Keywords: spermatogenesis, spermatid cyst, mitochondria, basal body, centriolar adjunct, axoneme, acrosome, nuclear shaping, chromatin condensation, individualization, fertilization

Abbreviations: CA, centriolar adjunct; Cby, Chibby; Cnn, Centrosomin; IC, individualization complex; MT, microtubule; PCM, pericentriolar material; PtdIns(4,5)P2, phosphatidylinositol 4,5-bisphosphate; Unc, uncoordinated

Drosophila melanogaster spermatids undergo dramatic morphological changes as they differentiate from small round cells approximately 12 μm in diameter into highly polarized, 1.8 mm long, motile sperm capable of participating in fertilization. During spermiogenesis, syncytial cysts of 64 haploid spermatids undergo synchronous differentiation. Numerous changes occur at a subcellular level, including remodeling of existing organelles (mitochondria, nuclei), formation of new organelles (flagellar axonemes, acrosomes), polarization of elongating cysts and plasma membrane addition. At the end of spermatid morphogenesis, organelles, mitochondrial DNA and cytoplasmic components not needed in mature sperm are stripped away in a caspase-dependent process called individualization that results in formation of individual sperm. Here, we review the stages of Drosophila spermiogenesis and examine our current understanding of the cellular and molecular mechanisms involved in shaping male germ cell-specific organelles and forming mature, fertile sperm.

Introduction

Drosophila melanogaster is a powerful system for studying spermiogenesis, as the stages of sperm development are easy to examine and a variety of molecular genetic techniques permit dissection of the cellular processes involved. Drosophila spermiogenesis was first described at an ultrastructural level 40 years ago by Tates, Tokuyasu and others.1-12 The stages of spermiogenesis are readily identified in live squashed preparations cultured in vitro.13-16 Cell morphogenesis during spermiogenesis largely depends on stored mRNAs that are transcribed during meiotic prophase and translated at later stages of sperm development (reviewed in refs. 17, 18). Screens for male-sterile mutants have identified numerous genes involved in spermiogenesis,19-25 and newer techniques such as targeted gene disruption and RNA interference promise to reveal additional factors that are required (reviewed in ref. 26). For previous excellent reviews of Drosophila spermatogenesis, see refs. 13, 27–29. Here, we present a discussion of the stages of spermiogenesis, followed by a description of molecular and cellular mechanisms involved in formation and morphogenesis of sperm-specific organelles and mature, individual sperm.

Early stages of spermiogenesis. Spermiogenesis begins immediately after meiosis, when clonally related groups of 64 interconnected spermatids begin to undergo the morphological changes required for sperm development. At normal cultivation temperatures (25°C), the entire process takes approximately five days, or half of the time it takes to go from the initial stem cell division to production of mature sperm (reviewed in ref. 2A). At a cellular level, the first change observed is coalescence of the mitochondria around the basal body at one side of the nucleus. This is followed by mitochondrial agglomeration and migration of the basal body near the nuclear envelope (Fig. 1A). Subsequently, the mitochondria fuse to form the nebennern (Fig. 2A), which consists of two enlarged mitochondrial derivatives that wrap around each other in a manner resembling an onion.3,11 During mitochondrial fusion, the basal body (Fig. 2F) becomes embedded in the nuclear envelope, and the nuclear envelope itself becomes asymmetrical, with nuclear pores being restricted to the side where the basal body docks (Fig. 2J). Also in this region, the dense body, a microtubule (MT) and actin-rich structure involved in transport and nuclear shaping, begins to form (Fig. 2S). The acroblasts, a Golgi-derived organelle, develops on the side of the nucleus opposite the basal body (Fig. 2H), where it serves as the site of formation of the acrosome (Fig. 2I), a specialized membrane bound organelle required for fertilization.

Spermatid elongation. Elongation of each group of 64 spermatids occurs within the syncytial cyst. During early stages of elongation, the cyst becomes polarized such that all of the nuclei localize to one end and the growing ends of the sperm tails are found at the other (Fig. 1B and C; Fig. 2L and M). Ring canals composed of proteins found in the cleavage furrow during cytokinesis localize to the growing ends of elongating cysts (Fig. 2L), as do membrane skeletal proteins.30 The elongating spermatids are connected along their length by intercellular bridges, and plasma membrane deposition is required to provide sufficient
most of its length, the axoneme is surrounded by ER membranes that associate intimately with the two giant mitochondrial derivatives of the nebenkern as they unfurl and elongate along the flagellar axoneme (Fig. 2D).

membrane to enclose the individual sperm at the end of differentiation (reviewed in ref. 13). Elongation of the flagellar axoneme is coordinated with cyst elongation, and the distal portion of the axoneme is ensheathed in a ciliary membrane that is contiguous with the plasma membrane (Figs. 1B and 2G). Throughout

Figure 1. For figure legend, see page 199.
Nuclear shaping and chromatin condensation. Spermatid elongation is accompanied by dramatic changes in nuclear shape (Fig. 1D and Figure 2O–R).9 Following meiosis, onion stage spermatids contain spherical nuclei that are approximately 5 μm in diameter (Fig. 2A, J and O). During sperm development, the nuclei become thinner and the chromatin condenses, until finally, at the end of spermiogenesis, the nuclei are needle-shaped and approximately 10 μm long (Fig. 2R, W and X). Roughly halfway through elongation and nuclear shaping, a burst of post-meiotic transcription produces a set of mRNAs that are transported to the growing ends of the spermatid cysts.33

