient is linear in the temperature $T$, in contrast to a gas of bosons or of 3 distinguishable particles which have a constant low-temperature 3-body recombination rate. A spin-polarized gas of fermions, on the other hand, has an even stronger suppression of the low-temperature recombination rate, which varies as $T^2$. This might be expected to give very long-lived Fermi gases when fully polarized, but near a $p$-wave Fano-Feshbach resonance in spin-polarized $^{40}$K (the point where the $p$-wave scattering volume $V_p \rightarrow \infty$), the recombination coefficient has been measured (Regal et al., 2003) and calculated (Suno et al., 2003a,b), and found to approach within an appreciable fraction of the unitarity limit for the atom loss rate at total relative energy $E$:

$$K^\text{max}_3 = \frac{\hbar^5}{m^3} \frac{144 \sqrt{3} \pi^2}{E^2}. \quad (59)$$

In addition to an explosion of effort to understand the many-body physics of the BCS-BEC crossover problem, there has also been extensive fruitful effort directed towards understanding this system from a few-body point of view. See in particular (Akkineni et al., 2007; Alhassid et al., 2008; Bulgac et al., 2006; Chang and Bertsch, 2007; Kestner and Duan, 2007; Werner and Castin, 2006; Zinner et al., 2009). And in fact one limit of the many-body problem, the “high energy limit” can be accurately treated using the virial or cluster expansion. Exciting progress in computing virial coefficients for three particles (Castin and Werner, 2013; Liu et al., 2009) and for four particles (Yan and Blume, 2016) has been contributed in landmark theoretical papers during the past decade, as well as tested in a few impressive experiments. (Nascimbene et al., 2010)

E. A step beyond independent particles: the Tan Contact

The standard methods used in most many-body calculations usually start with a mean-field wavefunction ansatz, in some cases going one step farther to the level of Bogoliubov theory or, what is essentially equivalent, the random phase approximation (Esry, 1997; Fetter and Walecka, 2003). These approximations have a demon-
strated track record of describing gross global properties of many-body systems, for properties such as chemical potentials, total energies, and excitation frequencies (Dalfovo et al., 1999; Giorgini et al., 2008). One thing that should be kept in mind about such treatments is that they are based on ridiculously inaccurate cartoon-level wavefunctions of the many-body system at interparticle distances less than the van der Waals length. However, the behavior over larger distances of order of the long de Broglie wavelengths in the system, it turns out to be reasonable. To understand the flaws in the full many-body wavefunction ansatz used to derive the Gross-Pitaevskii equation, the workhorse equation of Bose-Einstein condensation theory, recall that it is a product of independent orbitals $\psi_i$, i.e. $\Psi(\vec{r}_1, \vec{r}_2, ..., \vec{r}_N) = \psi(\vec{r}_1)\psi(\vec{r}_2)\cdots\psi(\vec{r}_N)$. Why is this a patently absurd hypothesis? Because it says that each particle’s probability amplitude is independent of the instantaneous positions of all other particles; but in reality, there simply must be, in the “true” wavefunction of the system, a two-body character (at the very least) when the distance between any two particles of the gas gets comparable to the interaction length scale in the potential energy function between those particles (the van der Waals length in the case of isotropic atoms). For two $^{87}$Rb atoms in spin-stretched magnetic substates, for instance, the zero-energy wavefunction of any two approaching atoms in the Rb BEC must have the 39 nodes as the interparticle distance is varied which are guaranteed to be there by Levinson’s theorem (Rodberg and Thaler, 1970; Taylor, 1972) since the Rb dimer has 39 triplet bound states in the $L = 0$ orbital partial wave. (For an ultracold atomic gas, higher partial wave physics is normally suppressed by the centrifugal barrier, so we will focus only on the s-wave physics in this discussion.) This behavior is often incorporated into Monte Carlo (MC) calculations by using a “Jastrow-type” variational trial function (or a guiding function in the case of diffusion MC), which includes a product of all zero energy two-body pair wavefunctions (Carlson et al., 2015; Dalfovo et al., 1999; Giorgini et al., 2008).

To see why the cartoon-level approximation gives such a good description of many properties, consider the zero-range Fermi pseudopotential representation of the interaction between two low energy particles, i.e. $V(\vec{r}_{ij}) = \frac{2\pi a_{ij}\hbar^2}{\mu_{ij}}\delta(\vec{r}_{ij})$, where $a_{ij}$ is the scattering length between particles $i$ and $j$ and $\mu_{ij}$ is their reduced mass. In the important paper by Fermi (1934), he proved that this potential gives an accurate interaction energy of two particles with finite range potentials in the zero energy limit, even when highly inaccurate zeroth-order wavefunctions are utilized; this rescues many-body predictions of energies and other gross properties of the many-body system. The success of this “rescue” is documented by (Holzmann and Castin, 1999) who demonstrate that the behaviors over large distance scales of mean field and Bogoliubov wavefunctions are quite reasonable, even though their Hamiltonian does not contain the large number of two-body bound states whose presence would cause rapid, short-range oscillations in any “exact” wavefunction of all alkali metal atoms in a many-body gas.

Nevertheless, some properties of the many-body system go beyond those global properties that are well described by a separable wavefunction ansatz and its crude improvements at the next level of approximation. One such property identified by Shina Tan in a groundbreaking series of papers (Tan, 2008a,b,c) is the “high energy” limit of the pair correlation function. This Tan contact parameter has now been measured for a Fermi gas (Sagi et al., 2013, 2012) as well as for a BEC (Wild et al., 2012), and those experiments have confirmed the basis two-body physics on which Tan’s ideas are based. In brief, one way of looking at the Tan contact is to acknowledge that there will be a range of distances, as two zero-energy particles begin to approach each other at smaller and smaller distances $r_{ij}$, where the wavefunction must be proportional to:

$$\Psi \propto \frac{1}{a_{ij}} - \frac{1}{r_{ij}}$$

(60)

In a sense the physics of the Tan contact is just the tip of the iceberg, because at higher momenta one begins to probe the full momentum space wavefunction of two-body subsystems, which have a complicated structure that in general depends on the detailed nature of their short range interactions. For instance, in a gas of Rb or K atoms, one can expect that the momentum space wavefunction above $k_{vdW} \sim 1/\ell_{vdW}$ or at energies above a few MHz should exhibit deviations from the contact prediction based on the scattering length alone. Experimental measurements to date appear to be mostly in the 10-100 kHz regime. Nevertheless, there a wide energy range, high compared to many body excitation frequencies but low compared to van der Waals energy scales, where Tan’s contact and scattering length two-body physics controls the major departure of the atomic quantum gas from a description in terms of non-interacting independent particle wavefunctions (Blume and Daily, 2009; Braaten et al., 2010; Braaten and Platter, 2009; Corson and Bohn, 2016; Hudson et al., 2014; Sykes et al., 2014; Yan and Blume, 2013; Yin and Radzihovsky, 2016; Yin and Blume, 2015).

F. Towards many-body theory with realistic interactions

If a mean field separable wavefunction ansatz is attempted in a variational calculation that uses realistic atom-atom interactions, the results are disastrous and the total energy is overestimated by many orders of magnitude (Esry and Greene, 1999). Basically, the mean-
field wavefunction is unable to make the wavefunction negligibly small at small distances where the atom-atom potential is hugely repulsive. An exact solution of the Schrödinger equation would of course make the wavefunctions exponentially small in such classically forbidden regions, something that no independent particle wavefunction is “smart enough” to accomplish. Quantum Monte Carlo calculations, however, are able to solve for ground states of many particle systems and they are smart enough to make the wavefunctions exponentially small in regions of strong repulsion. For instance, some of the best calculations of helium cluster energies have been obtained using diffusion Monte Carlo calculations (Blume and Greene, 2002; Lewerenz, 1997). Obtaining excited state information from Monte Carlo calculations is notoriously difficult and limited, however, which makes the technique difficult to use for determining scattering properties.

One hybrid theory that has shown promise combines Monte Carlo and adiabatic hyperspherical ideas (Blume and Greene, 2000). The basic idea is to carry out a diffusion Monte Carlo calculation to find the energy of the system at a fixed hyperradius. By repeating the calculation for many different hyperradii, one maps out the ground state potential energy curve of the system. Then, within the adiabatic approximation that neglects coupling to higher potential curves, at least elastic scattering and a class of excited bound state properties can be computed. That approach has been used to compute hyperspherical potential curves (including diagonal adiabatic correction terms) for clusters of up to $N = 10$ $^4$He atoms, as is shown in Fig. 15, and observable properties such as binding energies and atom-cluster scattering lengths. There appear to be no competing calculations to date of the atom-cluster scattering lengths, for instance, beyond about $N = 6$ helium atoms, although excellent progress has been achieved up to $N = 6$, and in some cases beyond, by using Gaussian wavefunctions in combination with a Hamiltonian based on soft-core model potentials.

**V. ULTRACOLD ATOMS IN LOW DIMENSIONAL TRAPS**

The experimental realization of Bose-Einstein condensation in a dilute gas of alkali-atoms in 1995 (Anderson et al., 1995; Bradley et al., 1995; Davis et al., 1995) enables the investigation of pure quantum systems that lie at the interface among atomic, molecular, quantum optical physics and many-body physics. A key breakthrough emerging from the control of ultracold gaseous matter is the capability to tune interatomic interactions in strength and sign by means of magnetic or optical Fano-Feshbach resonances (Chin et al., 2010; Inouye et al., 1998; Köhler et al., 2006). Nowadays, this has triggered the next generation of quantum technologies that allow experimental creation and manipulation of low-dimensional ultracold gases (Bloch et al., 2008; Bongs and Sengstock, 2004; Cazalilla et al., 2011; Giamarchi, 2004; Imambekov et al., 2012; Kolomeisky and Straley, 1996; Lewenstein et al., 2012, 2007; Lieb et al., 2004; McKay and DeMarco, 2011) of bosonic or fermionic or mixed symmetry (Giorgini et al., 2008).

Degenerate ultracold atomic gases of reduced dimensionality then serve as a vehicle for experimental realizations and theoretical investigations of exotic quantum phases such as the Tonks-Girardeau gas (TG) (Girardeau, 1960; Tonks, 1936). The TG many-body phase consists of a one-dimensional gas of impenetrable bosons with infinite pairwise repulsion. A fundamental property of the TG gas is that it can be viewed as displaying a fermionization of the bosons. In this context, fermionization indicates that the infinite repulsion of the bosons creates a node when any two particles touch, so that the squared wavefunction of the infinitely repelling bosons coincides with that of a noninteracting fermionic gas. When the repulsive 1D interaction coefficient is cranked up beyond the pole and onto the side representing infinite attraction, the bosonic ensemble experiences a metastable many-body state, namely the “super Tonks-Girardeau” gas phase (Astrakharchik et al., 2005). Clearly the strength and the sign of interactions play an essential role in creating and probing these exotic many-body phases. It is therefore crucial to study in detail the collisional processes as modified by external confining potentials. Indeed, in these particular low-dimensional
two-body systems, the confinement generates significant modifications to the colliding pair scattering properties. Existing theoretical studies on bosonic collisions show that resonant scattering can be induced by the confinement, yielding the so-called confinement-induced resonance (CIR) effect (Dunjik et al., 2011a; Yurovsky et al., 2008). A CIR occurs when the length scale of the confinement becomes comparable to the $s$-wave scattering length of the colliding bosons and it produces a divergence in the 1D coupling coefficient that is interpreted as a Fano-Feshbach-like resonance. The additional control of low dimensional gaseous matter by varying the confinement frequency led to the experimental creation of the TG gas (Kinoshita et al., 2004; Paredes et al., 2004) and the Super-TG gas (Haller et al., 2009) in cigar-shaped traps.

Evidently, the deepening understanding of collision physics in the low-dimensional ultracold gases translates into an ability to manipulate and even to design new many-body phases by means of the external confinement.

A. Confinement-induced resonances: an interlude

Early seminal work by (Demkov and Drukarev, 1966) treated the motion of an electron in the presence of a uniform magnetic field as well as a zero-range potential. That study showed that the motion of the charged particle is bounded in the presence of the magnetic and zero-range potentials whereas in the magnetic free case the zero-range potential can not bind the electron. An additional control of low dimensional gaseous matter by varying the confinement frequency led to the experimental creation of the TG gas (Kinoshita et al., 2004; Paredes et al., 2004) and the Super-TG gas (Haller et al., 2009) in cigar-shaped traps.

The waveguide symmetry implies that the transverse part of the Laplacian in the Hamiltonian $H$ (see Eq. 61). The corresponding transverse eigenenergies are given by $E_{nm} = \hbar \omega_{\perp}(n + |m| + 1)$, with $n = 2 n_{\rho} = 0, 2, 4, ...$ being the quantum number associated with the nodes of the wave function in the $\rho$-direction and $m$ the azimuthal angular momentum. This relative Hamiltonian $H$ possesses azimuthal symmetry, so $m$ is a good quantum throughout all the configuration space. Here we concentrate on the case $m = 0$.

Remarkably, the prescription given in (Demkov and Drukarev, 1966) to regularize a divergent sum that arises in the derivation involves a very similar mathematical analysis as was used in the CIR treatment of (Olshanii, 1998) that results in a Hurwitz zeta function that is well-defined.

This means that the system interacts strongly at a finite value of the 3D scattering length, whereas in the
absence of the confinement the two bosons exhibit a comparatively weak interaction. This particular phenomenon is the so-called confinement-induced resonance (CIR). The main feature of this effect is that the corresponding resonance condition, \( a_s(E)/a_\perp = -1/c_1 \), can be met either by tuning the trapping frequency or by adjusting the scattering length via a Fano-Feshbach resonance, where \( a_\perp = \sqrt{\mu \omega_\perp / \hbar} \).

Figure 16 (Color online) The one-dimensional coupling strength \( g_{1D} \) (in units of \( \hbar^2 / \mu a_\perp \)) as a function of the ratio \( a_s(E)/a_\perp \). The orange solid line corresponds to the analytical expression given in Eq. (63). The black dots correspond to full numerical calculations where the two-body interactions are modeled via a 6-10 potential. The red star denotes the position of the confinement-induced resonance.

The treatment by (Olshanii, 1998) showed that the full Hamiltonian in Eq. (61) can be mapped onto an effective one-dimensional Hamiltonian with a delta function interaction between the two bosons, of strength \( g_{1D} \).

\[
H_{\text{eff}} = -\frac{\hbar^2}{2\mu} \frac{d^2}{dz^2} + g_{1D} \delta(z) , \quad g_{1D} = \frac{\hbar^2}{\mu a_\perp} \frac{2a_s(E)}{a_\perp} + c_1 a_s(E),
\]

where the constant \( c_1 \) is given by

\[
c_1(k) = \zeta \left( \frac{1}{2}, 1 - \frac{1}{4} (ka_\perp)^2 \right),
\]

with \( \zeta(\cdot, \cdot) \) the Hurwitz zeta function and for \( ka_\perp \ll 1 \) we have the value \( c_1 \approx -1.46035 \). Here \( k \) is the wavenumber associated with the total colliding energy \( E \).

