Optimal Investment Under Transaction Costs: 
A Threshold Rebalanced Portfolio Approach

Sait Tunc and Suleyman S. Kozat, Senior Member, IEEE

Abstract

We study optimal investment in a financial market having a finite number of assets from a signal processing perspective. We investigate how an investor should distribute capital over these assets and when he should reallocate the distribution of the funds over these assets to maximize the cumulative wealth over any investment period. In particular, we introduce a portfolio selection algorithm that maximizes the expected cumulative wealth in i.i.d. two-asset discrete-time markets where the market levies proportional transaction costs in buying and selling stocks. We achieve this using “threshold rebalanced portfolios”, where trading occurs only if the portfolio breaches certain thresholds. Under the assumption that the relative price sequences have log-normal distribution from the Black-Scholes model, we evaluate the expected wealth under proportional transaction costs and find the threshold rebalanced portfolio that achieves the maximal expected cumulative wealth over any investment period. Our derivations can be readily extended to markets having more than two stocks, where these extensions are pointed out in the paper. As predicted from our derivations, we significantly improve the achieved wealth over portfolio selection algorithms from the literature on historical data sets.

I. INTRODUCTION

Recently financial applications attracted a growing interest from the signal processing community since the recent global crises demonstrated the importance of sound financial modeling and reliable data processing [1], [2]. Financial markets produce vast amount of temporal data ranging from stock prices to interest rates, which make them ideal mediums to apply signal processing methods. Furthermore, due to the integration of high performance, low-latency computing recourses and the financial data collection infrastructures, signal processing algorithms could be readily leveraged with full potential in financial stock markets. This paper particularly focuses on the portfolio selection problem, which is one the most important financial applications and has already attracted substantial interest from the signal processing community [3]–[7].

In particular, we study the investment problem in a financial market having a finite number of assets. We concentrate on how an investor should distribute capital over these assets and when he should reallocate the distribution of the funds over those assets in time to maximize the overall cumulative wealth. In financial terms, distributing ones capital over various assets is known as the portfolio management problem and reallocation of this distribution by buying and selling stocks is referred as the rebalancing of the given portfolio [8]. Due to obvious reasons, the portfolio management problem has been investigated in various different fields from financial engineering [9], machine learning to information theory [10], with a significant room for improvement as the recent financial crises demonstrated. To this end, we investigate the portfolio management problem in discrete-time markets when the market levies proportional transaction costs in trading while buying and selling stocks, which accurately models a wide range of real life markets [8], [9]. In discrete time markets, we have a finite number of assets and the reallocation of wealth (or rebalancing of the capital) over these assets is only allowed at discrete investment periods, where the investment period is arbitrary, e.g., each second, minute or each day [10], [11]. Under this framework, we introduce algorithms that achieve the maximal expected cumulative wealth under proportional transaction costs in i.i.d. discrete-time markets extensively studied in the financial literature [8], [9]. We further illustrate that our algorithms significantly improve the achieved wealth over the well-known algorithms in the literature on historical data sets under realistic transaction costs, as anticipated from our derivations. The precise problem description including the market and transaction cost models are provided in Section II.

Determination of the optimum portfolio and the best portfolio rebalancing strategy that maximize the wealth in discrete-time markets with no transaction fees is heavily investigated in information theory
machine learning [12]–[14] and signal processing [15]–[18] fields. Assuming that the portfolio rebalancings, i.e., adjustments by buying and selling stocks, require no transaction fees and with some further mild assumptions on the stock prices, the portfolio that achieves the maximum wealth is shown to be a constant rebalanced portfolio (CRP) [11], [19]. A CRP is a portfolio strategy where the distribution of funds over the stocks are reallocated to a predetermined structure, also known as the target portfolio, at the start of each investment period. CRPs constitute a subclass of a more general portfolio rebalancing class, the calendar rebalancing portfolios, where the portfolio vector is rebalanced to a target vector on a periodic basis [8]. Numerous studies are carried out to asymptotically achieve the performance of the best CRP tuned to the individual sequence of stock prices albeit either with different performance bounds or different performance results on historical data sets [11], [12], [14]. CRPs under transaction costs are further investigated in [20], where a sequential algorithm using a weighting similar to that introduced in [19], is also shown to be competitive under transaction costs, i.e., asymptotically achieving the performance of the best CRP under transaction costs. However, we emphasize that maintaining a CRP requires potentially significant trading due to possible rebalancings at each investment period [15]. As shown in [15], even the performance of the best CRP is severally affected by moderate transaction fees rendering CRPs ineffective in real life stock markets. Hence, it may not be enough to try to achieve the performance of the best CRP if the cost of rebalancing outweighs that which could be gained from rebalancing at every investment period. Clearly, one can potentially obtain significant gain in wealth by including unavoidable transactions fees in the market model and perform reallocation accordingly.