Individualization and coiling of mature sperm. Following elongation and nuclear shaping, the mature sperm are invested with their own membranes in a process called individualization (Fig. 1C).3 Individualization requires formation of an individualization complex (IC) composed of 64 actin cones that form around the 64 needle shaped nuclei in a mature spermatid cyst (Fig. 2U and W). The individualization complex moves processively down the length of the cyst, stripping away unneeded organelles and cytoplasm, and resolving intercellular bridges to encase each sperm cell in its own plasma membrane. Following individualization, each group of mature sperm becomes coiled in a process that brings the entire length of the nearly 2 mm long sperm bundle into the base of the testis.6 After coiling, the sperm bundle is processed that bring the entire length of the nearly 2 mm long spermatid to the other tip of the testis, creating an acrosomal granule, from which will derive the acrosome. A dark, dense structure named the protein body forms in the nucleus, which is devoid of a nucleolus. Spermatids remain connected to each other via ring canals throughout most of spermiogenesis. (A) Each elongating spermatid contains an axoneme and two mitochondrial derivatives. Axoneme elongation occurs at the growing end, in the region enshrouded by the ciliary membrane. A ring of pericentriolar material called the centriolar adjunct forms around the basal body. Some of the proteins associated with the basal body, such as Unc, also localize to the ring centriole, a structure found at the edge of the ciliary cap that may be equivalent to a transition zone at the base of the cilium. Perinuclear microtubules organize at one side of the nucleus, forming the dense body. When the flagellar axoneme is about half its final length, the nucleus and the acrosome also start to elongate. (C) Each group of 64 spermatids is surrounded by two somatic cyst cells: a head cyst cell and a tail cyst cell. Elongated spermatid cysts are polarized, with all of the nuclei positioned in the head cyst cell, and the tails growing in the opposite direction. Fully elongated spermatids undergo individualization, a process in which F-actin containing investment cones form around the nuclei and then migrate in synchrony along the spermatids, stripping them of excess cytoplasm and unneeded organelles, and investing them with their own plasma membranes. As the cones move from head to tail, a cystic bulge forms around and in front of the cones. The excess cellular material is deposited in a waste bag at the end of the cyst. (D) As the nuclei elongate, they go through leaf, early canoe, late canoe and needle-shaped stages. The dense bodies and the acrosomes elongate together with the nuclei. Inside the nucleus, the chromatin is reorganized, and histones are replaced by transition proteins (Tpl) and then by protamines and Mst77F. During this histone to protamine transition, histones undergo various modifications (acetylation, ubiquitination), other proteins become sumoylated, transient breaks occur in the DNA strands and proteasome activity is high.

Mitochondrial Morphogenesis

Mitochondrial morphogenesis during insect spermiogenesis includes aggregation, fusion, membrane wrapping, unfurling and elongation.34 At the end of meiosis II, mitochondria aggregate together near one side of the nucleus and fuse to form two mitochondrial derivatives (major and minor) that wrap around each other in an onion-shaped structure called the nebenkern (Fig. 1A and Fig. 2A and J).33 The mechanism that drives mitochondrial aggregation and positioning of the nebenkern in a specific location near the nucleus is not fully understood. However, treatment with high doses of colchicine, a MT inhibitor, suggests that aggregation, but not fusion, depends on MTs (reviewed in ref. 13). Consistent with this idea, mutants for the dynein-associated protein Lis-1 occasionally form multiple nebenkerns, suggesting that dynein motor activity is required for aggregation.35

Mitochondrial fusion is mediated by Fuzzy onions (Fzo), a large, dynamin-related transmembrane GTPase, and the founding member of the mitofusin protein family.36 fzo mutants show defects in mitochondrial fusion and form many small, unprocessed mitochondrial derivatives, rather than a single large nebenkern. At later stages, multiple small elongating mitochondria are observed, approximately half of which resemble the major mitochondrial derivative. Mitochondrial fusion also requires the intramembrane protease Rhomboid-7 and optic atrophy 1 (Opal).37 Mutations in rho-7 and opal affect mitochondrial morphology in a manner similar to loss of fzo.

Mitochondrial fusion requires the dynamin-related protein Drp1, which is needed for normal clustering of mitochondria in primary spermatocytes and mitochondrial unfurling during elongation.38 The Pink1/Parkin pathway, which includes genes (pink1, parkin, DJ-1) whose homologs are mutated in human Parkinson disease, regulates mitochondrial morphogenesis.39,40 In parkin mutant spermatids, both mitochondrial derivatives form, but only the major derivative unfurls from the nebenkern and subsequently exhibits abnormal shaping and condensation during spermatid elongation.41 pink1 (PTEN-induced kinase-1) and DJ-1 mutant spermatids resemble parkin mutants,39,40,42,43 suggesting they share a common function. Genetic and biochemical data indicate Pink1 phosphorylates and activates Parkin, an E3 ubiquitin ligase, which in turn acts upstream of DJ-1.39,43,44 Since Pink1 and Parkin mark damaged mitochondria for destruction by autophagy (reviewed in ref. 45), it is tempting to speculate that the Pink/Parkin pathway may provide a mark that identifies the minor mitochondrial derivative and ensures its proper differentiation.
Mitochondrial fusion and fission are intimately connected, and a balance between the two is required to maintain proper mitochondrial morphology (reviewed in ref. 46). Genetic interactions between pink1/parkin and fzo, opa1 and drp1 suggest Pink1/Parkin promotes mitochondrial fission or inhibits mitochondrial fusion in developing spermatids. Recent experiments indicate Parkin ubiquitinates the Fzo-related Mfn protein to promote its degradation in Drosophila tissue culture cells. Since Fzo associates with spermatid mitochondria only around the time of fusion, Parkin may promote fission by stimulating Fzo degradation.

Mitochondrial elongation was recently shown to drive spermatid elongation (Fig. 2B and C). Indeed, axoneme and nebenkern elongation can proceed independently. Spermatids that lack axonemes still undergo elongation. In contrast, mutants for fzo and no mitochondrial derivative (nmd), which have small mitochondrial derivatives, exhibit severe elongation defects. Mitochondrial elongation occurs along cytoplasmic microtubules, and is mediated by Milton and dMiro, which have two small GTPase domains, form a conserved complex that links mitochondria to kinesin motors. Milton and dMiro anchor the two mitochondrial derivatives to the nucleus to facilitate their elongation.
Basal Body Development, Centriolar Adjunct Formation and Axoneme Initiation

Basal body development and axoneme initiation begin in primary spermatocytes, when the paired centrioles migrate to the cell periphery and act as basal bodies to template assembly of short cilia that extend from the cell surface. Immediately prior to metaphase of meiosis I, these elongated basal bodies internalize, together with caps of plasma membrane (Fig. 2E), to form MT organizing centers at the poles of the dividing cell. Following meiosis, each haploid spermatid inherits a single elongated basal body whose short axoneme remains surrounded by a membrane cap, or ciliary sheath. The basal body associates with cytoplasmic MTs during its movement toward the nucleus, where it becomes surrounded by the centriolar adjunct (CA) (Fig. 2K), an electron dense structure similar to the pericentriolar material (PCM) found in centrosomes. Once embedded in the nuclear envelope, the basal body functions as a MT-organizing center, nucleating assembly of both the flagellar axoneme and perinuclear MTs.