This effective two-body interaction derived from first principles can be utilized directly in a many-body Hamiltonian, which permits an exploration of the underlying physics associated with the Tonks-Girardeau gas. The effective Hamiltonian based on the coupling strength \( g_{1D} \) encapsulates all the relevant scattering information in the full Hamiltonian as well as the non-trivial modifications due to the trap. More specifically, as the ratio \( a_s(E)/a_\perp \) tends to \(-1/c_1\) the quantity \( g_{1D} \to \infty \). This particular feature is depicted in Fig.16 by the vertical dotted line where the position of the CIR is indicated by the red star.

In Fig. 16 the coupling constant \( g_{1D} \) is shown as a function of the ratio \( a_s(E)/a_\perp \). The black dots correspond to the full numerical solution of the Hamiltonian given in Eq. (61) where the two-body interactions are modeled by a 6-10 potential, i.e. \( V(r) = C_{10}/r^{10} - C_6/r^6 \). The orange solid line denotes the analytical result of the coupling constant \( g_{1D} \) given in Eq. (63) which agrees accurately with the numerical solution. Furthermore, Fig. 16 shows that as the ratio \( a_s(E)/a_\perp \) tends to infinity the coupling constant tends asymptotically to a weakly attractive limit in the effective 1D potential energy. The resonant 3D free-space two body interactions, on either the repulsive or attractive side, are modified into weakly attractive 1D forces due to the trapping geometry. This attractive force in the waveguide is determined solely by the \( c_1(k) \) constant and the oscillator length \( a_\perp \). Indeed, for \( a_s(E)/a_\perp \to \infty \) the coupling strength is \( g_{1D} \to \frac{\hbar^2}{2\mu a_\perp c_1} \).

Figure 17 (Color online) An illustration of the physical origin of confinement-induced resonances. Bound state energies in units of \( \hbar^2/\mu a_\perp \), i.e. \( E/\hbar a_\perp \) are depicted versus the ratio \( a_\perp/a_s \). The red dotted lines indicate the energy levels of the unperturbed two-dimensional harmonic oscillator, which act here as channel threshold energies. The black dashed line denotes the position of the confinement-induced resonance relevant in the ultracold limit. The black dashed curve illustrates the s-wave bound state in the absence of the trapping potential. The solid orange curve corresponds to the molecular confinement-induced resonance. The blue curve is the CIR bound state energy supported by all the closed channels.

Qualitatively, the CIR can be viewed as a bound state supported by all the closed channels whose energy coincides with the lowest channel threshold, as in a usual Fano-Feshbach resonance (Bergeman et al., 2003). This multichannel bound state produces only a single pole in the reactance operator, i.e. the tangent of the 1D even parity phase shift. To follow up on this idea, one can obtain the binding energies of the closed channel supported
bound state from the following transcendental equation, and its solution is the CIR resonance condition:

$$\frac{a_\perp}{a_s} = -\zeta\left(\frac{1}{2}, \frac{3}{2} - \frac{E_r}{2\hbar\omega_\perp}\right)$$

(65)

where $\zeta(\cdot, \cdot)$ is the Hurwitz zeta function. Note that the appropriate value of $E_r$ in the ultracold limit are in the range of few tens of kHz. On the other hand, the theoretical treatment suggests that at energies below the threshold of the open channel confinement-induced molecular states might be supported. Eq.(66) is derived by requiring all the scattering channels to be closed yielding a wavefunction that vanishes asymptotically. In this case the molecular confinement-induced energies obey the following transcendental equation:

$$\frac{a_\perp}{a_s} = -\sqrt{\frac{2\hbar\omega_\perp}{\hbar\omega_\perp - E_r}} - \zeta\left(\frac{1}{2}, \frac{3}{2} - \frac{E_r}{2\hbar\omega_\perp}\right)$$

(66)

Fig. 17 illustrates the relations in Eqs. (65) and (66), where the corresponding closed channel bound state (blue solid curve) and molecular CIR state (orange solid curve) energies are given as a function of the ratio $a_\perp/a_s$. The red dashed lines indicate the two dimensional harmonic oscillator eigenenergies in the absence of short range interactions, i.e. the values $E^{(1)} = \hbar\omega_\perp$ and $E^{(2)} = 3\hbar\omega_\perp$. The black dashed curve corresponds to the energy of an s-wave molecular pair in the absence of confining trap, i.e. $E_{\text{free}}/\hbar\omega_\perp = -\frac{a_\perp^2}{2a_s^2}$. We observe that the closed channel bound state (blue solid curve) tends to $3\hbar\omega_\perp$ as the ratio $a_\perp/a_s \rightarrow -\infty$, i.e. in the absence of short range interaction. As the ratio $a_\perp/a_s$ approaches the value $c_1 = 1.46035$ the bound state from the closed channels becomes degenerate with the threshold of the open channel, $E^{(1)} = \hbar\omega_\perp$ (see black star in Fig.17), and not coincidentally, the CIR resonance occurs at $a_\perp/a_s = c_1 = 1.46035$. Note that at $a_\perp/a_s > 1.46035$ and for energies less than $E^{(1)}$ the depicted blue line does not have any physical significance and it is just an analytic continuation of Eq.(65). In this energy regime all the channels should be closed and Eq. (65) refers to the case where the system possess a single open channel.

This analysis illustrates that the CIR has the character of a Fano-Feshbach resonance, where the collective bound state attached to all the closed channels lies in the low-energy continuum of the open channel. In addition, the confinement-induced molecular state (see orange solid line) exists regardless the strength of the short range interactions. This is a manifestation of the impact of the confinement since in free space collisions the bosonic pair forms a weakly bound state only for positive values of the s-wave scattering length. On the positive side of the abscissa in Fig. 17 as the ratio $a_\perp/a_s$ increases we observe that the energy of free space weakly bound molecule (black dashed line) coincides with the energy of the confinement-induced molecular state (orange solid line). This occurs at these values of scattering length since the two-body potential is deep enough forcing the wavefunction to vanish before the trapping potential becomes important. Therefore, in this limit the confinement-induced molecular state behaves as a free space bound state. Note that similar behavior is observed in the paper by (Demkov and Drukarev, 1966).

Figure 18 (Color online) Confinement-induced (black squares and lines) and Feshbach (blue line and circles) molecules. The solid lines correspond to the theoretical predictions whereas the circles and squares indicate the experimental measurements. The vertical dashed line indicates the position of the Feshbach resonance. taken from (Moritz et al., 2005)

An experiment by (Moritz et al., 2005) considered a Fermi gas of $^{40}\text{K}$ atoms in the presence of harmonic confinement. The $^{40}\text{K}$ atoms are prepared in two hyperfine states $|F = 9/2, m_F = -9/2\rangle$ and $|F = 9/2, m_F = -7/2\rangle$. Note that the third hyperfine $|F = 9/2, m_F = -5/2\rangle$ is not populated initially. The mutual interactions are tuned via a Feshbach resonance whose position is located at $B = 202.1\text{G}$ and its zero-crossing is at $B = 210\text{G}$. Thereafter, by employing radio-frequency spectroscopy confinement-induced molecules are generated and their binding energy is measured as a function of the scattering length and the confinement frequency. In Fig. 18 the binding energies of the confinement-induced (black solid line and squares) and the Feshbach (blue solid line and circles) molecule are depicted as a function of the magnetic field. The solid lines denote the theoretical predictions of (Dickerscheid and Stoof, 2005) whereas the scattered data are the experimental measurements. The blue dashed line indicates the position of the Feshbach resonance where a Feshbach molecule (blue line and circles) is only formed on the positive side of the resonance whereas no measurement occurs on the negative side. On the other hand, in the case
of confinement-induced molecule (black line and squares) we observe that there is always a bound state regardless
the sign of the s-wave interactions. This is in accordance
with the theoretical predictions. In addition, we may
note that the intersection point of the black line with the
blue dashed line, i.e. at the position of infinite scattering
length, the binding energy acquires its universal value,
\( E_B \approx 0.6\hbar \omega_L \). At this universal value the bind-
ing energy of the confinement-induced molecules depends
solely on the strength of the confinement. Note that the
strength of the confinement in (Moritz et al., 2005) is
tuned by changing the lattice depth \( V_0 \). Fig. 19 depicts
the binding energy of the confinement-induced molecule
as a function of the confinement strength in units of re-
coil energy \( E_r \). The black solid line refers to theoretical
calculations and the scatter data indicate the radio-
frequency measurements. Both theory (Dickerscheid and
Stoof, 2005) and experiment show sufficient agreement.
The minor disagreements between theory and experiment
in Figs. 18 and 19 associated with the effective range
corrections which are not included as was pointed out
by (Peng et al., 2012).

![Graph showing the binding energy of the confinement-induced molecules as a function of lattice depth.](image)

**Figure 19** The binding energy of the confinement-induced molecules as a function of the lattice depth \( V_0 \) in recoil units \( (E_r) \). The spectra are measured very close to the Feshbach resonance at magnetic field \( B = 202 \text{G} \). The black solid line indicates the corresponding theoretical calculations. Taken from (Moritz et al., 2005).

In the above mentioned analysis of s-wave confinement
induced resonances it is evident that zero-range approxi-
mations are employed. This means that the short-range
part of the Hamiltonian is treated in essence as a sin-
gle channel. In experiments, however, (see Fig. 18) the
main toolkit to tune the interactions or the s-wave scat-
tering length are the Feshbach resonances. This partic-
ular aspect implies that the short-range part must be
treated as a two-channel model in order to obtain a di-
rect comparison with the corresponding experimental
advances. Towards this pathway a tremendous amount of
theoretical effort is focused in order to incorporate ade-
quately the two-channel nature of Feshbach resonances
in the confinement-induced physics (Kristensen and Pri-
coupenko, 2015; Peng et al., 2012; Saeidian et al., 2012;
Yurovsky, 2005, 2006). All these works pointed out the
importance of the effective range corrections particularly
on the calculation of the binding energy of confinement-
induced molecules. In addition, it was shown that the
effective range corrections become more important for
narrow Feshbach resonances. Note that similar conclu-
sions were drawn also for fermionic species in harmonic
waveguides (Saeidian et al., 2015).

Another aspect which was excluded from Refs. (Berge-
man et al., 2003; Demkov and Drukarev, 1966; Olshanii,
1998) is that the total colliding energy is sufficient for
the pair atoms such that no excitation will occur be-
afore and after the collision. Lifting this constraint,
\( i.e. \), going beyond the single mode regime (Heß et al.,
2015; Moore et al., 2004; Saeidian et al., 2008) pre-
dicted numerically (Saeidian et al., 2008) and analyti-
cally (Heß et al., 2015; Moore et al., 2004) the emergent
inelastic confinement-induced resonances for bosonic and
fermionic exchange symmetries. In particular, (Heß et al.,
2015) considered also the higher partial wave interactions
going beyond \( s \)- and \( p \)-wave interactions and obtained
universal expressions for the position of all the inelastic
confinement-induced resonances.

A study by (Kim et al., 2006) studied distinguishable
particle collisions in the presence of a harmonic wave-
guide which yield the effect of dual confinement-induced
resonances. This type of resonances correspond to total
transmission due to the destructive interference of \( s \)- and
\( p \)- partial waves. The importance of high partial waves
on bosonic or fermionic systems in a cigar shaped trap
were considered by (Giannakeas et al., 2012). Due to
the anisotropy of the trap all the partial waves associated
with either bosonic or fermionic exchange symme-
try are coupled yielding in this manner coupled f-wave
confinement-induced resonances. The analysis of this
particular system is based on the idea of the local frame
transformation. This framework was employed for high-
lighting the underlining physics of fermionic collisions in
matter waveguides by (Granger and Blume, 2004) avoid-
ing the complications of zero-range and two-channel mod-
els. The following focuses on a system of spin-polarized
fermions in the presence of cigar-shaped traps and the
underlying details of the local frame transformation the-
ory.

2. Fermions in a cigar-shaped trap

It is also of extensive experimental and theoretical in-
terest to explore near-degenerate fermionic gases in low
dimensional traps, which requires a detailed understand-
ing of confinement-induced resonances between identical
fermions. In (Granger and Blume, 2004), a scattering
theory was developed to describe collisions between iden-
tional spin-polarized fermions in the presence of an axially symmetric harmonic trap. Owing to the Pauli exclusion principle, ultracold fermions interact in 3D with p-wave interactions instead of s-wave that was considered in the previous subsection. The p-wave theory requires somewhat different considerations, which we therefore consider in this subsection from the general viewpoint of the $K$-matrix theory; this highlights the behavior imposed on spin-polarized fermionic ensembles by the transverse trapping potential.

Again, the relative Hamiltonian for two spin-polarized fermions expressed in cylindrical coordinates has the same form as in given in Eq. (61). In contrast with the previous s-wave treatment, the spherically symmetric two-body interaction is not modeled by a pseudopotential terms in Hamiltonian $H$; this highlights the behavior imposed in this subsection from the general viewpoint of the $K$-matrix theory; this highlights the behavior imposed on spin-polarized fermionic ensembles by the transverse trapping potential.

In practice the length scales associated with the two potential terms in Hamiltonian $H$ are well separated, with $r_0$ of the short range potential typically orders of magnitude smaller than the waveguide potential oscillator length in a typical ultracold experiment, $a_\perp = \sqrt{\hbar/(\mu \omega_{\perp})}$. At small interparticle distance $r << a_\perp$, the orbital angular momentum is approximately conserved and therefore the two fermions experience a free-space collision with total colliding energy $E = \hbar^2 k^2/(2\mu)$. As usual, $\mu$ denotes the two-body reduced mass. In this case the $\ell'$-th linearly independent energy eigenstate expressed in spherical coordinates has the following form at $r_0 << r << a_\perp$:

$$\Psi_{\ell'}(r) = \sum_{\ell} F_{\ell}(r, \theta) \delta_{\ell \ell'} - G_{\ell}(r, \theta) K_{\ell\ell'}^{3D}, \quad (67)$$

where $F_{\ell}(r, \theta) \ (G_{\ell}(r, \theta))$ is the energy normalized regular (irregular) solution expressed in terms of spherical Bessel $j_{\ell}(r)$ (spherical Neumann $n_{\ell}(r)$) functions multiplied by the corresponding spherical harmonic $Y_{\ell,m}(\theta, \phi)$. The summation is performed over all odd $\ell$ angular momentum due the Pauli exclusion principle. The quantity $K_{\ell\ell'}^{3D}$ represents the elements of the reaction matrix $K_{\ell\ell'}^{3D}$ in three-dimensions. This $K$-matrix incorporates all the scattering information due to the short-range potential $V_{ab}(r)$, and for a spherically symmetric potential it is diagonal, but for anisotropic interactions such as the dipole-dipole type it could acquire off-diagonal elements in other contexts (Giannakeas et al., 2013).

