Abstract

Dynamics of a system that performs a large fluctuation to a given state is essentially deterministic: the distribution of fluctuational paths peaks sharply at a certain optimal path along which the system is most likely to move. For the general case of a system driven by colored Gaussian noise, we provide a formulation of the variational problem for optimal paths. We also consider the prehistory problem, which makes it possible to analyze the shape of the distribution of fluctuational paths that arrive at a given state. We obtain, and solve in the limiting case, a set of linear equations for the characteristic width of this distribution.

* This paper is dedicated to Rolf Landauer, with deep respect and admiration
I. INTRODUCTION

Large fluctuations, although infrequent, play a fundamental role in a broad range of processes, from diffusion in crystals to nucleation at phase transitions, mutations in DNA sequences, and failures of electronic devices. In many cases the fluctuating systems of interest are far from thermal equilibrium. Examples include lasers, pattern forming systems \[1\], trapped electrons which display bistability and switching in a strong periodic field \[2, 3\], and spatially periodic systems (ratchets) which display a unidirectional current when driven away from thermal equilibrium \[4\].

It was very clearly shown by Landauer \[5, 6\] that, whereas for systems in thermal equilibrium the probabilities of fluctuations are known at least in principle, for nonequilibrium systems there is no universal relation from which these probabilities can be obtained: even though the system mostly stays in the vicinity of one of locally stable states, the distribution over these stable states can be found only from global analysis. This distribution may be strongly affected by nonthermal perturbations in the rarely occupied intermediate states, i.e. by the large fluctuations which determine the probabilities of switching between the stable states (Landauer’s blowtorch theorem).

The major physical problems in the theory of large fluctuations are not only calculation of the fluctuation probabilities, but also analysis of the dynamics of large fluctuations. Understanding this dynamics is particularly important for controlling large fluctuations.

An intuitive approach to the theory of large fluctuations makes use of the optimal path concept. The optimal path is the path along which the system is most likely to move when it fluctuates to a given state from the vicinity of the stable state. Although trajectories of a fluctuating system are random, it is clear from Fig. 1 that the probabilities for the system which is found at a point \(q_f\) at an instant \(t_f\) to have arrived to this state along different paths are very different: e.g., it is unlikely that the system has been staying far from the equilibrium position for a long time, or that it has experienced an extremely large acceleration, as is the case for the paths 1 and 3 in Fig. 1.

Optimal paths and the probability distribution of the fluctuational paths are real physical objects: they have been observed in analog experiments \[7, 8, 9\] and digital simulations \[10\]. In the theory of large fluctuations, the pattern of optimal paths plays a role similar to that of the phase portrait in nonlinear dynamics.
The fundamental role of the distribution of fluctuational paths was recognized already by Onsager and Machlup [11]; in fact, they obtained optimal paths for a linear system in thermal equilibrium with the bath with a short correlation time (the approximation of Brownian motion). For such systems, whether they are linear or nonlinear, the optimal path to a given state is the time-reversed path from this state to the vicinity of the stable state in the neglect of fluctuations (the deterministic path) [9, 12]. This is no longer true for nonequilibrium systems, because, in general, they lack time reversibility. Even for simple nonequilibrium systems the pattern of optimal paths may have singular features [13, 14].

**FIG. 1:** (a) A particle with a coordinate $q$ fluctuating away from the bottom $q = q_b$ of the potential well $U(q)$ to a point $q_f$. (b) Various paths along which a particle can reach $q_f$ at a given instant $t_f$ in the course of the fluctuation; the probability densities for moving along different paths are exponentially different. With overwhelming probability the system moves to a point $(q_f, t_f)$ along an optimal path.