Early defects in centriole formation and organization lead to spermatids lacking basal bodies and axonomes. For example, mutations affecting Sas-6, Sak/Plk4, Sas-4/CPAP, Ana1 and Asterless/Cep152 abolish centriole duplication and flagellum assembly. For a review, see ref. 63.) Sak and Sas-6, but not Sas-4, are also required for assembly of a proximal centriole-like (PCL) structure recently identified in developing spermatids. This immature centriole, which contains Ana1 and requires the conserved centriolar protein POC1 for its assembly, is dispensable for axoneme assembly and male fertility, but may contribute to producing the second centriole at fertilization.

Several centriolar proteins with roles in recruiting PCM proteins to centrosomes localize to basal bodies and may be
important for CA assembly or function. For example, Sas-4, Drosophila pericentriole-like protein (D-Plp/CP309) and Spd-2 are required to recruit γ-tubulin, Centrosomin (Cnn) and other PCM proteins to centrosomes, and may serve similar functions at the CA. However, these proteins have different effects on spermatid differentiation. D-Plp mutants show fragmented centrioles and scattered basal bodies in the elongated cysts, whereas cnn and spd-2 mutant axonemes show a variable lack of central pair MTs.

Uncoordinated (Unc) localizes to distal end of the basal body and to the growing end of the sperm tail in a structure referred to as the ring centriole (Fig. 1A and B; L.F. and J.A.B., unpublished observations). Unc is needed for basal body and ciliary elongation in primary spermatocytes, and is required for robust accumulation of γ-tubulin at centrioles. In addition, unc mutants show severe defects in flagellar axoneme organization. Like Unc, Chibby (Cby), a conserved coiled-coil protein, is required for the centriole to basal body transition and normal axoneme assembly. Following meiosis, Cby initially colocalizes with Unc at basal bodies. However, during elongation, Cby relocates from the basal body to the ring centriole at the growing end of the sperm tail. Unc distribution is aberrant in cby mutants, with Unc extending a variable distance beyond the normal centriole length. Interestingly, similar defects in Unc distribution and axoneme assembly are also observed in spermatids in which the plasma membrane lipid phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂) has been depleted by ectopic expression of a lipid phosphatase. Hence, Cby and PtdIns(4,5)P₂ may perform a common function in regulating Unc localization during spermatid elongation.

Mutants for Bld10/Cep135 share similarities with unc and cnn. bld10 mutants have short centrioles and basal bodies, like unc mutants, and axonemes that lack central pair MTs, like cnn mutants. Bld10 localizes in the lumen of the basal body, at both the proximal end, close to the nuclear membrane, and the distal end, at the site of axoneme assembly, and is also found in the PCL. Notably, Bld10 is dispensable for recruitment of γ-tubulin, Cnn and other PCM proteins. Since Bld10 localizes to the transition zone, and this is the region where central pair MTs originate, it is possible that Cnn affects Bld10 activity in this region.

**Basal Body Movement and Docking at the Nuclear Envelope**

Docking and continued association of the basal body at the nuclear envelope is essential for formation of mature, motile Drosophila sperm. Movement of the basal body to the spermatid nucleus and attachment to the nuclear envelope requires proper microtubule and dynein organization. γ-tubulin appears important for this process, as defects in basal body docking at the nuclear envelope are seen in mutants for the γ-tubulin ring complex (γ-TuRC) subunits Grip75 and Grip128. In grip75 and grip128 mutants, spermatid nuclei fail to associate with basal bodies, become scattered along the elongated cysts and exhibit defects in nuclear shaping, a MT-dependent process. Importantly, mature axonemes of normal architecture form in grip75 and grip128 mutants, indicating that γ-TuRC is dispensable for axoneme assembly. Hence, γ-TuRC likely nucleates assembly of MTs involved in migration of the spermatid basal body to the nucleus or in attachment of the basal body to the nuclear envelope. The basal body proteins Unc and Dilatory (Dila/CEP131) are required for tight association of basal bodies with spermatid nuclei. Since Unc and Dila are needed for robust CA accumulation of γ-tubulin, these mutants may be defective in γ-TuRC-dependent MT nucleation.

Dynein activity is also important for basal body docking, as several mutants with defects in basal body–nucleus attachment affect dynein-associated proteins. Null mutants for tctex-1, which encodes the 14kDa dynein light chain (Dlc90F), are male sterile and show nuclear scattering in later stages of elongation. Most of the nuclei do not shape properly, especially those that are not associated with a basal body. Tctex-1 mediates cytoplasmic dynein localization at the nuclear membrane in early spermatids. In wild-type spermatids, dynein and its accessory factor dynactin are distributed in the region of the nuclear envelope where the basal body is attached. However, this dynein localization is lost in tctex-1 mutants. Asunder (Asun/Mat89Bb) colocalizes with dynein at the perinuclear surface in primary spermatocytes and spermatids, and has a role in recruitment of dynein–dynactin at the nuclear membrane. Asun is dispensable for recruitment of centrosomal proteins. Nuclei are scattered in asun mutant cysts, similar to unc, and do not shape normally. Like γ-TuRC, dynein is dispensable for axoneme assembly, as axonemes can be nucleated from free, unattached, basal bodies in tctex-1 and asun mutants.

It is not known whether dynein may play a direct role in anchoring the basal body at the nuclear envelope. However, recent data provide strong support for the idea that dynein mediates migration of the basal body toward the nuclear envelope prior to docking. Mutants for Lis-1, the Drosophila homolog of the human lissencephaly protein LIS1, show a defect in internalization of the elongated basal bodies from the cell surface in primary spermatocytes. As a result, the meiotic spindle poles localize aberrantly at the plasma membrane, resulting in spindle defects. Similar phenotypes are also observed in tctex-1 mutants, indicating that these defects are likely caused by a loss of dynein activity. Indeed, Lis-1 is required for dynein–dynactin localization at the nuclear membrane during meiosis and in early spermatids. Lis-1 localization requires Asun, suggesting these proteins act together to regulate this process.