In these lines, the optimal portfolio selection problem under transactions costs is extensively investigated for continuous-time markets [21]–[24], where growth optimal policies that keep the portfolio in closed compact sets by trading only when the portfolio hits the compact set-boundaries are introduced. Naturally, the results for the continuous markets cannot be straightforwardly extended to the discrete-time markets, where continuous trading is not allowed. However, it has been shown in [25] that under certain mild assumptions on the sequence of stock prices, similar no trade zone portfolios achieve the optimal growth rate even for discrete-time markets under proportional transaction costs. For markets having two stocks, i.e., two-asset stock markets, these no trade zone portfolios correspond to threshold portfolios, i.e., the no trade zone is defined by thresholds around the target portfolio. As an example, for a market with two stocks, the portfolio is represented by a vector $b = [b_1 \ 1-b]^T$, $b \in [0, 1]$, assuming only long positions [8], where $b$ is the ratio of the capital invested in the first stock. For this market, the no rebalancing region around a target portfolio $b = [b_1 \ 1-b]^T$, $b \in [0, 1]$, is given by a threshold $\epsilon$, $\min\{b, 1-b\} \geq \epsilon \geq 0$, such that the corresponding portfolio at any investment period is rebalanced to a desired vector if the ratio of
the wealth in the first stock breaches the interval \((b - \epsilon, b + \epsilon)\). In particular, unlike a calendar rebalancing portfolio, e.g., a CRP, a threshold rebalanced portfolio (TRP) rebalances by buying and selling stocks only when the portfolio breaches the preset boundaries, or “thresholds”, and otherwise does not perform any rebalancing. Intuitively, by limiting the number of rebalancings due to this non rebalancing regions, threshold portfolios are able to avoid hefty transactions costs associated with excessive trading unlike calendar portfolios. Although TRPs are shown to be optimal in i.i.d. discrete-time two-asset markets (under certain technical conditions) [25], finding the TRP that maximizes the expected growth of wealth under proportional transaction costs is not solved, except for basic scenarios [25], to the best of our knowledge.

In this paper, we first evaluate the expected wealth achieved by a TRP over any finite investment period given any target portfolio and threshold for two-asset discrete-time stock markets subject to proportional transaction fees. We emphasize that we study two-asset market for notational simplicity and our derivations can be readily extended to markets having more than two assets as pointed out in the paper where needed. We consider i.i.d. discrete-time markets represented by the sequence of price relatives (defined as the ratio of the opening price to the closing price of stocks), where the sequence of price relatives follow log-normal distributions. Note that the log-normal distribution is the assumed statistical model for price relative vectors in the well-known Black-Scholes model [8], [9] and this distribution is shown to accurately model real life stock prices by many empirical studies [8]. Under this setup, we provide an iterative relation that efficiently and recursively calculates the expected wealth over any period in any i.i.d. discrete time market. This iterative relation is evaluated using a certain multivariate Gaussian integral for the log-normal distribution. We then provide a randomized algorithm to calculate the given integral and obtain the expected growth. This expected growth is then optimized by a brute force method to yield the optimal target portfolio and threshold to maximize the expected wealth over any investment period. Furthermore, we also provide a maximum-likelihood estimator to estimate the parameters of the log-normal distribution from the sequence of price relative vectors, which is incorporated into the algorithmic framework in Simulations section since these parameters are naturally unknown in real life markets.