In the present paper we provide a general formulation of the problem of optimal paths for nonequilibrium systems driven by Gaussian noise. In Sec. II, based on a path-integral expression for the transition probability density, which allows for a prefactor, we derive an integral variational functional for optimal fluctuational paths. In Sec. III we provide a formulation of the prehistory problem for the distribution of fluctuational paths to a given state. This formulation is reduced to a linear integro-differential equation; the explicit form of this equation depends on the form of the correlation function of the noise. In Sec. IV we discuss the solution of this equation in the case where the destination state is close to the stable state of the system. Sec. V contains concluding remarks.
II. LARGE FLUCTUATIONS INDUCED BY GAUSSIAN NOISE WITH AN ARBITRARY POWER SPECTRUM

Nonlinear systems driven by nonthermal Gaussian noise form an important and fairly general class of nonequilibrium systems. In spite of seeming simplicity, they display a variety of interesting effects, unidirectional current in periodic structures being an example [4]. Substantial progress in the theory of large fluctuations in such systems has been made within the last two decades, particularly by implementing the path integral technique (see [15, 16, 17, 18, 19] and references therein). So far this technique has been applied to systems driven by the noise which is a component of a Markov process [19], in which case the reciprocal power spectrum of the noise $1/\Phi(\omega)$ is a polynomial in $\omega^2$, where

$$\Phi(\omega) = \int dt \, e^{i\omega t} \phi(t), \quad \phi(t) = \langle f(t) f(0) \rangle. \quad (1)$$

It is advantageous to express the characteristics of fluctuations in the system in terms of the noise power spectrum, since $\Phi(\omega)$ can often be measured in experiment. The shape of $\Phi(\omega)$ depends on the source of the noise and the coupling between the dynamical system and this source.

The noise with $\Phi^{-1}(\omega)$ of the form of a polynomial in $\omega^2$, although interesting, is not the most general type of noise. An important example of Gaussian noise with a non-polynomial $\Phi^{-1}(\omega)$ is the noise with Gaussian power spectrum in the central part

$$\Phi(\omega) = D \exp \left[ - (\omega^2 - \Omega_0^2)^2 / 4\Omega_0^2\sigma^2 \right], \quad |\omega^2 - \Omega_0^2| \lesssim \sigma^2. \quad (2)$$

In particular, noise of this sort is produced by the electric field of inhomogeneously broadened (in particular, Doppler-broadened) radiation.

A. Transition probability in a system driven by Gaussian noise

In this section we provide a general formulation of the problem of large fluctuations induced by Gaussian noise. We consider stationary systems or systems in a time-periodic field. To simplify notations, we will assume that the system under consideration is described by one dynamical variable, $q$. The Langevin equation of motion is then of the form:

$$\dot{q} = K(q; t) + f(t), \quad K(q; t + T) = K(q; t), \quad (3)$$
where \( f(t) \) is the zero-mean stationary noise. We assume that the noise is characterized by a certain correlation time \( t_{\text{corr}} \) over which its correlation function decays (at least exponentially, in the limit of large time).

For weak noise intensities, over a time \( t \) which exceeds \( t_{\text{corr}} \) and the characteristic relaxation time in the absence of noise \( t_{\text{rel}} \), the system will approach the stable state \( q^{(0)}(t) \) and will then perform small fluctuations about it. In periodically driven systems the state \( q^{(0)}(t) \) is also periodic and is given by the equation

\[
\dot{q}^{(0)} = K(q^{(0)}; t), \quad q^{(0)}(t + T) = q^{(0)}(t).
\]  

(we assume that the period of the state \( q^{(0)} \) is the same as that of the periodic driving).