At large distances the waveguide geometry prevails and imposes cylindrical symmetry on the wave function, and the total collision energy gets apportioned between the transversal and longitudinal degrees of freedom. The energy can be expressed at $|z| > r_0$ as $E = \hbar \omega_\perp (2n + |m| + 1) + \hbar^2 q_n^2/(2\mu)$, where the term $\hbar \omega_\perp (2n + |m| + 1)$ refers to the energy of the transversal part of the Hamiltonian and $q_n$ is the channel momentum, i.e.is the momentum of the particles in the $z$ direction. In this region the $n'$-th linearly-independent scattering wave function at energy $E$ can be expressed in cylindrical coordinates as:

$$\Psi_{n'}(r) = \sum_n f_n(z, \rho) \delta_{nn'} - g_n(z, \rho) K_{nn'}^{1D}, \quad (68)$$

where the quantity $K_{nn'}^{1D}$ represents the elements of the quasi-1D reaction matrix $K_{nn'}^{1D}$ and where $(f_n(z, \rho), g_n(z, \rho))$ are the energy normalized (regular, irregular) standing wave solutions solely in the presence of the trap. The specific form of the regular and irregular solutions which obey the Pauli exclusion principle have odd $z$-parity for $m = 0$ and are given by:

$$\begin{pmatrix} f_n(z, \rho) \\ g_n(z, \rho) \end{pmatrix} = (2\pi^2 q_n)^{-1/2} \Phi_n(\rho) \begin{pmatrix} \sin q_n z \\ -z \cos q_n z \end{pmatrix} \quad (69)$$

where $\Phi_n(\rho)$ are the $m = 0$ eigenfunctions of the two-dimensional harmonic oscillator and the $z$-dependence describes motion in the unbounded coordinate. For collisions of spin-polarized fermions the factor $z/|z|$ corresponds to the anti-symmetrization operator.

From the Hamiltonian $H$ in Eq. (61) it is evident that the corresponding Schrödinger equation is non-separable over all the configuration space. However, as mentioned above there are two distinct subspaces where the resulting Schrödinger equation is separable and where all the relevant scattering information can be expressed in terms of reaction matrices, namely $K_{3D}^{3D}$ [see Eq. (67)] and $K_{1D}^{1D}$ [see Eq. (68)]. The main idea is to define a frame transformation which will permit to express the $K_{1D}$ reaction matrix in terms of the short range $K_{3D}^{3D}$. Intuitively, the frame transformation $U$ permits us to propagate outwards to the asymptotic region the information of the collisional events occurred close to the origin.

An unusual property of this frame transformation is that it is not unitary. This arises due to the fact that the solutions given in Eq. (67) and Eq. (68) obey different Schrödinger equations. However, since Hamiltonian $H$ in Eq. (61) possesses length scale separation implying the existence of an intermediate region where both potentials are negligible. This means that in this subspace Eqs. (67) and (68) approximately satisfy the same Schrödinger equation, i.e. the Helmholtz equation. Therefore, in this Helmholtz region one employs locally the above mentioned frame transformation. The concept of the local frame transformation was introduced by (Fano, 1981a; Harmin, 1982a,b) and extended by (Giannakeas et al., 2016; Granger and Blume, 2004; Greene, 1987; Robicheaux et al., 2015; Wong et al., 1988; Zhang and Greene, 2013).

The local frame transformation is derived by matching the energy normalized regular solutions $f_n(r)$ and $F_{\ell}(r)$
on a surface $\sigma$ at a finite distance $r_0 < r < a_\perp$ inside the Helmholtz region. Formally, for $r < a_\perp$, $U$ obeys the relation

$$f_n(r) = \sum_\ell F_\ell(r) U_{\ell n}^T, \quad \text{with} \quad U_{\ell n}^T = \langle \{f_\ell \mid f_n\} \rangle, \quad r < a_\perp,$$

(70)

where $U^T$ denotes the transpose of the frame transformation matrix $U$, the symbol $\langle \{\cdot\} \rangle$ indicates that the solutions $F_\ell$ and $f_n$ are integrated only over the solid angle $\Omega = (\theta, \phi)$. Note that the matrix elements $U$ are independent of the distance $r$. This occurs since the matching of the regular solutions takes place in the Helmholtz region where both solution possess same $r$ dependence. In addition, since the set of solutions in Eqs. (67) and (68) are real standing-wave solutions, the matrix $U$ is real.

It was pointed out by (Fano, 1981a) that the irregular parts of Eqs. (67) and (68) can be interconnected by matching in the Helmholtz region the corresponding principal value Green's functions, written in the different coordinate systems. Formally, the irregular solutions obey:

$$g_n(r) = \sum_\ell G_\ell(r)[U^{-1}]_{\ell n}, \quad r < a_\perp.$$

(71)

After inserting Eqs. (70) and (71) into the scattering wave function $\Psi(r)$ in Eq. (67), the $K^{1D}$ matrix is seen to be expressed in terms of the short range $K^{3D}$ compactly as

$$K^{1D} = U K^{3D} U^T,$$

(72)

where the short range $K^{3D}$ includes all the odd partial waves for the spin-polarized fermions. Also, the $K^{1D}$ matrix depends on the total collision energy $E$.

The $1D$ matrix contains information about the asymptotically open- and closed-channel components of the wavefunctions. To describe the closed-channel components, solutions given in Eq. (68) can be analytically continued by setting the channel momentum $q_n$ to be $q_n \to i\lvert q_n \rvert$, in the usual spirit of quantum defect theory. Then one can derive the local frame transformation $U$ which possesses the same functional form as for the open channels. Note that the local frame transformation $U$ in the open channels only for $p$-wave interactions obeys the relation $U_{\ell=1n} = \sqrt{2 \over a_\perp \sqrt{\kappa}} P_\ell(\kappa a_\perp)$ where $P_\ell(\cdot)$ indicates the $\ell$-th Legendre polynomial. This yields the same expression for $K^{1D}$ shown in Eq. (72). The only drawback from these manipulations is that the resulting $K^{1D}$ matrix corresponds to a scattering solution which does not (yet) obey the proper boundary conditions asymptotically. This is because the closed channel parts of the wave function given in Eq. (68) contains exponentially growing pieces at $|z| \to \infty$. One sees readily after substituting $q_n \to i\lvert q_n \rvert$ that the regular and irregular solutions in Eq. (69) for the closed channel components have both exponentially decaying and growing pieces. Therefore, in order to enforce the physically accepted asymptotic boundary conditions in Eq. (68) concepts from multichannel quantum defect theory are employed (Aymar et al., 1996).

Initially, the scattering wave function in Eq. (68) is separated into open ($"o"$) and closed ($"c"$) channels. Then, linear combinations are chosen by demanding that the exponentially growing pieces in the closed channels are canceled. Formally, we have the following relation for the wave function:

$$\begin{pmatrix} \psi_{oo} & \psi_{oc} \\ \psi_{co} & \psi_{cc} \end{pmatrix} \begin{pmatrix} B_{oo} \\ B_{co} \end{pmatrix} = \begin{pmatrix} f_o \ 0 \\ 0 \ f_c \end{pmatrix} - \begin{pmatrix} g_o \ 0 \\ 0 \ g_c \end{pmatrix} \begin{pmatrix} K_{oo}^{1D} & K_{oc}^{1D} \\ K_{co}^{1D} & K_{cc}^{1D} \end{pmatrix} \begin{pmatrix} B_{oo} \\ B_{co} \end{pmatrix},$$

where the matrices $B_{oo}$ and $B_{co}$ denote the linear combination coefficients. By eliminating the closed channels the linear combination coefficients acquire the values

$$B_{oo} = 1 \quad \text{and} \quad B_{co} = \left(f_c - K_{cc}^{1D}\right)^{-1} K_{co}^{1D},$$

(73)

where the term $f_c / g_c$ $|z| \to \infty \to -i1$.

The physical wave function, which involves only open channels asymptotically since the closed-channel components decay exponentially, acquires the following form at $|z| \to \infty$:

$$\Psi_{phys} = f_o - g_o[K_{oo}^{1D} + iK_{oc}^{1D}(1 - iK_{cc}^{1D})^{-1} K_{co}^{1D}]$$

(74)

Here the effects of the closed channels on the open channel scattering are included in the corresponding physical $K$-matrix, given by:

$$K_{oo}^{1D, \ phys} \equiv K_{oo}^{1D} + iK_{oc}^{1D}(1 - iK_{cc}^{1D})^{-1} K_{co}^{1D}.$$  

(75)

The resonances of the collision complex appear as poles of the $K_{oo}^{1D, \ phys}$ matrix. More specifically, the $K_{oo}^{1D, \ phys}$ exhibits resonant features at zero eigenvalues of the matrix $(1 - iK_{cc}^{1D})$. Therefore, this argument can be recast into the form of a determinantal equation:

$$\text{det}(1 - iK_{cc}^{1D}) = 0.$$  

(76)

Note that despite the appearance of the imaginary unit $i$ in the preceding equations, all of these physical wavefunctions and reaction matrices are real. When all channels are closed, the roots of Eq. (76) yield the bound state energies. When one or more channels are energetically open, the roots of the above closed-channel determinant approximately identify the real parts of resonance energies. Eq. (76) shows why a confinement-induced resonance can be viewed as a Fano-Feshbach type of resonance.
Consider next the situation where the two fermions collide in the single mode regime, meaning that the relative collision energy lies between the lowest two transverse thresholds. In addition, these ultracold spin-polarized fermions interact at short distances via $p$-wave interactions only. Phase shifts associated with higher 3D partial waves are entirely neglected. Accordingly, the determinant equation has one nonzero root, and the $K_{oo}^{1D, \text{phys}}$ matrix takes the following form:

$$K_{oo}^{1D, \text{phys}} = K_{oo}^{1D} + iK_{oc}^{1D}(1 + \frac{i}{1 - i\gamma}K_{cc}^{1D})^{-1}K_{cc}^{1D}$$

where $\gamma = Tr(K_{cc}^{1D})$. Note that the $Tr(K_{cc}^{1D})$ is an infinite sum which formally diverges and in order to obtain a meaningful answer an auxiliary regularization scheme is employed. In the particular case a Riemann zeta function regularization scheme is used. Note that such techniques are totally avoided in the generalized form of the local frame transformation theory (Giankanakes et al., 2016; Robicheaux et al., 2015). In addition, Eq. (77) is further simplified by substituting $(K_{cc}^{3D})_{\ell\ell'} = \tan \delta_{\ell=1}(E)\delta_{\ell',\ell} - 1$, i.e. using the fact that only $p$-wave phase shifts $\delta_{\ell=1}(E)$ are non-zero. Next, in Eq. (77) we substitute the corresponding local frame transformation for the closed channels only $U_{\ell=1n} = \sqrt{2} \frac{\delta}{ik|q_n|}P_{\ell=1}(\frac{\delta q_n}{k})$ where $P_{\ell}(\cdot)$ indicates the $\ell$-th Legendre polynomial. Eq. (77) now reads

$$K_{oo}^{1D, \text{phys}} = -6V_p a_\perp^3 q_0 a_\perp \left[ 1 - \frac{12}{5} \frac{V_p}{a_\perp^3} \zeta(-\frac{1}{2}, \frac{3}{2} - \frac{E}{2\hbar\omega_\perp}) \right]^{-1},$$

(78)

where the terms inside the square brackets provide the resonance condition for the position of the $p$-wave confinement-induced resonances. The term $V_p$ denotes the energy-dependent 3D scattering volume which is defined by $V_p(E) = -\tan \delta_{\ell=1}(E)/k^3$ ($k = \sqrt{2\mu E/\hbar^2}$).

The quantity of greatest experimental relevance is the effective interaction strength between two 1D spin-polarized fermions which contains the corresponding $p$-wave confinement-induced physics. As was shown in (Girardeau and Olshanii, 2004; Kanjilal and Blume, 2004; Pricoupenko, 2008) this effective 1D interaction is related to the corresponding $K$-matrix [see Eq. (78)] according to the following relation:

$$g_{1D}^\perp = -\frac{\hbar^2 a_\perp}{\mu q_0} K_{oo}^{1D, \text{phys}}.$$

(79)

This coefficient controls the strength of effective zero-range pseudopotential that is relevant for describing the interaction of identical fermions in 1D in both few-body and many-body contexts, namely:

$$V_{\text{pseudo}}(z) = \frac{\hbar^2 a_\perp}{\mu q_0} \frac{d}{dz} \delta(z) \frac{d}{dz}. $$

(80)

The left (or right) arrow indicates that the derivative operator acts on the bra (or ket) respectively. In the idealized limit of a zero-range potential, this pseudopotential produces a discontinuous wavefunction that obeys the required antisymmetry of the identical fermion wavefunction. This might seem problematical since one normally requires wavefunctions in Schrödinger wave mechanics to be continuous, but it can be accommodated theoretically as is discussed, for instance, by (Cheon and Shigehara, 1999).

Fig.20 illustrates the dependence of the effective coupling constant $g_{1D}^\perp$ as a function of the $V_p/a_\perp^3$ in the low-energy regime. The two fermions interact strongly at the position of $p$-wave confinement-induced resonance (see the red star in Fig.20) whereas in the limit of $V_p/a_\perp^3 \rightarrow 0$ the corresponding effective interaction vanishes. Interestingly, for strong $p$-wave interactions, i.e. $V_p/a_\perp^3 \rightarrow \infty$ the spin-polarized fermions experience a weak attraction due to the transversal harmonic confinement. The location of this divergent interaction strength is called the $p$-wave confinement-induced resonance, and it occurs where the scattering volume of the $p$-wave phase shift is finite and satisfies the resonance condition, namely $V_p/a_\perp^3 = [12\zeta(-1/2, 3/2 - E/(2\hbar\omega_\perp))]^{-1}$.

Apparently, the theoretical scope of confinement-induced resonances is addressed mainly to the elastic collisional aspects of particles with either bosonic or fermionic exchange symmetry. However, in the experimental advances of (Günter et al., 2005; Haller et al., 2010; Lamporesi et al., 2010; Sala et al., 2013) the confinement-induced physics is probed via atom loss measurements which inherently are inelastic scattering processes. These processes mainly emerge due to mechanisms, such as three-body recombination, coupling of the two-body center-of-mass and relative degrees of freedom, spin-flips etc. Theoretically, the few-body collisions in the presence of external confinement are investigated by
Figure 21 (Color online) Schematic illustration of the alignment of the spins with respect to pancake and cigar-shaped traps (a) in a pancake configuration all the spin alignments are permitted. (b) and (c) refer to cigar-shaped traps where in (b) [(c)] only the $|m| = 1$ ($m = 0$) spin configuration of the $p$-wave interactions is allowed. (Taken from (Günter et al., 2005).)

(Blume, 2014; Gharashi et al., 2012; Mora et al., 2005a, 2004, 2005b) addressing the three and four-body aspects of the confinement-induced physics where a detailed discussion can be found in the excellent review by (Blume, 2012a).