Several proteins are thought to mediate attachment of the basal body to the nuclear envelope. For example, Spag4, a conserved, testis-specific SUN domain protein, is required for basal body anchoring to the spermatid nucleus. In early round spermatids, Spag4 localizes to the nuclear envelope in a hemispherical cap, similar to cytoplasmic dynein heavy chain (Dhc). During nuclear elongation, Spag4 associates with the basal body and the dense body. Spag4 mutant males are sterile, with scattered nuclei and basal bodies. Similar defects are observed in mutants for Yuri Gagarin (Yuri), a coiled-coil cytoplasmic protein that colocalizes with Spag4 at the nuclear envelope cap, basal body and dense body. Interestingly, the two proteins strongly colocalize at the invagination in the nuclear envelope where the basal body embeds, suggesting they may anchor the basal body to the
nucleus. Spag4 is required for dynein–dynactin localization at the basal body, whereas both Spag4 and dynein are needed for Yuri localization.77 How Spag4, a predicted inner nuclear membrane protein, regulates cytoplasmic dynein is unclear. KASH domain proteins in the outer nuclear membrane typically link SUN domain proteins to cytoplasmic MTs (reviewed in ref. 79). However, the KASH domain proteins Klarsicht and MSP-300 are dispensable for basal body docking.77 One possibility is that nuclear pores, which localize in the area where the basal body attaches to the nuclear envelope, help provide the missing link.

Two additional factors are required for basal body docking: the poly(A) polymerase Gld2 and the membrane lipid PtdIns(4,5)P_2.32,70,80 In gld2 mutants, γ-tubulin associates with basal bodies, but these are not consistently located near the scattered nuclei. It is unclear whether the primary defect is in basal body migration or docking, and polyadenylation of transcripts encoding proteins involved in these processes is unaffected.80 Basal bodies also fail to associate consistently with nuclei in spermatids in which PtdIns(4,5)P_2 has been severely or partially depleted.32,70 In cases where the basal body is found adjacent to the nuclear envelope, docking is defective, and axonemes extend from the unanchored basal bodies.70 Severe depletion of PtdIns(4,5)P_2 is accompanied by excess accumulation of the CA proteins Unc, Cnn and γ-tubulin and defects in axoneme assembly. It will be of interest to determine whether Gld2 and PtdIns(4,5)P_2 regulate common targets involved in basal body docking.

**Axoneme Assembly and Modifications**

Drosophila has a canonical 9+2 flagellar axoneme, with nine outer doublet MTs and a central pair, the basic structure of most motile eukaryotic cilia and flagella. The outer doublet MTs associate with dynein “arms.” These consist of flagellar dyneins encoded by genes on the Y chromosome,81,82 which is required for male fertility.83 A set of nine accessory MTs surrounds the basal body, whereas both Spag4 and dynein are needed for sperm motility.87,88,91 The basal body and CA proteins Unc, Cnn and Cby (see above), as well as Touch-insensitive-larvaB (TilB) are also required for axoneme assembly.68,71,99 Moreover, an important aspect of axoneme assembly and maturation is post-translational modification of axonemal MTs.

Axonemal MTs are post-translationally modified through tyrosination, polyglutamylation, polyglycylation and acetylation (reviewed in ref. 100). Polyglycylation, polyglutamylation and most of the other posttranslational modifications occur at the exposed, highly charged C-terminal tails of α- and β-tubulin, whereas α-tubulin acetylation occurs on lysine-40, which is found on the inner surface of the MTs (reviewed in ref. 101). Developing Drosophila flagellar axonemes contain acetylated α-tubulin, as well as glutamylated and glycylated α- and β-tubulins.102-105 In Drosophila sperm, all α-tubulin is acetylated (Fig. 2M and V), whereas only a subset of axonemal tubulins are glutamylated and glycylated.89,106 Glutamylation occurs during or shortly after axoneme assembly, and it precedes and is required for glycylation.106 Polyglycylation occurs in late stages of spermiogenesis (Fig. 2W),103,107 at the time of individualization. Axonemal MTs and accessory MTs are differentially posttranslationally modified. The central pair and the accessory MTs are heavily polyglutamylated, whereas outer doublet MTs have only small amounts of glutamylation.

Tubulin modifications are important for axoneme assembly and formation of mature, fertilized sperm. Mutations in β2-tubulin at position Gly56, where acetylation occurs, lead to defects in axoneme assembly.108 Depletion of either of the two highly expressed glyclases, TTL3A or TTL3B, leads to strong reduction in polyglycylation, resulting in defects in sperm maturation and in male sterility.109

Transport of glycine to the sperm flagellum might be regulated by the neurotransmitter transporter-like (Ntl) protein, a member of the NSS/SLC6 family.110 Ntl is a spermatid-specific glycine transporter that localizes to the ER and is found along the ER-derived axial sheath that surrounds the axoneme. ntl mutants make sperm that are immotile and fail to be transferred to the seminal vesicle.110 Post-translational glycylation of sperm tubulin is reduced in ntl mutants, supporting previous reports that glycylation is important for stability and motility of MT-based machinery.107,108

Ciliary and flagellar axonemes are assembled at their distal tips within a specialized pocket of the plasma membrane termed the ciliary membrane, or sheath.93 (For a review, see ref. 94.) In most cells, axoneme assembly is directed by intraflagellar transport (IFT), a process that employs MT motors and trafficking proteins to transport preassembled axonemal subunits and other proteins to and from the tip of the axoneme. Drosophila spermatids have a ciliary membrane that ensheaths the growing portion of the flagellar axoneme (Fig. 1A and B).31,32 However, assembly of the spermatid flagellar axoneme is independent of IFT,95,96 raising the question of how tubulin dimers access the growing tip. One possibility is that mRNAs encoding tubulin subunits and other axonemal proteins may be actively translated within the ciliary pocket. Consistent with this idea, ribosomes are present in the space between the tip of the elongating axoneme and the overlying ciliary membrane.11
Nuclear Morphogenesis and Chromatin Reorganization

Nuclear morphogenesis during spermiogenesis includes two major aspects (Fig. 1D): elongation of the nucleus (nuclear shaping) and chromatin reorganization (condensation). Nuclear shaping is driven by MTs that emanate from the basal body and associate with the nuclear envelope. Concomitantly, chromatin condensation occurs by switching from a histone-based chromatin configuration, present in early round spermatid nuclei, to a protamine-based configuration, present in mature sperm nuclei.