In the course of a large fluctuation, the dynamical system is brought from the attractor to a distant point \( q_f \) at the instant \( t_f \) (cf. Fig. 1). For this to happen the system should have been subjected to finite forcing over certain time. Different realizations of the force \( f(t) \) can result in the same final state. The system trajectories \( q(t) \) for each realization of \( f(t) \) are deterministic rather than random, and they are independent of the characteristic noise intensity

\[
D = \max \Phi(\omega).
\]  

(5)

The probability density of realizations of \( f(t) \) is given by the functional (cf. )

\[
\mathcal{P}[f(t)] = \exp \left[ -\frac{1}{2D} \int dt \, dt' \, f(t) \hat{F}(t-t') f(t') \right],
\]  

(6)

where the operator \( \hat{F}(t) \) is related to the correlation function of the noise \( \phi(t) \) by the expression

\[
\int dt_1 \hat{F}(t-t_1) \phi(t_1-t') = D\delta(t-t').
\]  

(7)

In some cases (in particular, for the noise \( f(t) \) being a component of a Markov process) a formal solution of this equation can be written as

\[
\hat{F}(t) = D\delta(t)/\Phi(-id/dt).
\]  

(8)

Here, we have taken into account that the noise correlation function is even, \( \phi(t) = \phi(-t) \), as is also the noise power spectrum, \( \Phi(\omega) = \Phi(-\omega) \).

One can write the probability density \( p(q_f, t_f) \) for the noise-driven system to arrive at the point \( q_f \) at the instant \( t_f \), provided it has started from the point \( q_i \) at the initial instant
t_i, as a path integral
\[
p(q_f, t_f) = \left\langle \int_{q_i \approx q^{(0)}(t_i)}^q Dq(t) \delta [q(t) - q_{det}(t; f|q_i)] \right\rangle.
\] (9)

Here, \(q_{det}(t; f|q_i)\) is the solution of the dynamical equation of motion (3) for a given realization of the noise \(f(t)\), and \(\delta[q(t) - q_{det}(t)]\) is the functional delta-function: it peaks at the function \(q(t)\) equal to \(q_{det}(t)\). The averaging \(\langle \ldots \rangle\) means integration over \(f(t)\) with the probability density functional (6) as a weighting factor [20]. In what follows we assume that \(t_i \to -\infty\) and the initial point is close to the attractor, \(q_i \approx q^{(0)}(t_i)\). In this case the function \(p(9)\) gives the stationary probability distribution, which is periodic in time for the time-periodic force \(K\) in (3), \(p(q_f, t_f) = p(q_f, t_f + T)\).

It is convenient to perform averaging over \(f\) in (9) by writing the \(\delta\)-function in the form of a path integral over an auxiliary variable \(k(t)/D\). Using standard transformations [16, 20, 21] one can show that the expression for \(p(q_f, t_f)\) can be written in the following form:
\[
p(q_f, t_f) = C \int Df(t) \mathcal{P}[f(t)] \int D\frac{k(t)}{D} Dq(t) \times \exp \left\{ \int_{t_i}^{t_f} dt \left[ i \frac{k(t)}{D} [\dot{q} - K(q; t) - f(t)] - \frac{1}{2} K'(q; t) \right] \right\}, \quad K'(q; t) \equiv \frac{\partial K(q; t)}{\partial q},
\] (10)

where \(C\) is the normalization constant, and \(\mathcal{P}[f(t)]\) is the probability density functional for the random force [6].

B. Variational problem for optimal paths

If \(D\) is sufficiently small, as we assume, then, for all \(f(t)\) which result in a large fluctuation to a given state, the values of the probability density functional [6] are exponentially small; they also exponentially strongly differ from each other for different \(f(t)\). Thus one would expect that there exists one realization \(f(t) = f_{opt}(t)\) which is exponentially more probable than the others. This realization provides the maximum to the functional [6] subject to the constraint that the system described by Eq. (3) is driven to a designated state \(q_f\). Respectively, there are in fact two interrelated through (3) optimal paths: that of the system, \(q_{opt}(t)\), and that of the force, \(f_{opt}(t)\) [15, 19].

Formally, optimal paths can be obtained for small \(D\) by evaluating the path integral (10) by the steepest descent method. It follows from Eqs. [6], (10) that the optimal paths
provide the minimum to the functional
\[ R[q(t), \lambda(t), f(t)] = \frac{1}{2} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' f(t) \hat{F}(t-t') f(t') + \int_{t_i}^{t_f} dt \lambda(t) [\dot{q} - K(q; t) - f(t)], \] (11)
where \( \lambda(t) \equiv -ik(t) \); one can think of \( \lambda(t) \) as of a Lagrange multiplier that relates to each other the optimal realization of the random force and the path of the system.