Portfolio management problem is studied with transaction costs in [26] on the horse race setting, which is a special discrete-time market where only one of the asset pays off and the others pay nothing on each period. This basic framework is then extended to general stock markets in [25], where threshold portfolios are shown to be growth optimal for two-asset markets. However, no algorithm, except for a special sampled Brownian market, is provided to find the optimal target portfolio or threshold in [25]. To achieve the
performance of the best TRP, a sequential algorithm is introduced in [27] that is shown to asymptotically achieve the performance of the best TRP tuned to the underlying sequence of price relatives. This algorithm uses a similar weighting introduced in [19] to construct the universal portfolio. We emphasize that the universal investment strategies, e.g., [27], which are inspired by universal source coding ideas, based on Bayesian type weighting, are heavily utilized to construct sequential investment strategies [3], [5], [11], [13]–[18]. Although these methods are shown to “asymptotically” achieve the performance of the best portfolio in the competition class of portfolios, their non-asymptotic performance is acceptable only if a sufficient number of candidate algorithms in the competition class is overly successful [15] to circumvent the loss due to Bayesian type averaging. Since these algorithms are usually designed in a min-max (or universal) framework and hedge against (or should even work for) the worst case sequence, their average (or generic) performance may substantially suffer [12], [28], [29]. In our simulations, we show that our introduced algorithm readily outperforms a wide class of universal algorithms on the historical data sets, including [27]. Note that to reduce the negative effect of the transaction costs in discrete time markets, semiconstant rebalanced portfolio (SCRP) strategies have also been proposed and studied in [12], [15], [20]. Different than a CRP and similar to the TRPs, an SCRP rebalances the portfolio only at the determined periods instead of rebalancing at the start of each period. Since for an SCRP algorithm rebalancing occurs less frequently than a CRP, using an SCRP strategy may improve the performance over CRPs when transaction fees are present. However, no formulation exists to find the optimal rebalancing times for SCRP to maximize the cumulative wealth. Although there exist universal methods [13], [15] that achieve asymptotically the performance of the best SCRP tuned to the underlying sequence of price relatives, these methods suffer in realistic markets since they are tuned to the worst case scenario [15] as demonstrated in the Simulations section.

We begin with the detailed description of the market and the TRPs in Section II. We then calculate the expected wealth using a TRP in an i.i.d. two-asset discrete-time market under proportional transaction costs over any investment period in Section III. We first provide an iterative relation to recursively calculate the expected wealth growth. The terms in the iterative algorithm are calculated using a certain form of multivariate Gaussian integrals. We provide a randomized algorithm to calculate these integrals in Section III-C. The maximum-likelihood estimation of the parameters of the log-normal distribution is given in Section IV. The paper is then concluded with the simulations of the iterative relation and the optimization of the expected wealth growth with respect to the TRP parameters using the ML estimator in Section V.
II. Problem Description

In this paper, all vectors are column vectors and represented by lower-case bold letters. Consider a market with \( m \) stocks and let \( \{x(t)\}_{t \geq 1} \) represent the sequence of price relative vectors in this market, where \( x(t) = [x_1(t), x_2(t), \ldots, x_m(t)]^T \) with \( x_i(t) \in \mathbb{R}^+ \) for \( i \in \{1, 2, \ldots, m\} \) such that \( x_i(t) \) represents the ratio of the closing price of the \( i \)-th stock for the \( t \)-th trading period to that from the \( (t-1) \)-th trading period. At each investment period, say period \( t \), \( b(t) \) represents the vector of portfolios such that \( b_i(t) \) is the fraction of money invested on the \( i \)-th stock. We allow only long-trading such that \( \sum_{i=1}^{m} b_i(t) = 1 \) and \( b_i(t) \geq 0 \). After the price relative vector \( x(t) \) is revealed, we earn \( b^T(t)x(t) \) at the period \( t \). Assuming we started investing using 1 dollar, at the end of \( n \) periods, the wealth growth in a market with no transaction costs is given by

\[
S(n) = \prod_{t=1}^{n} b^T(t)x(t). \tag{1}
\]

If we use a CRP [10], then we earn \( \prod_{t=1}^{n} b^T x(t) \), at the end of \( n \) periods ignoring the transaction costs. This method is called “constant rebalancing” since at the start of each investment period \( t \), the portfolio vector \( b(t) = [b_1(t), b_2(t), \ldots, b_m(t)] \) is adjusted, or rebalanced, to a predetermined constant portfolio vector, say, \( b = [b_1, b_2, \ldots, b_m] \) where \( \sum_{i=1}^{m} b_i = 1 \). As an example, at the start of each investment period \( t \), since we invested using \( b \) at the investment period \( t-1 \) and observed \( x(t-1) \), the current portfolio vector, say \( b_{\text{old}}(t) \),

\[
b_{\text{old}}(t) \triangleq \left[ \frac{b_1 x_1(t-1)}{\sum_{i=1}^{m} b_i x_i(t-1)}, \ldots, \frac{b_m x_m(t-1)}{\sum_{i=1}^{m} b_i x_i(t-1)} \right]^T,
\]