(Günter et al., 2005) experimentally investigated $p$-wave collisions of spin-polarized fermions in the presence of cigar-shaped and pancake traps. The degenerate gas constitutes of fermionic $^{40}K$ atoms where their mutual interactions are tuned by means of a $p$-wave Feshbach resonance at 198 G which possesses a double peaked feature. As was shown by (Ticknor et al., 2004) et al the doublet structure of a $p$-wave magnetic Feshbach resonance is associated with the different projections of the orbital angular momentum, i.e. $|m| = 1$ and $m = 0$ for $\ell = 1$ and it occurs due to the magnetic dipole-dipole interactions. (Günter et al., 2005) et al. showed that this feature yields particular signatures also in low-dimensional arrangements. Qualitatively the impact of the double-peaked Feshbach resonance is depicted in Fig.21 where three configurations are considered for pancake and cigar-shaped traps. In particular, panel (a) corresponds in a pancake trap where all the projection alignments, i.e. $|m| = 1$ and $m = 0$, are considered. In Fig.21(b) a cigar-shaped trap is considered whose longitudinal direction is perpendicular to the magnetic field. This implies that the $|m| = 1$ configuration of the $p$-wave Feshbach resonance mainly contributes in the scattering process whereas collisional events associated with $m = 0$ component of the Feshbach resonance are suppressed. Finally, in Fig.21(c) the quasi-one dimensional trap is aligned with the magnetic field, whereby the $m = 0$ component dominates the $p$-wave collisions.

By measuring the atom loss signal the impact of the multiplet Feshbach resonance is illustrated in Fig.22 for five different trap configurations. In particular Fig.22 considers (a) a three dimensional optical trap where the double-peaked feature of the $p$-wave resonance stands out. In Fig.22(b), the potassium atoms are confined in a pancake-shaped trap and the two components of the Feshbach resonance prevail where a confinement induced shift is observed with respect to the measurements of panel (a) is observed. In Fig.22(c) the Fermi gas is confined in a quasi-one dimensional trap with its longitudinal direction positioned perpendicular to the magnetic field. In contrast to panels (a) and (b) of Fig.22, only the $|m| = 1$ component of $p$-wave resonance is pronounced whereas the trapping potential induces a shift with respect to the corresponding resonance in Fig.22(a). Similarly, in Fig.22(d) the Fermi gas is confined in a cigar-shaped trap with the longitudinal direction being aligned with the magnetic field. In this case, solely the $|m| = 0$ component of the Feshbach resonance contributes appreciably, and it is shifted towards larger values of field strength with respect to the corresponding
measurements of Fig. 22(a) verifying in this manner the theoretical predictions of (Granger and Blume, 2004). Finally, a tight three-dimensional optical lattice is considered in Fig. 22(e) where no pronounced losses are observed since the atoms are effectively confined in “zero” dimensions and asymptotic scattering states are restricted.

From a theoretical viewpoint, (Peng et al., 2014) considered fermionic collisions around a p-wave Feshbach resonance in the presence of quasi-two-and quasi-one-dimensional traps. In particular, (Peng et al., 2014) takes into account the multiplet structure of the p-wave Feshbach resonance and study within a zero-range model the impact of the relative orientation of the magnetic field with the trapping potentials on the collisional processes. In this manner, the experimentally, i.e., (Günter et al., 2015), observed spin alignment-dependent confinement-induced resonances for spin-polarized fermions were also verified theoretically by (Peng et al., 2014).

B. Confinement-induced resonances: delving deeper

The above discussion has only considered quasi-one dimensional harmonic type of confinement for producing confinement-induced resonances. The rapid technological advances in laser trapping techniques have opened a new avenue that enables ultracold atoms to be confined in arbitrary geometries. From a theoretical viewpoint, this requires extensions of the boundaries of our understanding of confinement-induced physics to include more general types of trapping potentials. Many of the generalizations discussed in the present subsection have been reviewed in (Blume, 2012a; Zinner, 2012).

In this direction, (Idziaszek and Calarco, 2006; Petrov et al., 2000; Petrov and Shlyapnikov, 2001; Pricoupenko, 2008) considered ultracold collisions in the presence of quasi-two dimensional traps. In particular, (Petrov and Shlyapnikov, 2001) within the zero range approximation studied bosonic collisions in pancake-shaped traps. The pancake trap modifies the properties of 3D binary collisions yielding two-dimensional confinement-induced resonances. This particular type of resonance also fulfills a Fano-Feshbach scenario as do the quasi-one-dimensional resonances. However, due to the pancake geometry a confinement-induced resonance occurs when the two-body potential is not sufficiently deep to produce a true 3D universal bound state, i.e. where the corresponding free space scattering length is negative. Again, this differs from the quasi-one-dimensional confinement-induced resonances in the low energy limit, which occur at positive values of the s-wave scattering length. The theoretical predictions of (Petrov and Shlyapnikov, 2001) were experimentally confirmed by (Fröhlich et al., 2011). (Fröhlich et al., 2011) explored the collisional aspects of a two-component Fermi gas in a pancake trap around a free space Fano-Feshbach resonance. By employing radio-frequency spectroscopic techniques measured molecule formation on the negative side of Fano-Feshbach resonance.

(Idziaszek and Calarco, 2005; Peng et al., 2010) studied confinement-induced resonances in the presence of an anisotropic waveguide, using a pseudopotential model of the two-body collisions. The anisotropy is induced by considering a transverse harmonic potential in the $x - y$ plane, with different frequencies in the $x$ and $y$ directions. Theory suggests that the system in this type of geometry possesses only one confinement-induced resonance, whose position can be tuned by adjusting the confining frequency aspect ratio (Peng et al., 2010). Moreover, similar conclusions emerged from (Zhang and Zhang, 2011) which considered a two-channel model for the short-range 3D interaction. The simple fact that an anisotropic harmonic waveguide should exhibits only one confinement-induced resonance was not confirmed by the experiment of (Haller et al., 2010). More specifically, (Haller et al., 2010) conducted experiments on Cs atoms confined in quasi-one-to-quasi-two dimensional traps. In the regime of anisotropic traps through atom loss measurements the corresponding observations showed signatures of two confinement-induced resonances.

The double peak feature was theoretically resolved by proposing two possible loss mechanisms. One was associated with multichannel inelastic processes (Melezhik and Schmelcher, 2011) and the second one was related to the mere fact that trapping potential in the (Haller et al., 2010) exhibit an anharmonicity (Peng et al., 2011; Sala et al., 2012). The anharmonicity of trap induces a coupling between the center-of-mass and relative degrees of freedom of the colliding pair. This coupling enables the two particles to form a molecule without requiring a third particle since the binding energy can be distributed to the center of mass degrees of freedom. After implementing these considerations in the theory, two confinement-induced resonances do indeed emerge which confirm the experimental observations of (Haller et al., 2010). More recently, in order to pinpoint the physical origin of the double confinement-induced resonances, (Sala et al., 2013) considered experiments with $^6$Li atoms in an anharmonic waveguide. More specifically, in that experiment, the trapping potential was loaded with only two $^6$Li atoms in the ground state of the external potential. Therefore, three-body effects as well as multichannel inelastic multichannel effects were excluded (Melezhik and Schmelcher, 2011). In this manner, it a double peak structure was observed in atom loss measurements which are attributed to two confinement-induced resonances.

Dealing with ultracold collisions in arbitrarily-shaped transversal potentials (Robicheaux et al., 2015; Zhang and Greene, 2013) developed theories based on local frame transformation theory, which can predict a broader class of confinement-induced resonances. These theoretical treatments also include two-body collisions be-
This idea by considering one atomic species, e.g. A (Catani et al., 2001). However, in the treatments of (Robicheaux et al., 2015; Zhang and Greene, 2013) the center of mass is coupled with the relative degrees of freedom for particles of finite mass, so they have thus far only been applied in the limit of an infinitely massive particle which is struck by a much lighter one. (Peano et al., 2005) considered the coupling of the center of mass in an arbitrary transversal potential, using the Green’s function formalism to solve the corresponding Schrödinger equation directly in the laboratory frame. Apart from arbitrary quasi-one-dimensional potentials, (Peano et al., 2005) considered also the case of two-component ultracold gases in harmonic traps where atoms have different polarizabilities; they therefore experience different harmonic oscillator confining frequencies which results in coupled center-of-mass and relative degrees of freedom. In both cases, (Peano et al., 2005) theoretically predicted that the corresponding scattering observables should exhibit more than one resonant feature associated with the confinement-induced resonances. Similarly, (Kim et al., 2005) developed a theory yielding only qualitative predictions since the Hilbert space associated with the closed channel physics was not taken into account. This aspect, however was taken into account by (Melezhik and Schmelcher, 2009) which predicted confinement-induced resonant molecular formation.

(Massignan and Castin, 2006) and (Nishida and Tan, 2008, 2010, 2011) focused on mixed-dimension collisions in ultracold gases, under the assumption that different atomic species experience move in different numbers of spatial dimensions, such as when a 3D gas of atoms interacts with either different atoms or the same atoms in different internal states that are trapped in an optical lattice. Again, for this mixed-dimension system the center of mass and relative degrees of freedom are inherently coupled. The concept of mixed dimensionality arises from the fact that in a mixture of ultracold gas different particles, i.e. A and B species, experience different confinement frequencies. The confinement frequencies depend on each atom’s polarizability and the laser frequency. Therefore, by adjusting the laser frequency at a zero of polarizability of one atomic species, i.e. A atoms, only the B atoms will experience the trapping potential. The proposed technique of (LeBlanc and Thywissen, 2007; Massignan and Castin, 2006) for species-selective dipole potentials was first realized by (Catani et al., 2009). (Nishida and Tan, 2010) studied this idea by considering one atomic species, e.g. A atoms, to be totally unconfined, i.e. they move in three dimensions, while the B atoms are trapped in a tight spherical trap (a “zero dimension” configuration), or a cigar-shaped (quasi-one-dimensional configuration) trapping potential, or a pancake-shaped trap (quasi-two dimensional configuration). In addition, particles A and B are assumed to collide at small distances with s-wave interactions only. This gives rise to an infinite series of a particular type of confinement-induced resonances which possess high orbital angular momentum character despite the fact that the two-body collisions are dominated by s-wave interactions. (Massignan and Castin, 2006) This effect emerges from the combination of pure s-wave interactions and the fact that the two-body collisions take place in mixed-dimensions which couples the angular momenta of the A and B atomic species. The theoretical predictions (Nishida and Tan, 2008, 2010) have apparently been observed by (Lamporesi et al., 2010), who created a mixed-dimensional confinement of two ultracold atomic species, namely $^{41}$K and $^{87}$Rb. The $^{41}$K atoms are trapped in two-dimensions whereas the $^{87}$Rb atoms move in three-dimensions, which is achieved by implementing species-selective dipole trapping techniques (Catani et al., 2009; LeBlanc and Thywissen, 2007; Massignan and Castin, 2006). In this mixed-dimensional configuration (Lamporesi et al., 2010) observed up to five resonances by measuring 3-body losses, in good agreement with theoretical resonance positions.

Pair collisions within a three-dimensional optical lattice were theoretically investigated by (Cui et al., 2010; Fedichev et al., 2004). (Fedichev et al., 2004) utilized the tight-binding framework and assumed that the range of the two-body interactions is far smaller than the lattice spacing, i.e. $d$, and the size of the ground state in a lattice side, i.e. $\ell_0$. Also the curvature within the lattice sites is approximated as a harmonic oscillator, which permits a decoupling of the center of mass and relative degrees of freedom. Furthermore, in the tight binding model (Fedichev et al., 2004) assumed that the effective mass of the particles is large enough such that the size of the ground state within the lattice site is small compared to the lattice spacing whereas effects arising from higher Bloch bands were excluded. Based on these considerations (Fedichev et al., 2004) predicted a confinement-induced resonance that occurs at negative values of the s-wave scattering length. The resonance condition simply reads $a_s \sim \ell^*$, where $\ell^* = \ell_0 \sqrt{D_0/(4 \ln 2)}$, with $D_0$ the tunneling amplitude to neighboring lattice sides in the lowest Bloch band. (Köhl et al., 2005) conducted experiments on a degenerate Fermi gas in the presence of a three-dimensional optical lattice. They observed that the Feshbach resonance within the optical lattice exhibits an additional shift from the corresponding Feshbach resonance in the absence of the external potential, which verified the theoretical predictions of (Fedichev et al., 2004). (Cui et al., 2010) extended the theoretical stud-
ies of (Fedichev et al., 2004) and quantitatively described Bloch wave scattering at different lattice depths. Also, higher Bloch bands are taken into account as well as intraband effects which occur in the lowest Bloch band. (Cui et al., 2010) showed that in the case of true molecular states and at moderate lattice depths the higher Bloch bands effects play crucial role since their neglect overestimates binding energies.

C. Synthetic spin-orbit coupled systems

Experimental and theoretical efforts on the confinement-induced physics in low dimensional systems consider a regime where the two-body interactions are short-ranged and isotropic. Lifting the latter constraint permits us to generalize the concept of the confinement-induced resonances in physical systems which are mainly governed by anisotropic binary interactions.

The experimental realization of spin-orbit coupled Bose-Einstein condensates opens new avenues to explore the collisional aspects of such exotic systems. Developments in this rapidly evolving field have been reviewed by (Williams et al., 2012; Zhai, 2015). For example, in free space collisions, spin-orbit coupling yields a mixed-partial wave scattering process that alters the corresponding Wigner threshold law (Cui, 2012; Duan et al., 2013; Wang and Greene, 2015). (Zhang et al., 2012; Zhang and Zhang, 2013; Zhang et al., 2014) studied the impact of reduced dimensionality on these physical systems in the presence of quasi-one and quasi-two dimensional traps.

In particular, (Zhang et al., 2014) considers resonant collisions of spin-orbit coupled cold atoms with Raman coupling in the presence of an axially symmetric harmonic waveguide. As a first order approximation, effects due to the coupling of the center-of-mass and relative degree of freedom are neglected by considering the case of zero center-of-mass momentum. Then the relative Hamiltonian, apart from the kinetic energy, two-body and confinement potential terms, possesses two additional terms:

(i) The spin-orbit coupling term $H_{\text{SOC}} = \frac{\hbar \gamma}{m} (\sigma_z^2 - \sigma_1^2)$ and

(ii) Raman coupling term $H_{\text{Raman}} = \frac{\gamma}{2} (\sigma_z^2 + \sigma_1^2)$. $\sigma_{1,2}$ with $i = x, z$ represents the spin Pauli matrices for each particle, $k$ indicates the relative kinetic energy, $m$ is the atom's mass. $\Omega$ represents the strength of the two-photon Raman coupling and $\gamma = 2\pi \hbar \sin(\theta/2)/\lambda$ indicates the spin-orbit coupling constant where $\lambda$ is the Raman laser wavelength and $\theta$ denotes the angle between the lasers.

Both spin-orbit and Raman coupling influence inherently the position of the resulting confinement-induced resonance. A confinement-induced resonance always exists regardless the sign of the $s$-wave scattering length only in the case where the Raman coupling strength is less than spin-orbit coupling strength, i.e. $\gamma < 2\Omega$. For strong Raman coupling, i.e. $\Omega \gg 2\gamma$ the position of the confinement-induced resonance occurs only at smaller values of the ratio $a_s/a_\perp$, namely $a_s/a_\perp \sim 1/\sqrt{\Omega}$. This provides in essence an extra means to manipulate the position of a CIR without the need of a Fano-Feshbach resonance to tune the magnitude of the 3D scattering length. Note that similar findings were reported also by (Zhang and Zhang, 2013).