Variational equations for the trajectories that provide an extremum to the functional (11) are of the form
\[ \int dt' \hat{F}(t-t') f(t') - \lambda(t) = 0, \quad \dot{\lambda}(t) + K'(q; t) \lambda(t) = 0, \quad \dot{q}(t) - K(q; t) - f(t) = 0. \] (12)
In the problem of the stationary probability density for the system to be in the state \( q_f \) at the time \( t_f \) (this probability density is periodic in \( t_f \) with the period \( T \)), the boundary conditions for Eqs. (12) take the form (cf. [19])
\[ f(t) \to 0 \quad \text{for} \quad t \to \pm \infty, \quad \lambda(t) \to 0 \quad \text{for} \quad t \to -\infty, \quad \lambda(t) = 0 \quad \text{for} \quad t > t_f, \quad q(t) \to q(0) \quad \text{for} \quad t \to -\infty, \quad q(t_f) = q_f. \] (13)
In deriving the boundary conditions (13) for \( t \to -\infty \), we took into account that the system fluctuates about the stable state for a long time before the large fluctuation starts (cf. Fig. 1). Respectively, one may set in [9] \( t_i \to -\infty, \quad q(t_i) = q(0)(t_i) \) (this is consistent with Eqs. (12)). On the other hand, the motion of the system after it has reached the point \( q_f \) is not important for the large fluctuation. Therefore the constraint on \( f(t) \) is lifted for \( t > t_f \). Clearly, the force decays to zero for \( t > t_f \).

The boundary conditions should be modified if one considers the problem of escape from a metastable state. By generalizing the arguments [19] to the case of a non-polynomial reciprocal power spectrum \( 1/\Phi(\omega) \), one can show that the optimal escape path corresponds to the system approaching the unstable periodic state \( q_u(t) \) (the saddle state) for \( t_f \to \infty \), and \( \lambda(t_f) \to 0 \) for \( t_f \to \infty \), because in this case \( \int_0^T dt K'(q_u(t); t) > 0 \). The analysis of the escape problem is beyond the scope of the present paper.

Eqs. (12), (13) provide a complete set of equations for the interconnected optimal fluctuational paths of the system and the force, \( q_{opt}(t|q_f, t_f) \) and \( f_{opt}(t|q_f, t_f) \), for reaching the state \( q_f \) at the instant \( t_f \). The probability to reach this state, according to Eq. (10), is of the form
\[ p(q_f, t_f) \propto \exp \left[ -R(q_f, t_f)/D \right], \quad R(q_f, t_f) = R[q_{opt}, \lambda_{opt}, f_{opt}] \equiv \min R[q, \lambda, f]. \] (14)
where $\lambda_{opt}(t)$ is the optimal Lagrange multiplier as given by Eqs. (12), (13).

We note that Eqs. (12), (13) may have several solutions. In this case, the physically meaningful solution is the one that provides the absolute minimum to the functional $R$. The criterion of applicability of the approach is $R/D \gg 1$ - it is this condition that determines how small should the noise intensity $D$ be.

An important feature of fluctuations induced by non-white noise, as it is clear from (12), (13), is that the optimal force $f_{opt}(t)$ does not become equal to zero once the system has reached the state $q_f$. Time evolution of the optimal force is given by the equation

$$ f_{opt}(t) = \int_{-\infty}^{t_f} dt' \tilde{\phi}(t-t')\lambda_{opt}(t'), \quad \tilde{\phi}(t) = D^{-1}\phi(t). \quad (15) $$

The function $\tilde{\phi}(t)$ is the noise correlation function rescaled so that it was independent of the characteristic noise intensity $D$ (the noise correlator $\phi \propto D$, cf. (1), (5)).