should be adjusted back to \( b \). If we assume a symmetric proportional transaction cost with cost ratio \( c \), \( 0 \leq c \leq 1 \), for both selling and buying, then we need to spend approximately \( \sum_{i=1}^{m} b_i,\text{old}(t) S(t) |b_i,\text{old}(t) - b_i|c \) dollars for rebalancing. Note that if the transaction costs are not symmetric, the analysis follows by assuming \( c = c_{\text{sell}} + c_{\text{buy}} \) by [20], where \( c_{\text{sell}} \) and \( c_{\text{buy}} \) are the proportional transaction costs in selling and buying, respectively. Since a CRP should be rebalanced back to its initial value at the start of each investment period, a transaction fee proportional to the wealth growth up to the current period, i.e., \( S(t) \), is required for each period \( t \). Hence, constantly rebalancing at each time \( t \) may be unappealing for large \( c \).

To avoid such frequent rebalancing, we use TRPs, where we denote a TRP with a target vector \( b \) and a threshold \( \epsilon \) (with certain abuse of notation) as “TRP with \( (b, \epsilon) \)”. For a sequence of price relatives
Fig. 1: A sample scenario for threshold rebalanced portfolios.

Vectors $\mathbf{x}^n \triangleq [\mathbf{x}(1), \mathbf{x}(2), \ldots, \mathbf{x}(n)]$ with $\mathbf{x} \in \mathbb{R}_+^m$, a TRP with $(\mathbf{b}, \epsilon)$ rebalances the portfolio to $\mathbf{b}$ at the first time $\tau$ satisfying

$$\frac{b_j \prod_{t=1}^{\tau} x_j(t)}{\sum_{k=1}^m b_k \prod_{t=1}^t x_k(t)} \notin [b_j - \epsilon_j, b_j + \epsilon_j]$$

for any $j \in \{1, 2, \ldots, m\}$, thresholds $\epsilon_j$, and does not rebalance otherwise, i.e., while the portfolio vector stays in the no rebalancing region. Starting from the first period of a no rebalancing region, i.e., where the portfolio is rebalanced to the target portfolio $\mathbf{b}$, say $t = 1$ for this example, the wealth gained during any no rebalancing region is given by

$$W(\mathbf{x}^n | \mathbf{b}^n \in \mathcal{E}_{nc}^n) = \sum_{k=1}^m b_k \prod_{t=1}^n x_k(t),$$

where $\mathbf{b}^n = [\mathbf{b}(1), \mathbf{b}(2), \ldots, \mathbf{b}(n)]$ with $\mathbf{b}(t)$ is the portfolio at period $t$ and $\mathcal{E}_{nc}^n$ is the length $n$ no rebalancing region defined as

$$\mathcal{E}_{nc}^n = \{\mathbf{b}^n \mid \mathbf{b}(1) = \mathbf{b}, b_j(t) \in (b_j - \epsilon_j, b_j + \epsilon_j), j \in \{1, 2, \ldots, m\}, t \in \{1, 2, \ldots, n\}\}.$$

A TRP pays a transaction fee when the portfolio vector leaves the predefined no rebalancing region, i.e., goes out of the no rebalancing region $\mathcal{E}_{nc}^n$, and rebalanced back to its target portfolio vector $\mathbf{b}$. Since the TRP may avoid constant rebalancing, it may avoid excessive transaction fees while securing the portfolio to stay close the target portfolio $\mathbf{b}$, when we have heavy transaction costs in the market.
For notational clarity, in the remaining of the paper, we assume that the number of stocks in the market is equal to 2, i.e., \( m = 2 \). Note that our results can be readily extended to the case when \( m > 2 \). We point out the necessary modifications to extend our derivations to the case \( m > 2 \). Then, the threshold rebalanced portfolios are described as follows.

Given a TRP with target portfolio \( b = [b, 1 - b]^T \) with \( b \in [0, 1] \) and a threshold \( \epsilon \), the no rebalancing region of a TRP with \((b, \epsilon)\) is represented by \((b - \epsilon, b + \epsilon)\). Given a TRP with \((b - \epsilon, b + \epsilon)\), we only rebalance if the portfolio leaves this region, which can be found using only the first entry of the portfolio (since there are two stocks), i.e., if \( b_{1, \text{old}}(t) \notin (b - \epsilon, b + \epsilon) \). In this case, we rebalance \( b_{1, \text{old}}(t) \) to \( b \).