D. Confined dipoles and dynamical CIR

Collisions of magnetic dipolar atoms or of polar molecules pose another physical system whose two-body interactions are inherently anisotropic. The concept of confinement-induced resonances for anisotropic two-body interactions has been considered both for quasi-two and quasi-one dimensional waveguide geometries. Such dipolar systems hold particular interest in the many-body realm for their potential to create novel new topological phases of matter, in addition to quantum information applications. (Baranov, 2008; Baranov et al., 2012) In a numerical study, (Hanna et al., 2012) explored the impact of a pancake geometry on nonreactive polar molecules where despite the fact that the confining potential yield broader resonances than in the absence of a trap, the location of resonances are extremely sensitive to the dipole moment strength. Apart from pancake geometries, the concept of dipolar confinement-induced resonances is also investigated in harmonic waveguides, i.e. in quasi-one dimensional traps (Bartolo et al., 2013; Giannakeas et al., 2013; Sinha and Santos, 2007) where the dipoles are aligned by an external field in a head-to-tail configuration. In particular, (Giannakeas et al., 2013; Shi and Yi, 2014) apply the local frame transformation theory and the pseudopotential techniques, respectively, showed the existence of a broad class of dipolar confinement-induced resonances which are characterized by mixed orbital angular momentum character due to the dipole-dipole interactions and the confinement.

Moreover, for $s$-wave dominated dipolar confinement-induced resonances their position depends linearly on the ratio of the length scale of dipolar forces over the trapping length scale, i.e. $\sim a_{\perp}/d$. Note that $(l_d, a_{\perp}) = (\mu d^2/\hbar^2, \sqrt{\hbar/\mu \omega_{\perp}})$ where $\mu$ indicating the reduced mass of the dipolar, $d$ is the corresponding dipole moment and $\omega_{\perp}$ indicates the confinement frequency. This linear dependence of position of the dipolar confinement-induced resonances on the ratio $\frac{l_d}{a_{\perp}}$ means that the collisional properties of dipoles in the presence of a confinement can be controlled by adjusting the strength of an external field and confining potential frequency in a regime accessible by the experimental advances.

Furthermore, (Shi and Yi, 2014) showed that by tilting the relative orientation of the external electric field with respect to the longitudinal axis of the harmonic
waveguide provides additional means to refine the tuning of dipolar confinement-induced resonance positions. (Simoni et al., 2015) studied the case of reactive polar molecules in cigar-shaped traps. In more detail (Simoni et al., 2015) numerically studied the impact of the reduced dimensionality on elastic, inelastic and reaction rates of collision of the reactive molecules in terms of the collisional energy and the strength of the dipole moments. The full four-body calculations are simplified by employing an asymptotic effective two-body model at large distances where the reactions are suppressed (Micheli et al., 2010). The reaction physics is introduced through a WKB-type boundary conditions at short distances that accounts for atom exchange phenomena. By varying the angle of an external electric field with respect to the longitudinal direction of the trap, i.e. trap axis, it is observed that the reaction rate is greatly suppressed for angles normal to the trap’s axis. For the case of a bosonic KRb molecule the reaction rate can only be efficiently suppressed under strong confinement without yielding any significant advantages over the reaction rate suppression in quasi-two dimensional trapping geometries.

Photon-assisted confinement-induced resonances arise when there is a dynamical mechanism to enhance resonant collisions in the presence of a waveguide. (Leyton et al., 2014) consider s-wave binary collisions in the presence of an RF driven harmonic waveguide whose confining frequency modulation permits the separation of the center of mass degrees freedom. The resulting time-dependent Schrödinger equation is solved within a zero-range approximation, i.e. using a Bethe-Peierls boundary condition at the origin of the relative degrees of freedom. The RF modulation of the transversal frequency permits to the two counter-propagating atoms to perform a transition from the continuum state to the confinement-induced molecular state by emitting one or multiple photons. This dynamical mechanism of photon-assisted confinement-induced resonances can result into a series of resonant features for a given number of photons.

### E. Inelastic few-body collisions in 1D

An intriguing implication of the exact integrability of the 1D Schrödinger equation for N equal mass particles that experience zero-range two-body potentials, and the existence of an analytically known solution due to (McGuire, 1964), is that there are no inelastic collisions. One way to understand this is that every time two particles collide, the final state of the two particles in momentum space is kinematically identical to the initial state, since transmission and reflection are indistinguishable. While the absence of all inelasticity including three-body recombination for this system is straightforwardly clear, given the exact solution of (McGuire, 1964), it is far from obvious how the inelasticity turns out to vanish when studied in the adiabatic hyperspherical representation. One way all inelasticity would vanish for a system would be if the hyperradial degree of freedom in the Schrödinger equation turns out to be exactly separable, because in that case all nonadiabatic coupling matrices would vanish. It is not that simple, however, in the case of identical 1D bosons with zero-range interactions, because the nonadiabatic coupling matrices are nonzero. Hence, the different adiabatic hyperspherical channels are coupled, at least locally. This issue was explored by (Mehta and Shepard, 2005), which numerically solved the coupled hyperradial equations that describe atom-dimer scattering.

Later, three-body recombination was calculated in this 1D identical boson system for both the zero range potential case and for a finite-range potential by (Mehta et al., 2007), again using the adiabatic hyperspherical representation. That study confirmed as well that there is no inelasticity, i.e. vanishing three-body recombination rate coefficient. In the hyperspherical representation, the recombination rate and the rates of all other inelastic processes vanish because there is complete destructive interference in the zero-range limit. For a 1D potential of finite range L, however, the study showed how the recombination rate increases for nonzero L > 0. The near-threshold behavior of the recombination rate is of interest for 1D and quasi-1D experiments, and it was demonstrated in (Mehta et al., 2007) that three identical particles have the same threshold behavior $K_{3D} \propto k^7$ regardless of whether the particles are spin polarized fermions or bosons. For three identical bosons in particular, this study shows more concretely that in strict 1D, $K_{3D} = C(L)(\hbar k/\mu)(ka)^6$, where k is the 1D wavenumber and a is the 1D two-body scattering length. Experimental evidence is quite limited in this topic, but the results measured to date, e.g. by (Tolra et al., 2004) appear not to have reached a regime very close to the strict 1D results, and are probably better viewed as probes of the crossover regime between 1D and 3D or between 1D and 2D.

### F. 2D, quasi-2D systems, and the super-Efimov effect

Two-dimensional systems in both few-body and many-body physics exhibit rich and fascinating behavior, involving logarithmic dependences of nearly all quantities that depend on distance and energy. In many-particle condensed-matter systems, prototypical phenomena that have generated extensive interest include the Berezinskii-Kosterlitz-Thouless(BKT)-transition (Berezinskii, 1971; Kosterlitz and Thouless, 1973; Thouless et al., 1982) relating to the formation and binding of 2D vortices, and of course the fractional quantum Hall effect (Stormer et al., 1999). Underlying the theoretical description of striking many-body phenomena
in 2D are the effective two-body and three-body interactions that are modified when a three-dimensional gas is squeezed into a pancake-shaped trap geometry.

The modification of the 3D atom-atom scattering information into an effective 2D interaction has been addressed by many authors, e.g. (Kanjilal and Blume, 2006; Wölkiewicz, 1991), with a more comprehensive list of references in (Dunjko et al., 2011b). Implications of 2D confinement for three-body recombination and for the formation of many-body phases were treated by (Petrov et al., 2000b), for a gas consisting of particles with finite-range interactions. The three-body problem in 2D for short-range interactions has more recently been examined in a hyperspherical coordinate framework by (D’Incao et al., 2015; D’Incao and Esry, 2014), including a nonperturbative study of 3-body recombination in that geometry. Two-body dipole-interacting particles in a 2D or quasi-2D gas are treated by many publications, two of which are (D’Incao and Greene, 2011; Kanjilal et al., 2007). The intriguing many-body phenomena that arise in dipolar systems have received extensive theoretical and experimental attention, as has been reviewed in (Baranov, 2008; Baranov et al., 2012).

One class of few-body treatments in two dimensions relates to fractional quantum Hall droplets having modest numbers of particles, typically from 3-10 electrons, or in the ultracold physics context, atoms or polar molecules. A few such explorations in recent years can be found in (Daily et al., 2015b; Rittenhouse et al., 2016; Wooten et al., 2017), which are just a sampling of the work that followed the famous paper by (Laughlin, 1983) on three 2D electrons in a perpendicular magnetic field. A degenerate perturbation theory treatment of semiconductor quantum dots in a strong magnetic field, which has numerous cases that can serve as useful benchmark calculations for comparison with few-body theory, can be found in (Jeon et al., 2007).

A provocative few-body prediction in recent years has been the super-Efimov effect, which deals with bound states of 3 $p$-wave interacting fermions in 2D. (Gao et al., 2015; Gridnev, 2014; Moroz, 2014; Nishida et al., 2013; Volosniev et al., 2014) The interactions are assumed in the derivation of this effect to have a finite range, and each interacting pair in the trimmer is assumed to have a zero-energy bound state in the symmetry with $|L_z| = 1$, also referred to as a resonant $p$-wave interaction. The resulting trimer energy level formula predicted in this case takes the double-exponential form: $E_n \propto \exp[-2e^{3\pi n/4+i\theta}]$ where $\theta$ is a nonuniversal constant defined modulo $3\pi/4$. Because the size of these super-Efimov states grows so rapidly with $n$, and also the successive binding energies shrink dramatically as $n$ increases, these will be challenging to observe experimentally. Whereas the successive energy levels in the ordinary homonuclear Efimov effect are less bound by a factor of 515, the corresponding ratio in the super-Efimov effect exceeds $10^9$. More promising than the homonuclear systems are heavy-heavy-light heteronuclear trimers, whose super-Efimov states can display a more favorable scaling, (Moroz, 2014) as is also the case in the ordinary Efimov effect for heteronuclear trimers. Another exploration of heavy-heavy-light trimers in 2D with resonant $p$-wave interactions is based on the conventional Born-Oppenheimer approximation (Efremov et al., 2013).

Recently, a theoretical treatment by (Nishida, 2017) has introduced the “semi-super Efimov effect”. This is in a system of four bosons in 2D, which exhibit a different scaling possible for an infinite pattern of energy levels and state sizes, in a scenario where the three-boson interactions are resonant but the two-body interactions are negligible. In the semi-super Efimov case, the state sizes are predicted to scale with the integer quantum number $n > 0$ in proportion to $\exp[(\pi n)^2/27]$.

The theory of the quasi-2D homonuclear three-boson problem has been treated in detail by (Levinsen et al., 2014; Yamashita et al., 2015). This topic is also sometimes referred to as the “crossover” from 3D to 2D. This study demonstrated how the finite number of universal 3-body states in 2D, where there is no true Efimov effect, (Bruch and Tjon, 1979; Nielsen et al., 2001; Nishida and Tan, 2011) connect with true Efimov states in 3D as one varies the degree of confinement in the transverse dimension. Three fermions in 2D are also treated theoretically in (Ngampruetikorn et al., 2013), by solving the Skorniakov-Ter-Martirosian(STM) integral equation (Skorniakov and Ter-Martirosian, 1957).

VI. FEW-BODY PHYSICS IN NUCLEAR AND CHEMICAL SYSTEMS

In previous sections, the current state of the art of few-body ultracold atomic physics has been presented, with an extended discussion of universality in three-body and four-body physics. However, the domain of few-body physics clearly extends beyond atomic systems, reaching many different branches of physics such as chemistry or nuclear or particle physics, among others. Indeed, few-body physics was born in nuclear physics motivated by the seminal paper of (Thomas, 1935), as pointed out above.

The premise of long de Broglie wavelength effective field theory is that for the low energy physics of a few- or many-body system below a certain characteristic energy scale, the behavior of the system should not be sensitive to the details of the Hamiltonian at distances much less than $\lambda$. Indeed, the physics behind such behavior is closely related with the concept of renormalization group theory (Wilson, 1971, 1983; Wilson and Kogut, 1974) One of the best pedagogical introductions to the strategy of systematically building in the correct long wavelength physics has been presented by (Lepage, 1989, ...
in the context of nonrelativistic Schrödinger quantum mechanics. In fact, the concept of effective field theory was spawned by the seminal work of Weinberg that attempted to understand the role of pion-exchange in nuclear forces (Weinberg, 1979, 1990, 1991). Example applications to Efimov physics and related few-body systems have been developed in detail by (Braaten and Hammer, 2006). Other studies that utilize model two-body and three-body Hamiltonians that produce key information such as the low energy two-body scattering length and effective range are making use of the spirit of low energy effective field theories even when they proceed via more direct solution of the few-body Schrödinger equation. We note as well that trions, excitons, and biexcitons occur as few-body problems in semiconductor physics, as is discussed, e.g. by (Patton et al., 2003).

This section is devoted to the study of major developments in few-body physics relevant for nuclear physics and chemistry. The few-body physics in chemical sciences will be presented in two guises: first, few-body physics based on classical trajectory calculations in hyperspherical coordinates involving neutrals and charged particles. Second, a full quantum mechanical treatment revealing the underlying universality of three-body collisions involving charged particles.

A. Hyperspherical methods in nuclear physics

The adiabatic hyperspherical technique has been introduced in previous sections of the present review, with examples of its methodology and applications in the field of atomic and molecular collisions. Reiterating, the basic idea behind this method is to reduce a complex multidimensional problem into set of coupled second-order ordinary differential equations in a single variable. The same idea can of course be applied in a field with tremendously different energy and length scales: nuclear physics, where the nature of the nucleon-nucleon and related interactions exhibit all the complexities of the strong nuclear force. For instance, both exotic nuclear systems and the three-nucleon problem, to name two classes of problems, have been studied using the adiabatic hyperspherical representation.

In nuclear physics the adiabatic hyperspherical technique follows the same scheme as is presented above in this review: the first step involves solution of the hyperangular equation where the hyperradius \( R \) is treated as a parameter, thereby giving hyperspherical potential energy curves and couplings. Then, these are employed to solve a set of coupled ordinary differential equations in the radial coordinate. With this strategy one can tackle the few- or many-nucleon interaction problem at different levels of sophistication. For instance, the cosmologically important reaction of three alpha particles to form \(^{12}\text{C}\) via the intermediate Hoyle state has been treated within the coupled-channel adiabatic representation by (Alvarez-Rodriguez et al., 2007, 2008; Suno et al., 2015). The calculation of hyperspherical potential curves and couplings by (Suno et al., 2015) was based on a binary \( \alpha - \alpha \) model Hamiltonian that accurately describes the \(^{8}\text{Be}\) resonance state, and a three-body term was chosen to represent some experimentally-known properties of \(^{12}\text{C}\) such as some particular energy levels. The final calculation gives a good energy and width in agreement with experimental values for the \( J^\pi_n = 0^+ \) Hoyle resonance state. The relevant adiabatic hyperspherical potential curves are shown in Fig. 23.