Nuclear shaping proceeds through several stages. In early round spermatids, the nucleus first becomes flat on one side, near the basal body. This flattened surface is fenestrated with nuclear pores and associates with perinuclear MTs, which organize into parallel bundles, forming the dense body, a structure analogous to the vertebrate manchette. The dense body, which also contains filamentous actin and the actin-binding protein anillin (Fig. 25 and T; L.F. and J.A.B., unpublished observations), is thought to provide support to the elongating nucleus. As elongation proceeds, the fenestrated portion of the nuclear envelope forms a cavity that fills with dense body MTs, which in turn associate with a layer of ER. At this stage, the nucleus becomes canoeshaped and a single layer of MTs associates with the convex side of the nucleus, where chromatin begins to condense. At later stages of nuclear shaping, the cavity disappears, and the dense body is disassembled and removed during individualization.

Several factors have been implicated in regulating nuclear shaping via dense body cytoskeletal proteins. For example, nuclear shaping is defective in mutants for CA proteins (e.g., Unc, Tctex-1, Grip75 and Grip128) where the basal body fails to embed in the nuclear envelope, indicating a role for the CA in nucleating perinuclear MTs. Yuri and Spag4 participate in basal body docking, but Yuri also associates with the dense body and is responsible for actin accumulation in this structure. In spag4 and yuri mutants, the nuclei partially elongate, but they do not maintain their shape (they bend and curl). Similar nuclear shaping defects are observed in spermatids that have defects in basal body docking due to reduced levels of PtdIns(4,5)P2 (L.F. and J.A.B., unpublished observations). Like Yuri, Mst77F, a protein related to linker histone 1-like protein from mammals, localizes to the dense body. Genetic interactions between mst77F and mutations in β2-tubulin suggest a role in MT organization (reviewed in ref. 113). Indeed, mutations in mst77F lead to defective nuclear shaping, small nuclei and male sterility. Nuclear shaping defects are also observed in mutants for the testis-specific proteasome subunit Pros6T. However, since Pros6T localizes to the nucleus, these defects likely reflect a role in chromatin condensation rather than dense-body dependent nuclear shaping.

Chromatin reorganization in spermiogenesis involves replacement of histones first by transition proteins and then by protamines (Fig. 1D). The histone to protamine switch starts in early cano stage nuclei and takes approximately five hours to complete in cultured Drosophila spermatids. Histones are probably degraded directly in the nucleus by the Pros6T-containing testis-specific proteasome. Before degradation, several histone modifications occur. Histone H3 is methylated at lysine 9 and 27, which typically marks transcriptionally inactive chromatin, while H2A is mono-ubiquitinated and H4 is hyper-acetylated. Histone H4 hyperacetylation is required for the histone to protamine switch because inhibition of histone acetyltransferases prevents degradation of histones and the switch to a protamine-based chromatin. However, a premature increase in the levels of histone H4 acetylation does not result in early onset of the histone to protamine switch, indicating that additional mechanisms might function to induce the switch.

Histone modifications likely facilitate access of chromatin remodeling proteins and enzymes, as the chromatin also becomes associated with the zinc finger protein CTCF, as well as small ubiquitin-related modifier (SUMO), the ubiquitin-conjugating enzyme UbcD6 and ubiquitin. Following histone removal, the transition-like protein Tpf1 is incorporated. Together with DNA breaks, may facilitate chromatin unwinding and assembly of protamine and Mst77F on the condensing DNA. Several of these regulators appear to play conserved roles in nuclear shaping and chromatin condensation in mammalian spermatogenesis. For example, SUMO is involved in nucleation of spermid MTs and nuclear shaping. Ubiquitination of H2A is required during nuclear shaping in mice and may destabilize nucleosomes to promote the histone to protamine transition.

Mature Drosophila sperm contain Mst77F, protamine A and protamine B as major chromatin components. mRNAs encoding Mst77F and protamines are translationally repressed until the elongated spermatid stage, after which these proteins accumulate in the nucleus. Mst77F has a dual role in chromatin condensation and nuclear shaping through its association with perinuclear MTs. Moreover, mst77F mutants are male sterile. In contrast, males with mutated protamines are fertile and have motile sperm, but about 20% of the sperm show defects in nuclear shaping. Since protamines are required in mice for production of fertile sperm, this raises the possibility that Mst77F acts in parallel with protamines to promote chromatin condensation and male fertility in Drosophila.

Despite progress in identifying factors involved in nuclear shaping and chromatin reorganization, the relationship of these two processes with each other and with other aspects of spermatid morphogenesis is not well understood. For example, the physical mechanism that links dense body MTs with the outer nuclear membrane and with the chromatin is unclear, although the SUN domain protein Spag4 is a candidate to link chromatin to the inner nuclear membrane. Several other processes may also be coordinated with nuclear shaping and chromatin condensation. First, a burst of post-meiotic transcription occurs midway through nuclear shaping and spermatid elongation. Whether chromatin condensation is required for post-meiotic transcription, and whether the dense body participates in nuclear export of the resulting mRNAs is unknown. Second, incorporation of the specialized telomeric protein K81 into Drosophila sperm chromatin is essential for the chromosomes to participate in embryonic divisions and for inheritance of paternal DNA. (For a review, see ref. 126.) How K81 binding to telomeres is...
coordinated with protamine incorporation remains unclear. Third, maturation of the acroblast and acrosome and formation of the actin-based investment cones involved in individualization occur in the region of the perinuclear MTs, but the role of the MTs and the dense body in these processes is poorly understood.

