(Dated: 1 November 2011)

We use optical transient-grating spectroscopy to measure spin diffusion of optically oriented electrons in bulk, semi-insulating GaAs(100). Trapping and recombination do not quickly deplete the photoexcited population. The spin diffusion coefficient of $88 \pm 12 \text{cm}^2/\text{s}$ is roughly constant at temperatures from 15 K to 150 K, and the spin diffusion length is at least 450 nm. We show that it is possible to use spin diffusion to estimate the electron diffusion coefficient. Due to electron-electron interactions, the electron diffusion is 1.4 times larger than the spin diffusion.

Keywords: Spin diffusion; Semi-insulating GaAs; Transient grating

The burgeoning field of semiconductor spintronics relies on moving spin-polarized electrons through distances comparable to the dimensions of an electronic device. The importance of spin transport has led to several studies of spin diffusion in GaAs quantum wells. Spin transport in quantum wells can differ markedly from the bulk material, due to to different scattering rates and especially to the different spin-orbit coupling. Nonetheless, there have been relatively few measurements of spin diffusion in bulk GaAs. In n-doped samples with $n = 1 \times 10^{10}$ and $2 \times 10^{10} \text{cm}^{-3}$, the spin diffusion coefficient $D_s$ ranged from 10 to 200 cm$^2$/s.

Spin diffusion in semi-insulating GaAs (SI-GaAs) has not been reported. SI-GaAs has been proposed as a platform for nuclear spintronics due to its low carrier density. Moreover, Kikkawa et al. showed that electrons could be optically oriented in SI-GaAs and would subsequently diffuse into an adjacent ZnSe film, maintaining their spin polarization. Since SI-GaAs is a ubiquitous substrate material for thin film growth and for spintronic devices, such spin diffusion is of practical consequence, whether intentional or not. In this work, we find that SI-GaAs has a large, temperature-independent spin diffusion coefficient.

We measured spin diffusion with an ultrafast transient spin grating, which measures the decay rate $\gamma_s$ of a spin-density wave (the “grating”) with wavelength $\Lambda$ and wavevector $q = 2\pi/\Lambda$. The grating amplitude decays—through spin relaxation, electron-hole recombination, and diffusion—at a rate of

$$\gamma_s(q) = D_s q^2 + 1/\tau_0.$$ 

Here, $D_s$ is the spin diffusion coefficient, and $\tau_0$ is the lifetime for trapping, recombination, and spin relaxation. Measurement at several $q$ determines $D_s$. We measure in a reflection geometry, and improve the detection efficiency by heterodyne detection. Noise is further suppressed by 95 Hz modulation of the grating phase and lock-in detection.

The SI-GaAs sample was grown by Wafer Technology. It was undoped, oriented (100), had room temperature resistivity $\rho \geq 10^7 \Omega\cdot\text{cm}$ and Hall mobility $\mu_H \geq 5000 \text{cm}^2/\text{V}\cdot\text{s}$.

The pump and probe pulses came from a mode-locked Ti:Sapphire laser with wavelength near 800 nm and repetition rate of 80 MHz. The two pump pulses were focused to a spot of 65 μm diameter with total fluence 3.0 μJ/cm$^2$ except as indicated; probe pulses were always a factor of 2.5 weaker. Assuming one photoexcited electron per absorbed photon in a 1 μm absorption length, we photoexcite $\sim 8.5 \times 10^{10} \text{cm}^{-3}$ carriers, greater than the typical concentration of deep traps in SI-GaAs. In this way we are able to measure motion of free carriers at times longer than the trapping time, and to use the density of photoexcited electrons as an estimate of the free-carrier density.

Figure 1 shows typical results of spin-grating measurements. After dropping rapidly for 0.5 ps, the diffracted signal—and the spin grating amplitude—decays exponentially at rate $\gamma_s$. Higher-$q$ gratings decay more quickly, as expected for diffusive motion. The solid lines show fits of the data to the form $A + B \exp[-\gamma_s(q)t]$. The size of the constant offset $A$ averages 2.5% of the exponential decay (and never exceeds 7%), so it does not significantly influence the values of $\gamma_s$. We speculate that the offset may arise from a small fraction of localized carriers.

We determined spin diffusion coefficients by fitting $\gamma_s(q)$ to Eq. 1, as shown in Fig. 2a. The measured...
$D_e$ represents electron spin diffusion with no appreciable contribution from the holes. The near-bandgap absorption of circularly polarized light by GaAs excites spin-polarized electrons and holes, but the hole spins rapidly randomize, leaving behind spin-aligned electrons. By fitting to times after the rapid initial decay, we obtain $\gamma_s$ for electrons only. Moreover, the photoexcited electron and hole populations are spatially uniform, so the electrons’ motion is not hindered by electron-hole Coulomb attraction, and spin diffusion may occur more quickly than ambipolar diffusion. Uniform excitation also precludes any photorefractive grating.

The 15 K data in Figs. 1 and 2 were all taken with pump fluence of 3.0 $\mu$J/cm$^2$. The signal size decreases at higher temperatures, so data were taken with fluences of up to 9.0 $\mu$J/cm$^2$. We found that fluence had a small effect on grating decay rate: as compared to 3.0 $\mu$J/cm$^2$, decay rates measured at 6.0 to 9.0 $\mu$J/cm$^2$ were typically slower by 5-20%, while attenuating to 1.5 $\mu$J/cm$^2$ did not change $\gamma_s$ at all. The origin of this fluence-dependent grating decay is a topic of further research. However, the measured changes in $\gamma_s$ are sufficiently small that they do not add much uncertainty to the measured $D_s$.