Fig. 1 represents a sample TRP in a discrete-time two-asset market and when the portfolio is rebalanced back to its initial value if it leaves the no rebalancing interval.

Before our derivations, we emphasize that the performance of a TRP is clearly effected by the threshold and the target portfolio. As an example, choosing a small threshold \( \epsilon \), i.e., a low threshold, may cause frequent rebalancing, hence one can expect to pay more transaction fees as a result. However, choosing a small \( \epsilon \) secures the TRP to stay close to the target portfolio \( b \). Choosing a larger threshold \( \epsilon \), i.e., a high threshold, avoids frequent rebalancing and degrades the excessive transaction fees. Nevertheless, the portfolio may drift to risky values that are distant from the target portfolio \( b \) under large threshold.

Furthermore, we emphasize that proportional transaction cost \( c \) is a key factor in determining the \( \epsilon \). Under mild stochastic assumptions it has been shown in [11], [19] that in a market with no transaction costs, CRPs achieve the maximum possible wealth. Therefore in a market with no transaction costs, i.e., \( c = 0 \), the maximum wealth can be achieved when we choose a zero threshold, i.e., \( \epsilon = 0 \) and a target portfolio \( b^* = \arg \max_b E[\log(bx_1 + (1 - b)x_2)] \), where \( x_1 \) and \( x_2 \) represent the price relatives of two-asset market [19]. On the other hand, in a market with high transaction costs, choosing a high threshold, i.e., a large \( \epsilon \), eliminates the unappealing effect of transaction costs. For instance, for the extreme case where the transaction cost is infinite, i.e., \( c = \infty \), the best TRP should either have \( \epsilon = 1 \) or \( b \in \{0, 1\} \) to ensure that no rebalancing occurs.

In this paper, we assume that the price relative vectors have a log-normal distribution following the well-known Black-Scholes model [8]. This distribution that is extensively used in financial literature is shown to accurately model empirical price relative vectors [30]. Hence, we assume that \( x(t) = [x_1(t), x_2(t)]^T \) has an i.i.d. log-normal distribution with mean \( \mu = [\mu_1, \mu_2] \) and standard deviation \( \sigma = [\sigma_1, \sigma_2] \), respectively, i.e., \( x(t) \sim \ln \mathcal{N}(\mu, \sigma^2) \). Here, we first optimize the wealth achieved by a TRP for the discrete-time market, where the distributions of the price relatives are known. We then provide a ML estimator for these parameters to cover the case where the means and variances are unknown. The ML
estimator is incorporated in the algorithmic framework in the Simulations section since the corresponding parameters are unknown in real life markets. The details of the maximum-likelihood estimation are given in Section IV.

III. THRESHOLD REBALANCED PORTFOLIOS

In this section, we analyze the TRPs in a discrete-time market with proportional transaction costs as defined in Section II. We first introduce an iterative relation, as a theorem, to recursively evaluate the expected achieved wealth of a TRP over any investment period. The terms in this iterative equation are calculated using a certain form of multivariate Gaussian integrals. We provide a randomized algorithm to calculate these integrals. We then use the given iterative equation to find the optimal $\epsilon$ and $b$ that maximize the expected wealth over any investment period.

A. An Iterative Relation to Calculate the Expected Wealth

In this section, we introduce an iterative equation to evaluate the expected cumulative wealth of a TRP with $(b - \epsilon, b + \epsilon)$ over any period $n$, i.e., $E[S(n)]$. As seen in Fig. 2 for a TRP with $(b - \epsilon, b + \epsilon)$, any investment scenario can be decomposed as the union of consecutive no-crossing blocks such that each rebalancing instant, to the initial $b$, signifies the end of a block. Hence, based on this observation, the expected gain of a TRP between any consecutive crossings, i.e., the gain during the no rebalancing regions, directly determines the overall expected wealth growth. Hence, we first calculate the conditional expected gain of a TRP over no crossing regions and then introduce the iterative relation based on these derivations.

For a TRP with $(b - \epsilon, b + \epsilon)$, we call a no rebalancing region of length $n$ as “period $n$ with no-crossing” such that the TRP with the initial and target portfolio $b = [b, 1 - b]$ stays in the $(b - \epsilon, b + \epsilon)$ interval for $n - 1$ consecutive investment periods and crosses one of the thresholds at the $n$th period. We next calculate the expected gain of a TRP over any no-crossing period as follows.