**Acroblast and Acrosome Formation**

The acroblast, first described by Tates,\(^3\) is composed of stacked Golgi cisternae adjacent to the spermatid nucleus (Fig. 1A, B and D). The acroblast forms in onset stage spermatids by coalescence and fusion of Golgi-derived membranes. Several Golgi and endosomal trafficking regulators with roles in spermatocyte cytokinesis are required for acroblast formation. These include Four way stop (Fws), the Drosophila homolog of the conserved oligomeric Golgi (COG) tethering complex subunit Cog5;\(^127\) Giotto (Gio), the Drosophila phosphatidylinositol transfer protein;\(^128\) the recycling endosome regulator Rab11;\(^129\) and Brunelleschi (Bru), the Drosophila homolog of the transport protein particle II (TRAPPII) complex subunit Trs120.\(^130\) Similarly, in mice, the Golgi-associated protein GOPC is required for acroblast formation.\(^131\) Little is known of the signals that promote acroblast formation, nor why the acroblast—unlike most Golgi bodies in Drosophila, which occur as paired individual stacks—resembles a Golgi ribbon (reviewed in ref. 132).

The role of the acroblast in secretory trafficking was initially suggested by the presence of glycosylation epitopes recognized by the lectin wheat germ agglutinin (WGA).\(^133\) The acroblast resembles the Golgi at a molecular level, as demonstrated by the presence of the Golgins Lava lamp (Lva) and GCC88, the Golgi matrix protein GM130, the glycosylation enzyme Golgi α-mannosidase II (GMII),\(^127,134\) and Golgi phosphoprotein-3 (Golph3) (Fig. 2H; L.F. and J.A.B., unpublished observations). Many of the proteins needed for acroblast formation, such as Fws, Rab11 and Bru and the Rab11 effector Nuclear fallout (Nuf), also localize at the acroblast.\(^127,130,134\) as do coatomer (COP I) and the clathrin adaptors GGA and AP-1, which were recently shown to localize to this organelle.\(^134,135\) Hence, these proteins may regulate trafficking within the acroblast itself. However, the roles of these proteins within the acroblast have been difficult to examine because of the organelle's small size. Moreover, the mechanism by which the condensed acrosomal granule, or acrosome, emerges from the acroblast is as yet unclear.

As in most metazoans, the acrosome (Fig. 1B and D) is critical for fertilization in Drosophila. Indeed, the acrosomal protein Sneaky (Snky), a polytopic transmembrane protein, is required for sperm plasma membrane breakdown during fertilization.\(^136\) Similarly, the Drosophila ferlin Misfire (Mfr) is required for sperm plasma membrane breakdown,\(^137\) but is dispensable for acrosome and acroblast assembly.\(^138\) In mammals, the acrosome is an acidified lysosome-related secretory organelle. It is not yet known whether the acrosome is acidified in flies, but the lysosomal marker GFP-Lamp localizes to the mature acrosome (Fig. 2I; L.F. and J.A.B., unpublished observations). Moreover, it is unclear whether the contents of the Drosophila acrosome are secreted. Upon fertilization, Snky-GFP and a secreted GFP remain within the acrosome.\(^136\) However, it is possible that hemifusion or formation of a small fusion pore between the acrosome and plasma membrane induces plasma membrane breakdown. It will be interesting to determine whether Mfr localizes to the acrosome, and whether Mfr and Snky directly participate in membrane fusion.

**Cyst Polarization**

Cysts of 64 early round haploid spermatids initially appear unpolared. However, by early stages of elongation, ring canals are observed to cluster along actin-rich cortical membranes at the distal (growing) ends of the elongating spermatids.\(^30\) Real-time imaging of elongating spermatids cultured in vitro demonstrates that spermatid polarization is determined at the earliest stages of elongation and requires normal levels of the plasma membrane PtdIns(4,5)P\(_2\).\(^32\)

Polarization of spermatid cysts requires the PIP 5-kinase Skittles (Sktl); Funnel cakes (Fun; also called Sec8), a subunit of the octameric exocyst complex involved in targeted membrane delivery;\(^32\) and Merlin (Mer), the Drosophila homolog of Neurofibromatosis-2.\(^139\) Mutations in sktl, fun and mer result in elongated spermatid cysts that are bipolar, with spermatid nuclei found at both ends and spermatids growing toward the middle, suggesting that these genes play a primary role in establishment of cyst polarity. Other mutants that show occasional defects in axoneme orientation include Yuri and Parkin,\(^41,78\) raising the possibility that basal body docking and mitochondrial morphogenesis influence spermatid polarization. In addition, a number of male-sterile mutants that are defective in elongation form non-polarized cysts. However, this is likely an indirect consequence of the failure in membrane addition.

Spermatid cyst polarization is germ cell intrinsic in that elongating spermatids can polarize in the absence of accompanying somatic cyst cells.\(^16,32\) However, the upstream signals that establish spermatid cyst polarity are currently unclear. One possibility is that this signal depends on activation of Rho family GTPases, which regulate cell polarity in multiple systems. In addition, PtdIns(4,5)P\(_2\) synthesis at the growing end may act in a positive feedback loop to maintain a high local concentration of Sktl and the exoyct, thereby reinforcing polarized growth during elongation.\(^32\)

**Membrane Outgrowth**

During elongation, Drosophila spermatids increase 150-fold in length, and the total surface area following individualization is estimated to be 5-fold greater than in early round spermatids.\(^5\) Hence, it is not surprising that secretory trafficking is critical for spermatid cyst elongation. Indeed, the most dramatic defects in cyst elongation are generally observed in mutants that also affect membrane trafficking during male meiotic cytokinesis. For example, mutations affecting the Golgi SNARE Syntaxin-5 (Syx5), the Cog5 homolog Fws, and the exocyst subunits Sec8 and Exo84 have defects in both cytokinesis and spermatid elongation.\(^32,127,140,141\) In addition, mutations affecting peroxisome
biogenesis, and therefore degradation of very long chain fatty acids (VLCFAs), also fail cytokinesis and elongation, indicating that membrane lipid composition is critical for plasma membrane growth. Proper levels of PtdIns(4,5)P_2 are important for elongation, as expression of high levels of a PtdIns(4,5)P_2 phosphatase blocks elongation, whereas expression of lower levels of the phosphatase or mutation of the PIP_5-kinase Sktl causes milder elongation defects.132,70

Other membrane trafficking mutants have more subtle defects. For example, mutations in *fwd*, which encodes Drosophila phosphatidylinositol 4-kinase IIIβ (Pf4KIIIβ) cause mild defects in elongation.130,143 These defects are dramatically enhanced when *fwd* is mutated in combination with the TRAPPII subunit bru,130 indicating that these genes act redundantly to promote cyst elongation. Partial loss-of-function mutations affecting the clathrin uncoating factor Auxilin result in defects in membrane deposition due to failure to form Golgi-derived clathrin-coated vesicles.144 However, elongation is only mildly affected, suggesting that other pathways can act redundantly with clathrin-mediated trafficking to promote plasma membrane expansion.