Fig. 2a shows the values of $D_s$ at several temperatures as determined from the fits to Eq. 1. The spin diffusion is roughly constant in temperature, and it is fast—comparable to that previously seen at low temperature in a quantum well with $\mu = 69000$ cm$^2$/V-s. This supports our conclusion that most photoexcited electrons remain mobile for times of at least $\tau_0$. (The values of $\tau_0$ were 60, 100, 28, and 23 ps at 15, 80, 110, and 150 K, respectively.) Noting that the spin lifetime $\tau_s \geq \tau_0$, the spin diffusion length $L_s = \sqrt{D_s \tau_s}$ is at least 450 nm.

This length, comparable to the optical absorption length, suggests the possibility of efficient spin injection from SI-GaAs into thin epilayers.

Finally, we infer electron diffusion from the measured spin diffusion. One must consider spin Coulomb drag, the effect of electron-electron collisions that transfer momentum between counter-diffusing spin-up and spin-down populations. This effect has been observed to suppress spin diffusion, relative to electron diffusion, by factors up to 8 in high-mobility quantum wells. The electron diffusion is

$$D_e = \frac{D_s}{\chi_0/\chi_s - \chi_0 e^2 \rho_{\uparrow\downarrow} D_s}. \tag{2}$$

Here $\chi_s$ is the spin susceptibility, $\chi_0 = \partial n/\partial \mu$ is the electronic susceptibility, and $\rho_{\uparrow\downarrow}$ is the spin transresistivity. Our inferred value of $D_e$ thus should be regarded as an estimate, since it depends—through $\chi_s$, $\chi_0$ and $\rho_{\uparrow\downarrow}$—on the density $n$ and heating $\Delta T$ of the photoexcited electrons, which are known only approximately.

We estimate $\rho_{\uparrow\downarrow}(T)$ from Fig. 1 of Ref. 14 and calculate $\chi_0(T)$ numerically for a noninteracting electron gas of density $n = 8.5 \times 10^{16}$ cm$^{-3}$ assuming spherical, parabolic bands. We use the Perdew-Wang parametrization for the exchange-correlation energy to obtain $\chi_0/\chi_s \approx 0.82$. Eq. 2 gives values of $D_e$ ranging from 110 to 140 cm$^2$/s. $D_e$ is consistently about 40% higher than $D_s$, showing the importance of electron-electron interactions even in this high-resistivity material.
As a check on $D_e$, we convert diffusion to mobility using the Einstein relation, $\mu_e = e \chi_0 D_e / n$. We find that $\mu_e$ increases from 7500 cm$^2$/V-s at the highest measured temperature to 13000 cm$^2$/V-s at the lowest. We are not aware of any measurement of electron mobility in SI-GaAs at low temperature. However, our mobility agrees reasonably with that of undoped n-GaAs at low temperature, while the room-temperature mobilities of SI-GaAs and of undoped n-GaAs are comparable. This rough agreement shows that transient spin gratings can complement transport in measuring $D_e$. The technique might be particularly useful in ferromagnets with a large anomalous Hall effect.

Our observation of roughly temperature-independent spin diffusion contrasts with the apparent strong temperature dependence in n-doped GaAs: a sample with $n = 2 \times 10^{16}$ cm$^{-3}$ had $D_s = 10$ cm$^2$/s at 4 K (Ref. 3), while one with $n = 1 \times 10^{16}$ cm$^{-3}$ had $D_s = 200$ cm$^2$/s at room temperature. In the absence of electron-electron interactions, the spin diffusion would equal the charge diffusion, $n \mu_e / e \chi_0$. Lowering temperature decreases $n / \chi_0$, but generally increases the mobility, two effects that partly cancel. At low $T$, $n / \chi_0$ approaches a nonzero minimum value due to degeneracy. Since our photoexcited density exceeds the densities studied in n-doped samples, degeneracy sets in at a higher temperature. Thus for the same $\mu(T)$ we would expect diffusion to in our samples to equal that of n-doped samples at 150 K, while exceeding it by a factor of 4 at low temperature. Differing mobility among our semi-insulating sample and the two n-doped samples reported likely accounts for the remaining differences in $D_s$.

Semi-insulating GaAs is an important substrate for spintronic materials and structures, and may also be useful for nuclear spintronics. We have measured its electron spin diffusion coefficient, $D_s$, under conditions in which most photoexcited carriers are not trapped. This coefficient, which is difficult to learn from transport measurements, measures the motion of electron spins. $D_s$ has a high value of $\sim 88$ cm$^2$/s, independent of temperature.

Our result suggests that SI-GaAs could be useful for injecting spin into adjacent layers. It also holds a lesson for optical-orientation experiments in which a film is measured on top of a SI-GaAs substrate: unless a barrier-layer is grown, spins in the substrate will likely diffuse into the material being measured. Finally, we have shown that one can use spin diffusion to estimate electron diffusion, if one takes proper account of electron degeneracy (through $\chi_0$), and of electron-electron interactions through the spin susceptibility and spin Coulomb drag.

4In what follows we assume electronic heating of $\Delta T = 30$ K. We have checked that the value of $D_e$ depends only weakly (8%) on $\Delta T$ in the range 0 K $\leq \Delta T \leq 200$ K. Varying $n$ from $8.5 \times 10^{15}$ to $1.2 \times 10^{17}$ cm$^{-3}$ changes $D_e$ by no more than 7%. The inferred $\mu_e$, on the other hand, varies strongly with $n$ and roughly as $1/(T + \Delta T)$.