The wealth growth of a TRP with $(b - \epsilon, b + \epsilon)$ for a period $\tau$ with no-crossing can be written as

$$S_{nc}(\tau) \triangleq b \prod_{t=1}^{\tau} [x_1(t)] + (1 - b) \prod_{t=1}^{\tau} [x_2(t)],$$

(5)

without the transaction cost that arises at the last period. To find the total achieved wealth for a period $\tau$ with no-crossing, we need to subtract the transaction fees from (5). If portfolio $b_1(t)$ crosses the threshold

\footnote{This is the special case of (3) for $m = 2$.}
at the investment period \( t = \tau \), then we need to rebalance it back to \( b \), i.e., \( b_1(t) = b \) and pay

\[
S_{\text{nc}}(\tau)c \left| \frac{b \prod_{t=1}^{\tau} (x_1(t))}{b \prod_{t=1}^{\tau} (x_1(t)) + (1 - b) \prod_{t=1}^{\tau} (x_2(t))} - b \right|, \tag{6}
\]

where \( c \) represents the symmetrical commission cost, to rebalance two stocks, i.e., \( b_{1,\text{old}}(\tau + 1) \) to \( b \), and \( b_{2,\text{old}}(\tau + 1) = 1 - b_{1,\text{old}}(\tau + 1) \) to \( 1 - b \). Hence, the net overall gain for a period \( \tau \) with no-crossing becomes

\[
S(\tau) = S_{\text{nc}}(\tau) - S_{\text{nc}}(\tau)c \left| \frac{b \prod_{t=1}^{\tau} (x_1(t))}{b \prod_{t=1}^{\tau} (x_1(t)) + (1 - b) \prod_{t=1}^{\tau} (x_2(t))} - b \right| = b \prod_{t=1}^{\tau} [x_1(t)] + (1 - b) \prod_{t=1}^{\tau} [x_2(t)] - c(b - b^2) \prod_{t=1}^{\tau} [x_1(t)] - \prod_{t=1}^{\tau} [x_2(t)] = \zeta_1 \prod_{t=1}^{\tau} [x_1(t)] + \zeta_2 \prod_{t=1}^{\tau} [x_2(t)], \tag{7}
\]

where \( \zeta_1 \triangleq b - 2c(b - b^2) \) and \( \zeta_2 \triangleq 1 - b + 2c(b - b^2) \) for \( b + \epsilon \) hitting and \( \zeta_1 \triangleq b + 2c(b - b^2) \) and \( \zeta_2 \triangleq 1 - b - 2c(b - b^2) \) for \( b - \epsilon \) hitting. Thus, the conditional expected gain of a TRP conditioned on that the portfolio stays in a no rebalancing region until the last period of the region can be found by calculating the expected value of \( \zeta \). Since, we now have the conditional expected gains, we next introduce an iterative relation to find the expected wealth growth of a TRP with \( (b - \epsilon, b + \epsilon) \) for period \( n \), \( E[S(n)] \), by using the expected gains of no-crossing periods as shown in Fig. 2.

In order to calculate the expected wealth \( E[S(n)] \) iteratively, let us first define the variable \( R(\tau) \), which is the expected cumulative gain of all possible portfolios that hit any of the thresholds first time at the \( \tau \)th period, i.e.,

\[
R(\tau) = E \left[ S(\tau) \Big| b^\tau \in \mathcal{E}^{\text{fc}}_\tau \right], \tag{8}
\]

where \( \mathcal{E}^{\text{fc}}_\tau \) denotes the set of all possible portfolios with initial portfolio \( b \) and that stay in the no rebalancing region for \( \tau - 1 \) consecutive periods and hits one of the \( (b - \epsilon) \) or \( (b + \epsilon) \) boundary at the \( \tau \)th period, i.e.,

\[
\mathcal{E}^{\text{fc}}_\tau \triangleq \{ b^\tau \in \mathcal{B}(b, \epsilon) \mid b(1) = b, b(i) \in (b - \epsilon, b + \epsilon) \forall i \in \{2, \ldots, \tau - 1\}, b(\tau) \notin (b - \epsilon, b + \epsilon) \}. \tag{9}
\]