Based on Eq. (15) one can predict how the system will move, most likely, after the state $q_f$ is reached. The trajectory of the system is described just by the equation of motion (3) with the random force given by Eq. (15). We note that, even for the state $q_f$ lying in the basin of attraction to the initially occupied stable state from which the fluctuation starts, on the way back from $q_f$ the system may come not necessarily to the same stable state, but to a different state. This is in contrast with what happens in systems driven by white noise, unless $q_f$ lies very close to the basin boundary. An example of such fluctuations in systems driven by colored noise was, in fact, considered in [19], although trajectories of the system after it has fluctuated to a remote state were not analyzed.

C. Vicinity of the stable state

To illustrate the solution of the variational problem (12), (13) we will consider a simple case where the state $q_f$ is close to the stable state $q^{(0)}(t_f)$, so that the force $K(q; t)$ can be linearized in $q - q^{(0)}(t)$, and yet the difference $|q_f - q^{(0)}(t_f)|$ is big enough so that the asymptotic expression (14) applies. With account taken of Eq. (7), we obtain:

$$ \lambda(t) = u(t, t_f)\lambda_f, \quad q(t) - q^{(0)}(t) = \int_{-\infty}^{t} d\tau f(\tau)u(\tau, t), \quad (16) $$

$$ u(t, t') = \exp \left[ \int_{t}^{t'} d\tau K'(q^{(0)}(\tau); \tau) \right]. $$
One can see from Eq. (16) that

$$\lambda_f = g^{-1}(t_f, t_f) \left[ q_f - q^{(0)}(t_f) \right], \quad g(t, t') = \int_{-\infty}^{t} d\tau \int_{-\infty}^{t'} d\tau' \tilde{\phi}(\tau - \tau') u(\tau, t) u(\tau', t').$$  \hspace{1cm} (17)

From Eqs. (15) - (17) one can find the activation energy (14) of reaching the state \(q_f\),

$$R(q_f, t_f) = \frac{1}{2} g^{-1}(t_f, t_f) \left[ q_f - q^{(0)}(t_f) \right]^2.$$  \hspace{1cm} (18)

The activation energy (18) is quadratic in the distance between the state \(q_f\) and the stable state \(q^{(0)}(t_f)\). The proportionality factor \(g^{-1}(t_f, t_f)\) depends on the shape of the noise power spectrum, and also on the dynamics of the system in the absence of noise. We note that, if the regular force \(K(q; t)\) is independent of \(t\), the stable state \(q^{(0)}\) is independent of \(t\), and the function \(g(t_f, t_f)\) is independent of \(t_f\), as expected.

### III. THE PREHISTORY PROBLEM

The distribution of paths for large fluctuations can be investigated and visualized through the analysis of the prehistory probability density, \(p_h(q_h, t_h \mid q_f, t_f)\). This is the conditional probability density for a system that (i) had been fluctuating about \(q^{(0)}(t)\) for a time greatly exceeding the relaxation time of the system \(t_{rel}\) and the correlation time of the noise \(t_{corr}\), and (ii) arrived to the point \(q_f\) at the instant \(t_f\), to have passed through (and been observed at) the point \(q_h\) at the instant \(t_h\), \(t_h < t_f\). Using the path-integral formulation (10) one can write the prehistory probability density as

$$p_h(q_h, t_h \mid q_f, t_f) = M \int D f(t) \mathcal{P}[f(t)] \int D \frac{k(t)}{D} \int_{q_i}^{q_f} D q(t) \delta [q(t_h) - q_h]$$

$$\times \exp \left\{ \int_{t_i}^{t_f} dt \left[ \frac{k(t)}{D} \left[ \dot{q} - K(q; t) - f(t) \right] - \frac{1}{2} K'(q; t) \right] \right\},$$  \hspace{1cm} (19)

$$\int dq p_h(q, t \mid q_f, t_f) = 1.$$  \hspace{1cm} (20)

The normalization constant \(M\) in the general expression for \(p_h\) (19) is defined by the condition (20). Throughout this section we assume that \(t_i \rightarrow -\infty\).