Figure 23 (Color online) Adiabatic hyperspherical potential curves computed for the triple-\( \alpha \) system by (Suno et al., 2015) for the \( J^\pi = 0^+ \) symmetry which contains the famous Hoyle resonance thought to be important in nucleosynthesis. Inset: the adiabatic potential curves at large hyper-radius.

Note that when this technique is applied to few-nucleon systems, one must keep in mind the distinctively different nature of the nucleon-nucleon forces compared to the atom-atom interactions. This difference comes from the fact that nuclear collisions can be understood to first order as resulting from the exchange of virtual pions between nucleons. In this sense, pions (\( \pi \)) can be viewed as the quanta of the nuclear force, and since they represent a massive scalar field their influence is associated with a Yukawa potential \( e^{-m_\pi r}/4\pi r \) (Weinberg, 1991). Indeed, the nucleon-nucleon potential can be modeled using an effective field theory based on the exchange of pions. This exchange leads to new and complicated interaction terms in the nucleon-nucleon potential, among them, the tensor interaction reads

\[
V(r_{ij}) = V_i(r_{ij})(\sigma_i \cdot \tau_j) \left[ 3\frac{(\sigma_i \cdot r_{ij})(\sigma_j \cdot r_{ij})}{r_{ij}^2} - \sigma_i \cdot \sigma_j \right],
\]

where \( \sigma_i \) and \( \tau_i \) represent the nuclear spin and isospin of nucleon \( i \), respectively. For a more detailed modern view of the nucleon-nucleon forces, including pion-less theories and chiral effective field theory, we recommend...
Ref. (Epelbaum et al., 2009).

The very complicated nature of the nucleon-nucleon interaction does not prevent the success of the adiabatic hyperspherical technique in nuclear physics, indeed hyperspherical coordinates were applied in the context of nuclear physics by (Delves, 1960) and (Smith, 1960) to study three-body nuclear systems (Fang and Tomusiak, 1977; Levinger, 1974; Valliers et al., 1976; Verma and Sural, 1979). Those studies, however, did not implement the adiabatic formulation and thus could not benefit from its insights and accelerated convergence. Hyperspherical methods were also applied to exotic nuclei, such as the hypertriton, and complex nuclei by including realistic nucleon-nucleon potentials (Clare and Levinger, 1985; Verma and Sural, 1979, 1982). The potential employed included the tensor interaction and many other components of the nucleon-nucleon force. In general, many theorists preferred to work with a set of coupled integral equations instead of coupled differential equations, which can be regarded as a procedure different from the adiabatic hyperspherical machinery most frequently adopted in atomic physics. More recently, however, the adiabatic hyperspherical approach has been employed to compute the triton bound state energy (Daily et al., 2015a) in a convergence exploration, using realistic nucleon-nucleon potentials with a three-body force as well. Other systems that have been considered include exotic species such as kaonic clusters involving three and four particles (Kez-erashvili et al., 2015).

B. Universality in nuclear systems

As discussed above, the nuclear forces are fundamentally different from the interactions in the context of ultracold atomic physics, since they derive from the electromagnetic interaction. Therefore, due to the very strong and short-ranged nature of the nuclear interactions, some aspects of universality can be expected to differ in nuclear systems compared with atomic and molecular species. In particular, some nuclear systems form halo nuclei (Cobis et al., 1998; Jensen et al., 2004a; Tanihata, 1996; Zhukov, 1993), which is a nuclear bound state formed by a tightly bound core and one or two valence nucleons. These valence nucleons are characterized to have a very small binding energy in comparison with the binding energy of the core nucleons, which is reflected in a highly extended bound state wave function. For this reason, halo nuclei exhibit very large radii compared to the core radius. The most familiar example of a halo nucleus is the deuteron, with an average neutron-proton separation of 3.1 fm that is three times larger than both the size of its component nucleons and the range of their interaction potential (both \( \approx 1\text{fm} \)). While halos also exist in atomic and molecular physics, they are far more prevalent in nuclear systems, with many studies even in large or medium-sized nuclei. See for instance (Hove et al., 2014, 2016) and references therein. In fact Efimov physics can be relevant to describing aspects of the wavefunction of a medium-sized nucleus like \(^{62}\text{Ca}\) with two outlying nucleons, (Hagen et al., 2013). Nevertheless this type of system exemplifies the Efimov-unfavored scenario with two light particles and one heavier particle that is discussed in (Wang et al., 2012d); based on the arguments presented there, it is unlikely that a “true Efimov state” exists in such systems.

Halo nuclei with two valence nucleons represent a good playground for three-body physics, since these nuclear systems are potential candidates to exhibit some properties associated with Efimov physics despite being Efimov-unfavored. These nuclei are found in the bottom of the neutron drip line: the line that describes the boundary beyond which the neutron-rich nuclides are unstable. Among the different kinds of two nucleon halo nuclei, the Borromean \(^2\) halo nuclei have received special attention since these have a three-body bound state, despite the fact that none of the two-body subsystems is bound. The most studied Borromean halo nuclei to date have been \(^6\text{He}\) and \(^{11}\text{Li}\) (Tanihata, 1996; Zhukov, 1993). A schematic representation of one such nucleus is shown in the inset of Fig. 24, concretely for \(^6\text{He}\). In this case, the core is an \(\alpha\) particle and the two valence nucleons are neutrons.

\(^2\) The term Borromean is associated with the coat of arms of the house of Borromeo family in the north of Italy, which consists in three interlayer rings. In particular, the symbol appears in the left escutcheon of the coat of arms. However, a similar symbol involving three triangles was already used in Norse mythology around the 7th century.
Figure 24 (Color online) Phillips plot for the triton energy $E_T$ as a function of the doublet $n\bar{n}$ scattering length $a_{n\bar{n}}^2$. The red dots stand for different theoretical calculations based on different kinds of two-body and three-body interactions (Benayoun et al., 1981; Fedorov and Jensen, 2002; Friar et al., 1984), whereas the blue square represents the experimental result. For a more detailed presentation of the Phillips plot for the triton, see the work of Efimov and Tkachenko (Efimov and Tkachenko, 1988). Inset: schematic representation of a halo nuclei with two valence nucleons, namely $^6\text{He}$.

On the other hand, three-body bound states in some nuclear systems show a universal behavior: a correlation between the dimer-nucleon scattering length and the nucleon trimer binding energy, which is known as the Phillips line (Phillips, 1968). This correlation is independent of the model employed for the calculations: such as a two-body contact interaction, three-body interaction terms, and it should also be present regardless of the method employed, i.e. an effective field theory approach, adiabatic hyperspherical treatment, or low energy Faddeev equations. Fig. 24 presents a Phillips plot for the triton including different theoretical results as well as the experimental data. This figure exhibits a linear correlation between the triton binding energy and the doublet neutron-deuteron scattering length $a_{n\bar{n}}^2$. However, other kinds of correlation may occur in different three-body nuclear bound states, see e.g. the work of Fedorov and Jensen (Fedorov and Jensen, 2002).

At least two halo nuclei have been seen as potential candidates to exhibit Efimov universality. However, the universality can only be claimed convincingly if the different excited state of the three-body system follow the predicted scaling law by Efimov, and those are not experimentally accessible by any currently existing capabilities. For instance in the case of $^6\text{He}$, which is also Borromean, it has been proven that a $p$-wave resonance exists in the $J = 3/2$ channel of $n - \alpha$ scattering which explains the nature of the three-body bound state. However, in the 1990’s (Fedorov et al., 1994) and (Amorim et al., 1997) explored the Efimov character of several halo nuclei, assuming that the ground state is also an Efimov state.

Their study suggested that $^{20}\text{C}$ is the only halo nucleus candidate that has appreciable Efimov state character, other than the triton.

Apart from normal nuclei, namely those that appear in the table of nuclides, there other hypernuclei contain strange quarks, and are the so-called strange nuclei. Some of these are classified as halo nuclei, and among them the simplest case is the hypertriton $^3\text{H}$: a three-body bound state formed by a neutron, a proton and the $\Lambda^0$. The $\Lambda^0$ is the lightest $\Lambda$ hyperon, a neutrally charged baryon similar to a neutron but slightly heavier, and its quark structure is $uds$; it has strangeness $-1$. The total binding energy of $^3\text{H}$ is $\approx 2.4$ MeV (Fujimura et al., 2008), whereas its breakup energy is $\approx 0.14$ MeV (Fujimura et al., 2008), which is very small in comparison with the binding energy of the deuteron $2.22$ MeV, and hence it can be considered as a two-nucleon halo nucleus. Indeed, it has been extensively studied (Cobis et al., 1997; Fedorov and Jensen, 2002; Gongleton, 1992). All of these studies suffer, however, from needing better experimental information concerning the n-A scattering length, so these works might be considered as qualitative or semi-quantitative approaches to the Efimov nature of the hypertriton. Nevertheless, new data coming from ALICE and STAR may help to understand better the nature of the n-A interaction, as well as to yield more accurate measurements of the lifetime of $^3\text{H}$ (ALICE Collaboration, 2016; STAR Collaboration, 2010; Zhu, 2013). On the other hand, a good understanding of the hyperon-nucleon interaction is needed for a proper understanding of high-density matter systems, such as neutron stars (Lattimer and Prakash, 2004; Lonardoni et al., 2014; Vidaña, 2013; Weber et al., 2007).

In nuclear systems, universal properties in the four-body sector can be identified. The clearest example is the case of the Tjon line (Tjon, 1975): a correlation between the binding energy of the $\alpha$ particle and the triton binding energy that persists across nearly all nucleon interaction models; in particular, this correlation is approximately linear. The origin of the Tjon correlation can be explained as an approximate independence of the four-body energy level spectrum on any four-body parameter. In other words, the Tjon analysis suggests that there is no need for a four-body parameter for the renormalization at leading order in the four-body sector (Platter et al., 2005, 2004), for energy levels in the universal regime. However, higher order corrections break the expected correlation leading to a band with some scatter depending on the short range physics, instead of a simple, well-defined line (Nogga et al., 2000).

C. Few-body physics and universality in chemistry

Traditionally the term few-body physics has been employed in nuclear physics, and subsequently it became
adopted in the context of atomic physics, especially in ultracold atomic systems (Burt et al., 1997; de Goey et al., 1986; Esry et al., 1999; Fedichev et al., 1996a; Hess et al., 1983, 1984; Suno et al., 2003a; Weber et al., 2003). However, in chemical physics it has not be the case, even though chemical physics studies hinge on our understanding of few-body physics. And of course a deep understanding of fundamental processes in chemical physics is frequently needed in other fields of physics and chemistry, notably in astrophysics, such as the three-body recombination of hydrogen in stellar formation (Flower and Harris, 2007; Forrey, 2013); in theoretical chemistry: transport coefficients in gases (Hirschfelder et al., 1954; Köhler and Saefer, 1983; Mason and Monchick, 1962; McCourt et al., 1991; Montero and Pérez-Ríos, 2014; Snider, 1960; Wang-Chang et al., 1964), reactive and non-reactive scattering (Child, 1974; Levine and Bernstein, 1987; Shui, 1972; Truhlar and Muckerman, 1975) and three-body recombination (Ermolova et al., 2014; Mansbach and Keck, 1969; Robicheaux, 2006), dissociative recombination of H$_3^+$ (Kokoouline and Greene, 2003; Kokoouline et al., 2001; Petignani et al., 2011); plasma physics (Zhadanov, 2002); and in cold chemistry (Hall and Willitsch, 2012; H"arter and Denschlag, 2014; Härter et al., 2012; Härter et al., 2013; Krüikow et al., 2016; Willitsch, 2012; Willitsch et al., 2008). Some of these characteristic and fundamental processes in chemical physics will be reviewed from a few-body perspective in the present section, in particular, those involving three-body processes, such as three-body recombination and dissociative recombination. Special emphasis will be given to universality in three-body recombination processes which are relevant to hybrid trap experiments.

Three-body processes can be viewed as a chemical reaction that converts three free atoms (or molecules or other particles) into diatomic molecules in the absence of external fields, i.e. the reaction $A + A + A \rightarrow A_2 + A$. One of the very first theoretical treatments of this reaction was developed by Keck (Keck, 1960, 1967) using a variational principle following a very early approach proposed by Wigner (Wigner, 1937). In particular, an upper bound for the three-body recombination rate was computed by dividing Regions of phase-space by a trial surface that acts as the boundary between reactants and products; this is now denoted the phase-space theory of reaction rates. Almost in parallel, Smith developed a more microscopic treatment for three-body recombination (Smith, 1962), and later (Shui et al., 1970) extended the previous theory of Keck, applying this theory to the recombination of nitrogen (Shui et al., 1970). An application to the recombination of hydrogen (Shui, 1972, 1973) found fair agreement with the fairly crude early experiments.

The phase-space theory of reaction rates was introduced by Keck (Keck, 1960) and an alternative was presented by Smith (Smith, 1962). Next, the mathematical foundations of a recent approach to calculation of classical three-body recombination rates are presented, after which applications to different systems involving neutrals as well as charged particles will be reviewed. Classical trajectory calculations in hyperspherical approach have been employed to derive different classical Newtonian threshold laws, which are reviewed here, with special emphasis on their universality. The quantum nature of few-body physics in chemical systems will be considered at the end, where the recombination of hydrogen atoms and the dissociative recombination of H$_3^+$ are covered, as fundamental benchmark systems in chemical physics.

1. General classical treatment of few-body collisions

Classically, a two-body collision is envisioned as one particle with a definite momentum moving towards a scattering center. The cross section is defined as an effective area on the plane perpendicular to the initial momentum of the incoming particle which contains the scattering center (Levine and Bernstein, 1987). In classical mechanics, the scattering cross section is determined in terms of the scattering probability for a given value of the impact parameter $b$. Recall that $b$ is defined as the component of the position vector which is perpendicular to the momentum vector of the incoming particle at infinite distance.

The concept of a two-body collision cross section is readily generalized to an arbitrary number ($n$) of dimensions. In particular, the cross section is defined as the effective scattering area of the $n - 1$ hyperplane perpendicular to the initial momentum of the incoming particle, for a given impact parameter $b$ and initial momentum $P_0$

$$\sigma_{\text{process}}(P_0) = \int \varphi_{\text{process}}(P, P_0) d^{n-1}b. \quad (82)$$

Here, the opacity function, $\varphi_{\text{process}}(b, P_0)$ is the probability that a trajectory with particular initial conditions leads to the collisional process under investigation, e.g., an inelastic collision, or formation of a particular product, etc.

The classical dynamics of few-body system can be obtained by recasting the degrees of freedom of the system at hand $d$ as a two-body collision in a $d$-dimensional space, as shown in Fig. (25). This figure represents the usual case where the center of mass motion is decoupled from the relative motion of the interacting particles. In this picture the three-body recombination cross section is written

$$\sigma_{\text{rec}}(P_0) = \frac{\int \varphi_{\text{rec}}(P, P_0) d\Omega P_0 d\Omega^0_0 b^4 db}{\int d\Omega P_0}, \quad (83)$$
where the quantity $d\Omega_{P_0}^0$ represents the differential element associated with the hyperradial of the initial momentum $P_0$. In Eq. (83) the averaging over the degrees of freedom associated with the initial momentum is shown explicitly, whereby the final average cross section depends only on the energy.