Here, \( \mathcal{B}(b, \epsilon) \) is defined as the set of all possible threshold rebalanced portfolios with initial and target portfolio \( b \) and a no rebalancing interval \( (b - \epsilon, b + \epsilon) \). Similarly we define the variable \( T(\tau) \), which is the expected growth of all possible portfolios of length \( \tau \) with no threshold crossings, i.e.,

\[
T(\tau) = E \left[ S(\tau) \Big| b^\tau \in \mathcal{E}^{\text{nc}}_\tau \right], \tag{10}
\]
where $E^{\text{nc}}_\tau$ denotes the set of portfolios with initial portfolio $b$ and that stay in the no rebalancing region for $\tau$ consecutive periods, i.e.,

$$E^{\text{nc}}_\tau \triangleq \{ b^\tau \in B_\tau(b, \epsilon) \mid b(1) = b, b(i) \in [b - \epsilon, b + \epsilon] \forall i \in \{2, \ldots, \tau\} \}. \quad (11)$$

Given the variables $R(\tau)$ and $T(\tau)$, we next introduce a theorem that iteratively calculates the expected wealth growth of a TRP over any period $n$. Hence, to calculate the expected achieved wealth, it is sufficient to calculate $R(\tau)$, $T(\tau)$, threshold crossing probabilities $P(b^n \in E^{fc}_n)$ and $P(b^n \in E^{nc}_n)$, which are explicitly evaluated in the next section.

**Theorem 3.1:** The expected wealth growth of a TRP $(b - \epsilon, b + \epsilon)$, i.e., $E[S(n)]$, over any i.i.d. sequence of price relative vectors $x^n = [x(1), x(2), \ldots, x(n)]$, satisfies

$$E[S(n)] = \sum_{i=1}^{n} P(E^{fc}_i)R(i)E[S(n-i)] + P(E^{nc}_n)T(n), \quad (12)$$

where we define $S_0 = 1$, $R(n)$ in (8), $T(n)$ in (10), $E^{fc}_i$ in (11) and $E^{nc}_n$ in (9).

\footnote{This is the special case of the definition in (4) for $m = 2$.}
We emphasize that by Theorem 3.1 we can recursively calculate the expected growth of any TRP over any i.i.d. discrete-time market under proportional transaction costs. Theorem 3.1 holds for i.i.d. markets having either \( m = 2 \) or \( m > 2 \) provided that the corresponding terms in (12) can be calculated.

**Proof:** By using the law of total expectation [31], \( E[S(n)] \) can be written as

\[
E[S(n)] = \int_{b^n \in \mathcal{B}_n(b, \epsilon)} E[S(n)|b^n]P(b^n)db^n,
\]

where \( \mathcal{B}_n(b, \epsilon) \) is defined as the set of all possible TRPs with the initial and target portfolio \( b \) and threshold \( \epsilon \). To obtain (12), we consider all possible portfolios as a union of \( n + 1 \) disjoint sets: (1) the portfolios which cross one of the thresholds first time at the 1st period; (2) the portfolios which cross one of the thresholds first time at the 2nd period; and continuing in this manner, (3) the portfolios which cross one of the thresholds first time at the \( n \)th period; and finally (4) the portfolios which do not cross the thresholds for \( n \) consecutive periods. Clearly these market portfolio sets are disjoint and their union provides all possible portfolio paths. Hence (13) can also be written as

\[
E[S(n)] = \sum_{i=1}^{n} \int_{b^n \in \mathcal{E}_{nc}^f} E[S(n)|b^n \in \mathcal{E}_{nc}^f]P(b^n \in \mathcal{E}_{nc}^f)db^n,
\]

where \( b^n_{i} \triangleq [b(i), b(i+1), \ldots, b(j)] \). To continue with our derivations, we define \( S_{i \rightarrow j} \) as the wealth growth from the period \( i \) to period \( j \), i.e., \( S_{i \rightarrow j} \triangleq \frac{S(j)}{S(i)} \). Assume that in the period \( \tau \), the portfolio crosses one of the thresholds and a rebalancing occurs. In that case, regardless of the portfolios before the period \( \tau \), the portfolio is rebalanced back to its initial value in the \( \tau \)th period, i.e., to \([b, 1 - b]^{T}\). Since the price relative vectors are independent over time, we can conclude that the portfolios before the period \( \tau \) are independent from the portfolios after the period \( \tau \), i.e., \( b(\tau) = b \) and every portfolio \( b(i) \) for \( i \in \{1, 2, \ldots, \tau - 1\} \) are independent from the portfolios \( b(j) \) for \( j \in \{\tau + 1, \tau + 2, \ldots, n\} \). Hence, the investment period where the portfolio path crosses one of the thresholds, i.e., \( \tau \), divides the whole investment block into uncorrelated blocks in terms of price relative vectors and portfolios. Thus, the wealth growth acquired up to the period \( \tau \), \( S_{1 \rightarrow \tau} \), is uncorrelated to the wealth growth acquired after that period, i.e., \( S_{\tau + 1 \rightarrow n} \). Hence, if we assume that a threshold crossing occurs at the period \( \tau \), then we have