We expect (and will confirm \textit{a posteriori}) that, for small \(D\), the distribution \(p_h(q, t \mid q_f, t_f)\) peaks sharply for \(q\) lying close to the optimal fluctuational path \(q_{opt}(t \mid q_f, t_f)\). Therefore in evaluating \(p_h\) one can expand the exponent in \(\mathcal{P}[f]\) and the term with \(k(t)\) in the exponent.
in Eq. (19) in the deviations $\delta f(t), \delta q(t), \delta k(t)$ from the optimal realizations of the random force $f_{opt}(t)$, the trajectory $q_{opt}(t)$, and $k_{opt}(t) \equiv i\lambda_{opt}(t)$.

In this paper we will not address the problem of singularities of optimal paths in systems driven by colored noise (19), which has been understood only recently for white-noise driven systems (14). If the point $(q_f, t_f)$ is far from singularities, it suffices to keep in the aforementioned expansion only the second-order terms in $\delta f(t), \delta q(t), \delta k(t)$. Integrating over $\delta f(t)$ and writing $\delta[q(t_h) - q_h]$ as an integral, one can re-write Eq. (19) in the following form

$$p_h(q_h, t_h | q_f, t_f) = M_1 \int_{-\infty}^{\infty} \frac{d^2 a}{2\pi D} \int \mathcal{D} \frac{k(t)}{D} \int \mathcal{D} q(t) \exp (-S[k(t), \delta q(t)]/D),$$

where the quadratic functional $S$ is given by the expression

$$S[k, \delta q] = \frac{1}{2} \int_{-\infty}^{t_f} dt dt' \delta k(t) \bar{\phi}(t - t') \delta k(t') - i \int_{-\infty}^{t_f} dt \delta k(t) [\delta \bar{q} - K'(t) \delta q(t)] - \frac{1}{2} \int_{-\infty}^{t_f} dt \lambda_{opt}(t) K''(t) \delta q^2(t) + i a[q(t_h) - q_h],$$

with

$$\delta k(t) = k(t) - k_{opt}(t) \equiv k(t) - i\lambda_{opt}(t), \quad \delta q(t) = q(t) - q_{opt}(t),$$

$$K'(t) \equiv K'(q_{opt}(t); t), \quad K''(t) \equiv K''(q_{opt}(t); t) = \partial^2 K / \partial q^2,$$

and with the boundary conditions

$$\delta q(-\infty) = \delta q(t_f) = 0, \quad \delta q(t_h) = q_h - q_{opt}(t_h), \quad \delta k(-\infty) = 0.$$

It is convenient to rewrite the expression for $S$ in the matrix form,

$$S[-i\psi_1, \psi_2] = \frac{1}{2} \int_{-\infty}^{t_f} dt dt' \left( \psi_1(t), \psi_2(t) \right) \tilde{\mathcal{H}}(t, t') \left( \begin{array}{c} \psi_1(t') \\ \psi_2(t') \end{array} \right) + i a[q(t_h) - q_h],$$

where $\tilde{\mathcal{H}}$ is a Hermitian operator,

$$\tilde{\mathcal{H}}(t, t') = \begin{pmatrix} -\bar{\phi}(t - t') & \delta(t - t') (K'(t') - d/dt') \\ \delta(t - t') (K'(t') + d/dt') & -\delta(t - t') \lambda_{opt}(t) K''(t) \end{pmatrix}.$$

In obtaining Eq. (25) we took into account the boundary conditions (23). As we will see, of immediate interest is the value of $S[\delta k, \delta q]$ for purely imaginary $\delta k$ and real $\delta q$, which justifies the unusual form of $S$ (24).
A. The variance of the prehistory probability distribution

Integration over $\delta k(t), \delta q(t)$ in the expression (21) can be performed by the steepest descent method. In this method, one has to find the extremum of the quadratic functional $S$, which requires solving the following equations for the extreme values of $\delta k = -i\psi_1(t), \delta q = \psi_2(t)$:

$$
\int_{-\infty}^{t_f} dt' \tilde{H}(t, t') \begin{pmatrix} \psi_1(t') \\ \psi_2(t') \end{pmatrix} = -ia(t_h - t) \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \psi_2(t_h) = q_h - q_{opt}(t_h)
$$

(26)

where the value of $a$ is determined by the boundary conditions (23).