2. Classical trajectory calculations in hyperspherical coordinates

The classical Hamiltonian for three particles with masses $m_1$, $m_2$ and $m_3$ moving in a given potential energy landscape $V(r_1, r_2, r_3)$ is

$$H = \frac{P_1^2}{2m_1} + \frac{P_2^2}{2m_2} + \frac{P_3^2}{2m_3} + V(r_1, r_2, r_3),$$  \hspace{1cm} (84)

where $p_i$ and $r_i$ represent the momentum and the vector position of the $i$th particle, respectively. This Hamiltonian can be recast in terms of the Jacobi coordinates $(\rho_1, \rho_2)$, depicted in Fig.(26) as in (Karplus et al., 1965)

$$H = \frac{P_1^2}{2m_{1,2}} + \frac{P_2^2}{2m_{3,12}} + \frac{P_{CM}^2}{2M} + V(\rho_1, \rho_2).$$  \hspace{1cm} (85)

Here $\frac{1}{m_{1,2}} = \frac{1}{m_1} + \frac{1}{m_2}$, $\frac{1}{m_{3,12}} = \frac{1}{m_3} + \frac{1}{m_1+m_2}$; $V(\rho_1, \rho_2)$ is the potential energy in terms of the relative Jacobi coordinates with the CM momentum a separated constant of motion. $P_1$, $P_2$ and $P_{CM}$ represent the canonical momenta conjugate to $\rho_1$, $\rho_2$ and $\rho_{CM}$, respectively. Finally, the relative Hamiltonian is

$$H = \frac{P_1^2}{2m_1} + \frac{P_2^2}{2m_3} + V(\rho_1, \rho_2).$$  \hspace{1cm} (86)

For three particles, the Hamilton equations of motion can be expressed in terms of Jacobi coordinates and momenta as follows:

\[
\frac{d\rho_{1,\alpha}}{dt} = \frac{\partial H}{\partial P_{1,\alpha}}, \hspace{1cm} \frac{dP_{1,\alpha}}{dt} = -\frac{\partial H}{\partial \rho_{1,\alpha}}, \hspace{1cm} (87a)
\]

where $i = 1, 2$ and $\alpha = x, y, z$ label the Cartesian coordinates of each Jacobi vector. Upon adopting the representation of Smith (Smith, 1962), a 6D position vector is constructed from the two mass-weighted Jacobi vectors as

$$\rho = \left( \begin{array}{c} \sqrt{\frac{m_1}{\mu}} \rho_1 \\ \sqrt{\frac{m_2}{\mu}} \rho_2 \end{array} \right),$$  \hspace{1cm} (88)

where $\mu = \sqrt{\frac{m_1 m_2}{M}}$. On the other hand, an equivalent 6D vector position can be expressed in terms of the bare Jacobi vectors as (Pérez-Ríos et al., 2014)

$$\rho_{bare} = \left( \begin{array}{c} \rho_1 \\ \rho_2 \end{array} \right).$$  \hspace{1cm} (89)

Similarly the canonical momenta are given by

$$P = \left( \begin{array}{c} P_1 \\ P_2 \end{array} \right)$$  \hspace{1cm} (90)

and

$$P_{bare} = \left( \begin{array}{c} \sqrt{\frac{\mu}{m_{1,2}}} P_1 \\ \sqrt{\frac{\mu}{m_{3,12}}} P_2 \end{array} \right),$$  \hspace{1cm} (91)

respectively. It can be shown that the relation between the coordinates $(\rho, P)$ and $(\rho_{bare}, P_{bare})$ defines a canonical transformation (Landau and Lifshitz, 1976; Maslov and Fedoriuk, 1981; Whittaker, 1937), and hence both sets of coordinates will describe the same phase-space volume. In other words, the scattering observables will be the same for either of these sets of coordinates, as one would expect. The 6D position vector $\rho$ or $\rho_{bare}$ links the three-body problem in 3D and the single particle problem in 6D, as is schematically presented in Fig.(26).

In the present approach the mass-weighted 6D vector position $\rho$ will be employed, in a minor difference from the conventions utilized in Ref. (Pérez-Ríos et al., 2014). Then the Hamiltonian is

$$H = \frac{P^2}{2\mu} + V(\rho).$$  \hspace{1cm} (92)
Now that the position and the momentum vectors have been defined in this 6D space, the concept of impact parameter as the projection of the position vector onto a hyperplane perpendicular to the initial momentum is clear. We now implement hyperspherical coordinates for the representation of the 6D vectors. In particular, it is convenient to implement Avery’s definition of the hyperangles (Avery, 1989) is chosen, where all the vectors can be represented by means of their magnitude \( r \) and five different hyperangles \( (\alpha_i, i = 1, 2, 3, 4, 5) \) as

\[
\mathbf{r} = \begin{pmatrix}
  r_1 \\
  r_2 \\
  r_3 \\
  r_4 \\
  r_5 \\
  r_6
\end{pmatrix} = \begin{pmatrix}
  r \sin \alpha_1 \sin \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  r \cos \alpha_1 \sin \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  r \cos \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  r \cos \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  r \cos \alpha_4 \sin \alpha_5 \\
  r \cos \alpha_5
\end{pmatrix}.
\]

(93)

Here the ranges of each angle are \( 0 \leq \alpha_i \leq 2\pi, 0 \leq \alpha_i \leq \pi, i = 2, 3, 4, 5. \) In particular, choosing the 3D \( z \) axis parallel to \( \mathbf{P}_2 \), expresses the initial momentum \( \mathbf{P}_0 \) as

\[
\mathbf{P}_0 = \begin{pmatrix}
  P_0 \sin \alpha_1 \sin \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  P_0 \cos \alpha_1 \sin \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  P_0 \sin \alpha_2 \sin \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  P_0 \cos \alpha_3 \sin \alpha_4 \sin \alpha_5 \\
  P_0 \cos \alpha_4 \sin \alpha_5 \\
  P_0 \cos \alpha_5
\end{pmatrix}.
\]

(94)

where \( 0 \leq \alpha_i^b \leq 2\pi, 0 \leq \alpha_i^c \leq \pi \) and \( 0 \leq \alpha_5^P \leq \pi \).

The impact parameter represents the components of the initial vector position of the system in the hyperplane perpendicular to the initial momentum of the incoming particle, as was introduced previously. Let us define \( \mathbf{b} \) as the impact parameter when the 6D vector position is \( \mathbf{ρ} \):

\[
\mathbf{b} = \begin{pmatrix}
  b \sin \alpha_1^b \sin \alpha_2^b \sin \alpha_3^b \sin \alpha_4^b \\
  b \cos \alpha_1^b \sin \alpha_2^b \sin \alpha_3^b \sin \alpha_4^b \\
  b \cos \alpha_2^b \sin \alpha_3^b \sin \alpha_4^b \\
  b \cos \alpha_3^b \sin \alpha_4^b \\
  b \cos \alpha_4^b \\
  0
\end{pmatrix}.
\]

(95)

where \( 0 \leq \alpha_1^b \leq 2\pi, 0 \leq \alpha_i^b \leq \pi, i = 2, 3, 4 \). Thus, \( \mathbf{b} \) is a mass-weighted version of the bare impact parameter \( \mathbf{b} \). These two impact parameters are related by \( d^6 \mathbf{b} = (m_{12}^0 m_{312}^0 / \mu)^{1/2} d^3 \mathbf{b} \), and hence the classical cross section is given by

\[
\sigma_{\text{process}}(P) = \frac{\int \varphi_{\text{process}}(\mathbf{b}, P) \, d\Omega_b^P \, d\Omega_b^c \, d\mathbf{b} \, d\mathbf{b} \, d\mathbf{b} \, d\mathbf{b} \, d\Omega_b}{(m_{12}^0 m_{312}^0 / \mu)^{1/2} \int d\Omega_b^P},
\]

(96)

where a normalization mass factor emerges as a consequence of the mass-weighted character of the 6D vector position.

The initial vector position \( |\mathbf{ρ}_0| = R \) is chosen in the asymptotic region where the interaction potential is negligible, thus the initial momentum satisfies \( E = P_0^2 / 2\mu \), where \( E \) is the incident collision kinetic energy. The hyperangles \( \alpha_i^P \) with \( i = 1, 2, 5 \), and the impact parameter hyperangles \( \alpha_j^b \), with \( j = 1, 2, 3, 4 \), are randomly generated subject to the constrained magnitude of the impact parameter \( |\mathbf{b}| \). The random distribution of these angles must of course be chosen consistent with their appropriate probability density function (Pérez-Ríos et al., 2014). Exploiting the orthogonality of the initial momentum \( \mathbf{P}_0 \) and the impact parameter \( \mathbf{b} \), the initial vector position is written as

\[
\mathbf{ρ}_0 = \mathbf{b} - \sqrt{R^2 - \mathbf{b}^2} \frac{\mathbf{P}_0}{P_0}.
\]

(97)

Eq. (97) generates \( \mathbf{ρ}_0 \) from \( R \), \( \mathbf{b} \) and \( \mathbf{P}_0 \). For a given set of initial conditions \( \mathbf{ρ}_0 \), \( R \), \( \mathbf{P}_0 \) and \( \mathbf{b} \), the information is
Figure 27 (Color online) Classical trajectories for three-body collisions at a relative collision energy $E = k_B T_{\text{in}}$ with $T_{\text{in}} = 1 \, \text{mK}$ (The Boltzmann constant $k_B$ will usually be omitted in quoting energies in the following). Classical trajectories associated with a three-body recombination event $\text{He} + \text{He} + \text{He} \rightarrow \text{He}_2 + \text{He}$ with $b = 97 \, \alpha_0$ , panel (a); $b = 1000 \, \alpha_0$ for $\text{Rb} + \text{Rb} + \text{Rb}^+ \rightarrow \text{Rb}_2^+ + \text{Rb}$ in panel (b); and $\text{Rb} + \text{Rb} + \text{Ba}^+ \rightarrow \text{Rb-Ba}^+ + \text{Rb}$ with $b = 1000 \, \alpha_0$ in panel(c).

transformed into the usual 3D space by means of Eqs.(88) and (90), where Hamilton’s classical equations of motion are numerically integrated up to a certain final time (Pérez-Ríos et al., 2014; Press et al., 1986). Then the coordinates are mapped back into the 6D space, and the classical three-body cross section is calculated by means of Eq.(96). This protocol is schematically presented in Fig. (26).

The present approach has been applied to neutral three-body recombination (Pérez-Ríos et al., 2014) and also to neutral-neutral-ion three-body recombination (Pérez-Ríos and Greene, 2015). Fig.(27) exhibits different trajectories associated with recombination events in several atomic systems: $\text{He} + \text{He} + \text{He}$ in panel (a), $\text{Rb} + \text{Rb} + \text{Rb}^+$ in panel(b) and $\text{Rb} + \text{Rb} + \text{Ba}^+$ in panel(c). These trajectories have been obtained by assuming a pair-wise potential $V(r_1, r_2, r_3) = v(r_{12}) + v(r_{23}) + v(r_{31})$, where $r_{ij}$ are the interparticle distances. In particular, for the helium atom-atom interaction the potential of Aziz et al., designated HFD-B3-FCI1 (Aziz et al., 1995) has been employed. The $3\Sigma$ potential of (Strauss et al., 2010) for $\text{Rb-Rb}$ is employed, and no spin-flip transitions are allowed in the theoretical model. The ion-atom interactions are described by the model potential $-\alpha_d(1-(r_m/r)^2)/2r^4$, where $\alpha_d$ denotes the static dipole polarizability of $\text{Rb}$, which is taken as $\alpha_d = 320 \, \text{a.u.}$, and $r_m$ represents the position of the minimum of the potential. For $\text{Rb}^+-\text{Rb}$, $r_m$ is taken from the quantum chemistry calculations of (Jraij et al., 2003), and the information needed for $\text{Ba}^+-\text{Rb}$ is adapted from (Krych et al., 2011). For details about the numerical solution method, Monte Carlo sampling and convergence see Refs. (Pérez-Ríos and Greene, 2015; Pérez-Ríos et al., 2014).

3. Classical three-body recombination for neutrals and ion-neutral-neutral systems

The hyperspherical classical trajectory method (Pérez-Ríos and Greene, 2015; Pérez-Ríos et al., 2014) has been applied to the recombination of three neutrals and to the ion-neutral-neutral recombination process. For a given collision energy $E_b = P_0^2/2\mu$, the average classical three-body cross section is given by

$$
\sigma_{\text{rec}}(P_0) = \int \frac{\varphi_{\text{rec}}(b, P_0) d\Omega^5_b d\Omega^5_{P_0} db}{\int d\Omega^5_{P_0} d\Omega^5_b},
$$

where $d\Omega^5_b$ and $d\Omega^5_{P_0}$ stand for the differential elements in the hyperangles associated with the impact parameter $b$ and the initial momentum $P_0$, respectively. $\varphi_{\text{rec}}(b, P_0)$ represents the opacity function or reaction probability for three-body recombination, that is, the probability that the reactants transform into the products of interest for a given set of initial conditions and impact parameter. Generally, such a probability shows a stereochemical dependence, but the hyperangular degrees of freedom can be averaged out, leading to

$$
\varphi_{\text{rec}}(b, P_0) = \int \frac{\varphi_{\text{rec}}(b, P_0) d\Omega^5_{P_0} d\Omega^5_b}{\int d\Omega^5_{P_0} d\Omega^5_b}.
$$

This integral is evaluated by Monte Carlo sampling. Over the different initial conditions and impact parameters, the sampling is performed by means of the probability distribution function in each degree of freedom, which can be laborious but is trivially parallelizable. The solution for $\varphi_{\text{rec}}(b, P_0)$ in Eq. (99) implies the maximum impact parameter that can produce a recombination process for a fixed $P_0$, denoted as $b_{\text{max}}(P_0)$. In other words, $\varphi_{\text{rec}}(b, P_0) = 0$ for $b > b_{\text{max}}(P_0)$. Finally, the three-body recombination cross section can be expressed as

$$
\sigma_{\text{rec}}(P_0) = \Omega^5_b \int_0^{b_{\text{max}}(P_0)} \varphi_{\text{rec}}(b, P_0) b^4 db,
$$

where $\Omega^5_b = 8\pi^2/3$ is the total integrated hyperangular solid angle associated with $b$ for a collision of 3 particles in 3D. This integral is evaluated by means of Monte Carlo importance sampling (Shui, 1972). Next, the energy-dependent three-body rate constant is defined as

$$
k_3(P_0) = \frac{P_0}{\mu} \sigma_{\text{rec}}(P_0).
$$
Figure 28 (Color online) Energy dependence of the three-body recombination rate of helium atoms in (cm$^3$/s), i.e. He + He + He → He$_2$ + He. Classical trajectory results following the classical treatment in 6D by means of hyperspherical coordinates; red points. The same results but restricted to total angular momentum $J = |\rho_1 \times P_1 + \rho_2 \times P_2| = 0$ shown as the blue circles. The quantum calculation for a fixed angular momentum and parity $J^{\pi} = 0^+$ is plotted as the solid line. The quantal results show a convergence within better than about 15% for $E = 1000$ K regarding the number of channels included and the parameters employed in the calculations.