In addition to trafficking, other factors also promote spermatic cyst elongation. These include cytoplasmic MTs and mitochondria (see above), as well as cytoskeletal regulators, such as RacGAP84C (also called RotundRacGAP), a negative regulator of the Rho family GTPases Rac and Cdc42.145,146 Loss of RacGAP84C leads to formation of short cysts with bulbous ends that lack plasma membrane between the spermatids and contain elongated, disorganized flagella.145 Similarly, loss of Drosophila dynein light chain-1 (Ddlc1) results in defects in maintenance of the spectrin-rich elongation complex at the growing end, and results in abnormal coiling of sperm tails and defects in membrane deposition that are enhanced by loss of one copy of cytoplasmic dynein heavy chain (Dhc) or dynactin (Glued).147 The similarity of these mutant phenotypes suggests that regulation of Rho family GTPase signaling and dynein-dependent vesicular trafficking are required to coordinate flagellar outgrowth with plasma membrane deposition during spermatid cyst elongation.

**Plasma Membrane Domains**

One crucial aspect of spermiogenesis is proper localization of signaling proteins involved in fertility. In Drosophila, these proteins primarily localize to two specialized plasma membrane domains: the proximal region overlying the acrosome and the distal (caudal) region at the tip of the sperm tail. These regions stain with fluorescent lectins that bind distinct sugar residues. Several lectins bind strongly to both the acrosomal and tail regions [e.g., concanavalin A (ConA)], whereas others bind either the acrosomal region [Dolichos biflorus agglutinin (DBA)] or the end piece of the tail ([e.g., wheat germ agglutinin (WGA)]). A lower level of lectin staining is present along the entire length of the sperm tail, but is absent from the plasma membrane overlying the sperm nucleus.

Among the sperm plasma membrane proteins stained by fluorescent lectins are several glycosidases: α-mannosidase, two β-hexosaminidase isoforms and α-L-fucosidase.149-152 These enzymes are concentrated in the acrosomal region as well as along the sperm tail. Staining with fluorescent markers reveals the presence of complementary sugar residues on the egg micropyle that may be critical for sperm binding and fertilization.148,151 Glycosylation is critical for sperm-egg interactions, as indicated by studies of the male sterile *casanova* mutant, which produces mature, motile sperm that are transferred to the female reproductive tract but are unable to fertilize eggs.153 *casanova* mutant sperm exhibit normal levels of a-mannosidase activity, but only half the β-hexosaminidase activity found in normal sperm. In addition, β-hexosaminidase is absent from the plasma membrane overlying the acrosome. This type of sperm-egg interaction appears broadly conserved, as glycoprotein recognition is also critical for gamete binding interactions in mammals (reviewed in refs. 154, 155).

Another protein that localizes to a specialized membrane domain during spermiogenesis is the polycystic kidney disease protein polycystin 2 (Pkd2), the Drosophila homolog of the transient receptor potential channel TRPP2 [also called Almost there (Amo)], which is dispensable for sperm development, but required for proper sperm storage in the female reproductive tract.156,157 Pkd2 localizes to the ER in primary spermatocytes but localizes to the tail end piece in mature sperm.157,158 A version of Pkd2 that carries a mutation found in autosomal dominant polycystic kidney disease results in Pkd2 retention in the ER, thereby blocking tail tip localization and resulting in sperm failing to reach the storage organ in the female genital tract.158

It will be of interest to learn where exactly Pkd2 localizes at the tip of the tail and whether its trafficking from the ER to the plasma membrane occurs during early or late stages of spermiogenesis. One possibility, based on the localization of mammalian Pkd2, is that Drosophila Pkd2 will be found to localize to the ciliary membrane that overlies the growing end of the flagellar axoneme.11,31,32 Not much is known about the mechanism of formation of this specialized membrane domain. However, it is thought to originate with endocytosis of the short axonemes that are formed in mature primary spermatocytes (see above). Following axoneme initiation, the centrioles are taken up into the cell, together with a cap of membrane. This membrane remains contiguous with the plasma membrane and covers the last ~4 μm at the growing end of the flagellar axoneme during spermatid elongation.11,31,32 Nothing is known of the protein composition of the ciliary membrane in Drosophila spermatids. However, Unc and Cby localize to the region of the ring centriole,69-71 which anchors the proximal portion of the ciliary membrane to the elongating axoneme. The membrane itself, which is located near the ring canals, can be visualized with YFP-Sktl (Fig. 2G) or a fluorescent PtdIns(4,5)P_2 reporter (PLC8-PH-GFP).32

**Individualization and Coiling**

The last steps in Drosophila spermiogenesis are the individualization (Fig. 1C) and coiling of mature sperm. Individualization proceeds via formation of the individualization complex (IC), which consists of 64 investment cones rich in filamentous actin. These initially form around the mature needle-shaped nuclei.
and then translocate down the length of the elongated spermatids, stripping away material unneeded in mature sperm.\textsuperscript{5,159} Translocation of the IC results in formation of a cystic bulge containing organelles, membranes and cytoplasm to be discarded in the waste bag at the end of individualization. Following individualization, the sperm undergo a process of coiling in which the 64 sperm tails wind around each other and retract into the base of the testis. The mature sperm are then released into the testis and transferred to the seminal vesicle, where they are stored until copulation.