The solution of Eq. (26) can be sought in terms of the Green function $G_{ij}(t, t')$ which provides the solution to the equation

$$
\int_{-\infty}^{t_f} dt' \hat{H}_{ij}(t, t')G_{ii}(t', t'') = \delta_{ij}\delta(t - t''), \quad G_{ij}(t, t') = G_{ji}(t', t), \quad G_{i2}(t, t_f) = 0.
$$

(27)

Here, summation is performed over repeated subscripts $i_1$; the subscripts $i, i_1, j$ take on the values 1,2. The functions $\psi_i$ in Eq. (26) are expressed in terms of the function $G$ as

$$
\psi_j(t) = [q_h - q_{opt}(t_h)]G_{j2}(t, t_h)/G_{22}(t_h, t_h).
$$

(28)

Clearly, the functions $\psi_j$ are proportional to the distance of the point $q_h$, for which the prehistory probability density is sought, to the optimal fluctuational path $q_{opt}(t_h|q_f, t_f)$.

Using Eq. (21), the prehistory probability density can be expressed in terms of the functions $\psi_{1,2}$, and then in terms of the Green function $G$,

$$
p_h(q_h, t_h|q_f, t_f) = \left(2\pi D\sigma_h^2(t_h|q_f, t_f)\right)^{-1/2} \exp\left(-\frac{[q_h - q_{opt}(t_h|q_f, t_f)]^2}{2D\sigma_h^2(t_h|q_f, t_f)}\right)
$$

(29)

$$
\sigma_h^2(t_h|q_f, t_f) = G_{22}(t_h, t_h).
$$

The distribution $p_h$ is Gaussian, with a maximum on the optimal path. It is seen from Eqs. (28), (29) that the variance of the distribution is given immediately by the component of the Green function $G_{22}(t_h, t_h)$. For very large $t_f - t_h$ the variance becomes independent of $t_f$, and Eq. (29) describes the stationary distribution about the stable state.

Alternatively, the problem of the variance of the prehistory probability distribution can be solved in terms of the eigenfunctions and eigenvectors of the appropriate Hamiltonian. For white-noise driven systems this method was discussed earlier [8].
We note that the above analysis makes it also possible to investigate the “post-history” probability distribution: the distribution of the paths of the system after it has fluctuated to a remote state. For white-noise driven systems, this distribution peaks at the path along which the system, prepared initially in the state $q_f$, goes down to the stable state $q^{(0)}$, as clearly demonstrated experimentally by Luchinsky and McClintock [9]. As discussed below Eq. (15), colored noise is not turned off once it has driven the system to a given state, and therefore it affects the motion of the system after the state $q_f$ has been reached.

Formulation of the post-history problem requires changing in all above equations to integration over the paths $q(t)$ and the auxiliary field $k(t)$ for $t$ varying from $-\infty$ to $\infty$ (instead of $-\infty$ to $t_f$), with the condition that the paths go through the state $q_f$ at the instant $t_f$.

The final answer is again given by Eq. (29), and the distribution peaks at the most probable path for the motion of the system after the state $q_f$ has been reached.