The results for the He-He-He classical three-body recombination rate are shown in Fig.(28). The quantum mechanical results shown in Fig. (28) were obtained using the R-matrix method to solve the coupled hyperradial equations in the adiabatic hyperspherical representation (Esry et al., 1996b; Lin, 1995; Wang et al., 2011a) to obtain the scattering matrix (Aymar et al., 1996).

Fig. (28) shows that classical trajectory results for $J = 0$ are in reasonably good agreement with the quantal results at collision energies $\sim 1$ K, which is the same order of magnitude as the van der Waals energy: this serves approximately as the transition energy between ultracold physics and thermal physics, as was pointed out in Ref. (Pérez-Ríos et al., 2014).

The same classical approach has been applied to the study of ion-neutral-neutral three body recombination at cold temperatures (Krúkow et al., 2016; Pérez-Ríos and Greene, 2015), which is important in ion-neutral hybrid trap experiments. Indeed three-body recombination reaction is the main loss mechanism for certain ionic species immersed in an ultracold high density neutral cloud(Härter and Denschlag, 2014; Härter et al., 2012; Härter et al., 2013; Krúkow et al., 2016). In particular, $^{87}$Rb$^+$ - $^{87}$Rb - $^{87}$Rb and $^{138}$Ba$^+$ - $^{87}$Rb - $^{87}$Rb were studied following the hyperspherical classical approach for collision energies ranging from $100\mu$K up to 10 mK, and the results are shown in Fig.(29).

The classical trajectory results presented in panels (a) and (b) of Fig.(29) have been obtained by restricting one of the hyperangles associated with the momentum, guaranteeing that 95% of the collision energy goes along the vector joining the ion and the center of mass of the neutrals. This dynamical constraint is a consequence of the typical experimental conditions: the energy of the ion is typically orders of magnitude higher than the energy of the neutrals (Härter and Denschlag, 2014; Willitsch, 2012; Willitsch et al., 2008) because of the trapped ion micromotion. As for the trajectories shown in Fig.(27), the same assumptions about the potential energy landscape and the same potentials were employed. In panels (a) and (b) of Fig.(29), the three-body recombination rate versus collision energy shows a power law dependence. The physics behind this numerical observation, including its derivation, was explained in Ref.(Pérez-Ríos and Greene, 2015), and is summarized below.

4. Classical threshold law for three-body recombination: universality in cold chemistry

In quantum mechanics the existence of threshold laws for elastic and inelastic collisions are familiar: the well-known Wigner threshold laws. These threshold laws represent the general trend of the cross section for different processes (here, elastic and inelastic collisions) as func-
tions of the collision energy. Analogously, there are also classical threshold laws, such as the famous Langevin cross section (Langevin, 1905) which establishes the behavior of the cross section at low collision energies for two-body ion-neutral collisions. Several years after that, Wannier found the classical threshold law for three-body collisions involving charged particles (Wannier, 1953), implementing a different approach than Langevin developed. Interestingly, in the case of three mixed-charge particles, e.g., two negative electrons escaping from a positive ion, the exponent in the energy-dependent rate constant is an irrational number which has been experimentally confirmed by measuring the double photoionization of He (Kossmann et al., 1988; Van der Wiel, 1972). The unusual threshold law exponent 1.127... was also obtained (Pérez-Ríos et al., 2014) following a classical capture model (Levine and Bernstein, 1987).

At low collision energies the scattering properties are mainly dominated by the long-range tail of the two-body interaction, which here are represented as $V(R) = -C_s/R^4$, with $s > 2$. We define the maximum impact parameter $b_{\text{max}}$ as the distance where the interaction potential is equal to the collision energy, i.e.

$$ E = \frac{C_s}{b_{\text{max}}^s}. \quad (102) $$

This denotes the distance where the motion of the colliding particles starts to deviate from the rectilinear uniform trajectory. This distance is the equivalent to the classical capture radius employed for the derivation of the Langevin cross section (Langevin, 1905; Levine and Bernstein, 1987), but assuming $V(R) = -\alpha_d/2R^4$ in that case. In analogy with the classical capture model, it is assumed that all the trajectories with $b \leq b_{\text{max}}$ will lead to a three-body recombination event, which of course is likely to be an overestimate. The three-body recombination cross section can then be expressed as the following (by virtue of Eq. (98))

$$ \sigma_{\text{rec}}(E_k) = \left( \frac{m_1^2m_3^2}{\mu^5} \right)^{-1/2} \frac{8\pi^2}{3} \int_0^{b_{\text{max}}(E_k)} \tilde{b}^4 db $$

$$ \propto \tilde{b}_{\text{max}}^5(E_k). \quad (103) $$

Eqs. (102), (103), after incorporating the relationship between momentum and energy ($P \propto E_k^{1/2}$), yield

$$ k_3(E_k) \propto \frac{1}{E_k^{5/5}} = E_k^{-26}. \quad (104) $$

Thus, the neutral three-body recombination rate constant at low collision energies should vary with energy in proportion to $k_3(E_k) \propto E_k^{-1/3}$ (Pérez-Ríos et al., 2014). Fig. (28) displays a numerical calculation of the three-body recombination rate coefficient for helium, showing that at low collision energies $k_3(E_k)$ follows a power law dependence as a function of $E_k$. A fit of the classical trajectory results to the functional form $(k_3(E_k) = \alpha d^6)$ gives the dashed-purple line. The fitting parameters obtained are $a=(5.89\pm3.145 \times 10^{-3})$ cm$^6$/s and $b = -0.26 \pm 0.07$, which is consistent with the predicted $k_3(E_k) \propto E_k^{-1/3}$ behavior (Pérez-Ríos et al., 2014).

The preceding derivation has assumed that all of the two-body interactions share identical long-range behavior, but an important case to consider is when different particle pairs have different interactions. This case has been explored in the context of determining the threshold law for ion-neutral-neutral three-body recombination (Pérez-Ríos and Greene, 2015). For that system, the two neutral atoms interact through a long-range van der Waals potential $V(R) = -C_6/R^6$, whereas the two ion-neutral interaction is dominated by the charge induced dipole interaction $V(R) = -\alpha_d/2R^4$. A classical capture model can be employed in analogy to the neutral three-body recombination derivation, but in this case the capture radius is given by

$$ E = \frac{\alpha_d}{b_{\text{2max}}^5}. \quad (105) $$

Here it has been assumed that the longer-range attractive ion-neutral interaction dominates over the neutral-neutral interaction. Plugging Eq. (105) into Eq.(103) the threshold behavior of the ion-neutral-neutral three-body recombination cross section is obtained as (Pérez-Ríos and Greene, 2015):

$$ \sigma(E_k) \propto E_k^{-5/4}, \quad (106) $$

and the associated rate constant reads as

$$ k_3(E_k) \propto E_k^{-3/4}. \quad (107) $$

Fig. (29) presents the numerical results for ion-neutral-neutral three-body recombination computed classically at low collision energies, as the points in both panes of the figure. Also shown is the threshold law given by Eq. (106) as the magenta solid line. Power law fits of the numerical results are represented by the dashed lines, and the fitting parameters are shown in Table I. Fig. (29) is
Table V Classical threshold law for the three-body recombination (TBR) cross section. A power law dependence of the TBR cross section as a function of the collision energy is assumed and used as a fitting function for the classical trajectory calculations (CTC) numerical results presented in Fig. (29). The errors quoted for the fitting parameters are associated with a confidence interval of 95%. Table adapted from Ref. (Pérez-Ríos and Greene, 2015).

| System                  | $\gamma (a_0^{-1})$ | $\beta$ (dimensionless) |
|-------------------------|----------------------|--------------------------|
| $^{87}$Rb$^+$ - $^{87}$Rb - $^{87}$Rb | $(7.94 \pm 2.72) \times 10^{-1}$ | $-1.178 \pm 0.068$ |
| $^{138}$Ba$^+$ - $^{87}$Rb - $^{87}$Rb | $(3.57 \pm 0.07) \times 10^{-1}$ | $-1.269 \pm 0.132$ |

Classical threshold law $-1.25$

a numerical confirmation of the predicted threshold law. And the fitted exponents in Table I confirm the validity of the derived classical threshold law.

Ion-neutral-neutral collisions play an important role in hybrid trap experiments where a high density of neutrals are in presence of a single ion or several of them (Härter and Deuschlag, 2014; Härter et al., 2012; Härter et al., 2013; Krükw et al., 2016), and hence hybrid trap experiments may elucidate the nature of ion-neutral-neutral three-body recombination. Indeed, very recently the three-body recombination rate for $^{138}$Ba$^+$ - $^{87}$Rb - $^{87}$Rb has been experimentally studied (Krükw et al., 2016), and the results of the experimental three-body recombination rate as a function of the micromotion energy $E_{\text{MM}}$ is shown as solid symbols in Fig. (30). In the same figure the open symbols stand for the classical trajectory results computed using hyperspherical coordinates (Pérez-Ríos et al., 2014). The theoretical three-body recombination rate constant presented in Fig. (30) is calculated by using the realistic energy distribution of the ion by means of a Monte Carlo simulation (Krükw et al., 2016). Fig. (30) show a good agreement between the classical trajectory calculations and in the experimental results, confirming on one hand the validity of the classical Newtonian treatment in cold chemistry, and on the other hand, supporting the classical threshold law, Eq. (107). Apart from the confirmation of the threshold law, this also has important implications in the chemistry that occurs after a three-body recombination event in a hybrid trap experiment, since the classical results suggest that the dominant product channel will be the formation of shallow molecular ions (Krükw et al., 2016; Pérez-Ríos and Greene, 2015). In fact our estimates suggest that classical mechanics should give a reasonable description of the three-body recombination process for Ba$^+$-Rb-Rb down to energies of the order of 100-200nK.

VII. CONCLUSIONS

This article reviews developments in only a modest subset of the many extremely vigorous and dynamic topics in the field of few-body physics. Anyone interested in exploring the multi-faceted aspects of this field and its interconnections with nuclear physics, chemical physics, and ultracold atomic and molecular physics is encouraged to explore the broader literature, and a good start would be the following set of review articles: (Baranov et al., 2012; Blume, 2012a; Braaten and Hammer, 2006; Frederico et al., 2012; Jensen et al., 2004b; Lin, 1995; Naidon and Endo, 2016; Nielsen et al., 2001; Petrov, 2012; Rittenhouse et al., 2011b; Sadeghpour et al., 2000; Wang et al., 2013, 2015a; Zimmer and Jensen, 2013). The ability to control interparticle interactions through Fano-Feshbach resonances or confinement-induced resonances continues to trigger novel experimental efforts, and theoretical progress on many fronts continues to be rapid as well. This field promises to continue stimulating new surprises in few-body and many-body physics in the years ahead. Here is one wish list for desirable development of improved understanding in several areas:

- (1) Further insights into the extent of universality for heavy-heavy-light systems with short-range interactions, including the role of van der Waals forces and the dependence on all parameters including the mass ratio.
- (2) Detailed theory and experiment to map out the universality of three-particle systems with all masses different, including of course the possible role of van der Waals universality.
- (3) Determination of $N$-body cluster states and recombination rates for both homonuclear and heteronuclear systems, with $N > 3$. There is a large parameter space to explore here, just for $N = 4$, for instance.
- (4) Controlled applications of external electromagnetic field dressing of the few-body systems to suppress or enhance inelastic processes. Progress in this area could potentially lead to the formation of a long-lived degenerate Bose gas at infinite two-body
scattering length, currently limited by three-body recombination processes.

- (5) Further development of experiments and theory for mixed-dimension few-body systems.

- (6) Experimental observation of log-periodic energy dependence of three-body recombination, which has been predicted to be visible for very large scattering lengths.

- (7) In the BCS-BEC crossover problem with a Fermi gas having more than two spin components, it will be interesting to see whether macroscopic collapse of the gas is possible when the interaction scattering lengths are negative, as was predicted by (Blume et al., 2008; Rittenhouse and Greene, 2008).

- (8) The three-body and four-body systems with strong electric and/or magnetic dipolar interactions has received some theoretical attention (Wang et al., 2011b,c) but little in the way of experimental tests to date, and in view of extensive current interest in polar molecule quantum gases, or strong magnetic dipolar atomic condensates and Fermi gases, far more work is needed from both perspectives. (Baranov et al., 2012; Kotochigova, 2014; Wang et al., 2015a; Zinner and Jensen, 2013)

- (9) It should be kept in mind that an accurate description of the two-body scattering length dependence of few-body phenomena hinges critically on having an accurate description of the atom-atom scattering lengths as functions of static and/or oscillating electromagnetic fields. Theory has improved to the point where a number of alternative techniques can provide this data, when developed in conjunction with experiments, including full close-coupling calculations (CC) (Berninger et al., 2013), the asymptotic bound state model (ABM) (Tiecke et al., 2010), and variants of multi-channel quantum defect theory (MQDT) with or without the additional frame transformation approximation (MQDT-FT) (Burke et al., 1998; Gao, 2008; Ruzic et al., 2013). Ref. (Pires et al., 2014a) and references therein provide comparisons of these different treatments, with application to the recently important heteronuclear system \(^{6}\text{Li} - ^{133}\text{Cs}\). While these theoretical descriptions have been generally successful, extensions and improvements are still desirable in order to gain the fullest possible control of the two-body physics underlying all of the few-body physics addressed in this review.

- (10) Further insights are also desired for systems such as the few-body version of the fractional quantum Hall problem, both in condensed matter systems and in ultracold atomic systems. Initial studies by (Daily et al., 2015b; Rittenhouse et al., 2016; Wooten et al., 2016) into that subject from the adiabatic hyperspherical perspective suggest that the corresponding 2D \(N\)-particle Schrödinger equation nearly separates in the hyperradial degree of freedom, both for bosons and fermions, as can be deduced from potential energy curves in those references. Moreover, some of the intriguing degeneracy patterns observed in that problem are deserving of further exploration.

VIII. ACKNOWLEDGMENTS

Different aspects of this work has been supported over the years by the National Science Foundation, the Department of Energy Office of Science, the AFOSR-MURI program on cold polar molecules, and the Bi-National Science Foundation. CHG specifically thanks many present and former colleagues, especially Doerte Blume, Jose D’Incao, and Brett Esry, for extended collaborations and access to their unpublished results and innumerable discussions. CHG also acknowledges the Alexander von Humboldt Foundation for supporting an extended stay at the Max-Planck Institute for Nuclear Physics and the University of Heidelberg, where part of the review article was completed. Many of the extensive revisions following submission were carried out with partial support from the Max-Planck Institute for the Physics of Complex Systems in Dresden.