Three cytoskeletal motor proteins are known to regulate individualization. Formation of investment cones requires myosin V, an unconventional myosin that localizes to the acrosome in late stages of spermiogenesis.\textsuperscript{160} Investment cone formation also requires Ddcl1, which localizes near the acrosome prior to cone formation and then to the cones once they are formed.\textsuperscript{161} Ddcl1 is needed for tight bundling of the elongated nuclei and proper investment cone organization. IC translocation requires myosin VI, another unconventional myosin that localizes to the leading edge of the cones.\textsuperscript{162} Surprisingly, myosin VI dimerization and processivity are not required for individualization, suggesting its motor activity is dispensable for IC movement.\textsuperscript{163,164} Instead, myosin VI appears to stabilize the investment cones as they progress.\textsuperscript{165}

The cones contain both unbranched (at the trailing end) and branched (at the leading edge) actin filaments and require regulators of actin polymerization for their formation.\textsuperscript{165} Actin turns over throughout the cones, and the rate of turnover is faster in moving cones than in those that have not yet initiated movement.\textsuperscript{15} Moreover, actin turnover appears important for movement, as actin but not MT inhibitors block IC progression. Actin bundling proteins (singed/fascin and quail/villin) colocalize with the unbranched filaments, whereas Arp2/3, Wasp, cortactin and bundling proteins (singed/fascin and quail/villin) colocalize with the branched actin filaments.\textsuperscript{166} Profilin, which regulates formin-dependent unbranched actin polymerization or stability, is initially highest at the nuclear end.\textsuperscript{175} As individualization proceeds, the highest levels of activated caspases are found associated with the cystic bulge and activated caspases are removed from the individualized portions of the maturing sperm.

Local activation of caspases near the nuclei and in the cystic bulge is achieved through the action of two different ubiquitin ligase complexes that are thought to target dBruce. The testis-specific Klhl10-Cul3 complex binds dBruce and is needed for caspase activation and IC formation.\textsuperscript{176} Ubiquitination of dBruce by the Cul3 complex results in redistribution to form a gradient with the highest concentration of dBruce at the elongating end of the spermatid cyst. The activity of the Cul3 complex is regulated by the E3 ubiquitin ligase inhibitor Scotti (Soti).\textsuperscript{175} Soti is transcribed postmeiotically and its mRNA localizes to the distal end of elongating spermatid cysts.\textsuperscript{33} Soti mRNA translation results in a gradient of Soti protein, with the highest concentration at the caudal end, similar to the gradient of dBruce.\textsuperscript{175} Soti competes with dBruce for binding Klhl10, thereby allowing caspase activation in proximity to the developing actin cones. Within the cystic bulge, dBruce is regulated by a SCF ubiquitin ligase complex (SkpA-Cul1-Ntc), which also binds dBruce and promotes caspase activation.\textsuperscript{177} Since the SCF complex localizes to the cystic bulge, it may trigger dBruce degradation and caspase activation as the IC moves down the individualizing cyst.

Despite steady progress in identifying factors involved in individualization, the signals involved in initiation of the process remain unclear. For example, it is unknown how actin cone assembly is stimulated at the nuclear end of the cyst in response to completion of elongation at the distal end. It seems likely that a signal that initiates at the caudal end is transmitted to the nuclear end. Moreover, the signal is germ cell autonomous, rather than originating in the surrounding somatic cyst cells, as individualization and proceed in the absence of cyst cells in vitro.\textsuperscript{15} Nonetheless, the nature of the initiating signal is unclear. It could
be that calcium is involved, since several of the postmeiotically transcribed mRNAs that localize to the growing end of the sperm tails encode predicted calcium-binding proteins.185 Alternatively, mitochondrial cytochrome-c (Cyt-c-d) activity may provide the necessary signal, as Cyt-c-d is required for caspase activation and initiation of IC movement.178 Another possibility is that the signal involves polyglycylation of axonemal MTs, a process in which Ntl might be involved.110

Conclusions and Future Outlook

The production of mature, fertile Drosophila sperm requires coordination of an array of morphogenetic processes affecting every organelle in the cell. Mitochondria fuse, unfurl, elongate, fill with crystalline material and degrade their DNA. Basal bodies migrate, dock at the nuclear envelope, form centriolar adjuncts and nucleate axoneme elongation. Axonemes assemble, acquire posttranslational modifications and become motile. Nuclei associate with dense bodies, elongate and condense their chromatin. Membrane trafficking becomes directed toward the acroblast and acrosome formation, as well as elongation of the spermatid cysts. The cysts acquire intrinsic polarity and specialized membrane domains overlying the acrosome and sperm tail tip. The mature sperm individualize and coil prior to transfer and storage in the seminal vesicle.

Beyond these morphological changes, mature sperm require specific signaling molecules, receptors and chromatin factors that are acquired during spermiogenesis and needed for fertilization and embryogenesis. The Pkd2 calcium channel localizes to the distal end of the sperm tail, where it promotes sperm storage in the female reproductive tract. Glycerolides present on the plasma membrane overlying the acrosome participate in sperm-egg recognition during fertilization. The acrosomal membrane protein Snky signals sperm plasma membrane breakdown upon entry into the oocyte. The presence of the K81 at telomeres provides protection of sperm chromat in and allows the paternal genome to participate in embryogenesis.

Drosophila sperm development has many parallels to spermiogenesis in other organisms, including mammals. During differentiation, mammalian spermatids develop in syncytial cysts and form specialized mitochondrial structures, perinuclear MT arrays, flagellar axonemes acrosomes and plasma membrane domains (reviewed in refs. 155, 179–184). Mammalian spermatid nuclei undergo shaping and chromatin condensation (reviewed in refs. 185 and 186). Removal of excess cytoplasm and individualization also occurs during mammalian spermatid terminal differentiation, and the removed residual bodies (the mammalian equivalent of waste bags) also display characteristics of apoptotic bodies.187 Moreover, mammalian sperm acquire signaling molecules and motility prior to participating in fertilization (reviewed in ref. 188). Hence, the molecular and cellular mechanisms uncovered by the study of Drosophila spermiogenesis will enhance our understanding of similar processes crucial to human male fertility and initiation of embryonic development.

Acknowledgments