**IV. PREHISTORY PROBABILITY DISTRIBUTION CLOSE TO THE STABLE STATE**

Explicit expressions for the prehistory probability density can be obtained if the final point $q_f$ lies close enough to the stable state $q^{(0)}(t_f)$, in which case the equations for optimal paths of the system and the force are linear. In the prehistory problem, to the lowest order in $|q_f - q^{(0)}(t_f)|$, one can neglect the term in (25) with $\lambda_{opt} K'' \propto q_f - q^{(0)}(t_f)$ (cf. (17)), and can also replace $K'$ by its value for the stable state. Eq. (26) may then be immediately integrated. After straightforward but somewhat tedious calculations one obtains the following expression for the reduced variance of the distribution $p_h$:

$$\sigma^2_h(t_h|q_f, t_f) = \left[ g(t_f, t_f)g(t_h, t_h) - g^2(t_f, t_h) \right] / g(t_f, t_f)$$

(30)

(the function $g(t, t')$ is defined in Eq. (17)).

We emphasize that Eq. (30) applies for an arbitrary shape of the power spectrum of the noise (however, we assume that the function $\tilde{\phi}(\tau)$ decays at least exponentially for $|\tau| \to \infty$). It applies also for an arbitrary periodic driving. It may be further simplified in the absence of periodic driving, in which case $K' = -\alpha = $ const, with $\alpha > 0$, and we obtain from (17)

$$g(t, t') = \frac{1}{2\pi} \int d\omega D^{-1}\Phi(\omega)(\alpha^2 + \omega^2)^{-1}e^{i\omega(t-t')}.$$  

(31)
This expression makes it simple to calculate the variance of the prehistory probability density for an arbitrary shape of the noise power spectrum $\Phi(\omega)$. The results of these calculations for noise with the Gaussian power spectrum centered at zero frequency are shown in Figs. 2. It follows from this figure that the noise color changes the broadening of the prehistory distribution very substantially. An important consequence of Eqs. (30), (31) is that the variance $\sigma_h^2(t_h | q_f, t_f) \propto (t_f - t_h)^2$ for small $t_f - t_h$. This is qualitatively different from the linear time dependence of $\sigma_h^2$ in the case of white noise, known from [7, 8]. The reason is that, for systems driven by colored noise, the mean square displacement over the time $\Delta t$, which is small compared to the noise correlation time $t_{\text{corr}}$, is proportional to $\Delta t^2$, not to $\Delta t$, as for white-noise induced diffusion.

![Graph](image)

FIG. 2: Time dependence of the scaled variance $\sigma_h^2$ of the prehistory probability density in a linear system driven by noise with the Gaussian power spectrum $\Phi(\omega) = D \exp(-\omega^2/2\alpha^2\sigma^2)$, for different values of the dimensionless variance of the noise spectrum $\sigma^2$. The time is scaled by the decrement of the system $\alpha = -K'(q(0))$.

For large $t_f - t_h$, which exceeds the relaxation time of the system and the correlation time of the noise $t_{\text{rel}}, t_{\text{corr}}$, the prehistory probability distribution goes over into the stationary distribution which is described by the function $R(q_h, t_h) = [q_h - q(0)(t_h)]^2/2\sigma_h^2$, where $R(q_h, t_h)$ is given by Eq. (18).
V. CONCLUSIONS

In contrast to white noise driven systems, for colored noise, after the noise has driven the system to a remote state $q_f$, it does not become small at a time. As the noise decays it drives the system further along a certain path. This path differs from the path which the system would follow if it were prepared in the state $q_f$ "by hand", not as a result of the fluctuation.

In the present paper we provided a general formulation of the problem of large fluctuations in systems driven by Gaussian noise. This formulation makes it possible to describe optimal fluctuational paths of the system, and also to evaluate the width of the tube of fluctuational paths that arrive at a given target state. The latter is done using the prehistory probability distribution for the system to have passed through a given point on its way to the target state. The tube of the fluctuational paths is centered at the optimal path. Evaluation of the width of the tube has been reduced to solution of a linear equation. Explicit results have been obtained for the fluctuations in the linear range close to the stable state, and the effect of noise color in this domain has been analyzed.