\[
E[S(n)|b^n_{1} \in \mathcal{E}_{\tau}^f, b^n_{\tau + 1} \in \mathcal{B}_{n-\tau}(b, \epsilon)] = E[S_{1 \rightarrow \tau}S_{\tau + 1 \rightarrow n}|b^n_{1} \in \mathcal{E}_{\tau}^f, b^n_{\tau + 1} \in \mathcal{B}_{n-\tau}(b, \epsilon)]
\]

\[
= E[S_{1 \rightarrow \tau}|b^n_{1} \in \mathcal{E}_{\tau}^f] E[S_{\tau + 1 \rightarrow n}|b^n_{\tau + 1} \in \mathcal{B}_{n-\tau}(b, \epsilon)].
\]
We next write (17) as a recursive equation.

\[ E[S(n)] = \sum_{i=1}^{n} \int_{b_i \in E_i^f} E[S_{1\rightarrow i}|b_i^1 \in E_i^f] E[S_{i+1\rightarrow n}|b(i) = b_i, b_{i+1}^n \in B_{n-i}(b, \epsilon)] \cdot P(b_i^1 \in E_i^f) \times P(b_{i+1}^n \in B_{n-i}(b, \epsilon)) \, db_i^n + \int_{b^n \in E_n^nc} E[S(n)|b^n \in E_n^nc] \cdot P(b^n \in E_n^nc) \, db^n. \]  \tag{16}

Since the integral in (16) can be decomposed into two disjoint integrals, (14) yields

\[ E[S(n)] = \sum_{i=1}^{n} \int_{b_i^1 \in E_i^f} E[S_{1\rightarrow i}|b_i^1 \in E_i^f] P(b_i^1 \in E_i^f) \, db_i^1 \int_{b_{i+1}^n \in B_{n-i}(b, \epsilon)} E[S_{i+1\rightarrow n}|b(i) = b_i, b_{i+1}^n \in B_{n-i}(b, \epsilon)] \times P(b_{i+1}^n \in B_{n-i}(b, \epsilon)) \, db_{i+1}^n + \int_{b^n \in E_n^nc} E[S(n)|b^n \in E_n^nc] P(b^n \in E_n^nc) \, db^n. \]  \tag{17}

We next write (17) as a recursive equation.

To accomplish this, we first note that

(i) \( R(i) \) is defined as the expected gain of TRPs with length \( i \), which crosses one of the thresholds first time at the \( i \)-th period and it follows that

\[ R(i) = E[S(\tau) \mid b^i \in E_i^f] \]
\[ = \frac{1}{P(E_i^f)} \int_{b^i \in E_i^f} E[S_{1\rightarrow i}|b^i \in E_i^f] P(b^i \in E_i^f) \, db^i, \]  \tag{18} \tag{19}

where we write \( P(E_i^f) \) instead of \( P(b^i \in E_i^f) \).

(ii) Then, as the second term, \( T(n) \) is defined as the expected gain of TRPs of length \( n \), which does not cross one of the thresholds for \( n \) consecutive periods. This yields

\[ T(n) = E[S(n) \mid b^n \in E_n^nc] \]
\[ = \frac{1}{P(E_n^nc)} \int_{b^n \in E_n^nc} E[S(n)|b^n \in E_n^nc] P(b^n \in E_n^nc) \, db^n. \]  \tag{20} \tag{21}

(iii) Finally, observe that the second integral in (17) is the expected wealth growth of a TRP of length \( n-i \), i.e.,

\[ E[S(n-i)] = \int_{b_{i+1}^n \in B_{n-i}(b, \epsilon)} E[S_{i+1\rightarrow n}|b(i) = b_i, b_{i+1}^n \in B_{n-i}(b, \epsilon)] P(b_{i+1}^n \in B_{n-i}(b, \epsilon)) \, db_{i+1}^n, \]  \tag{22}

where \( P(b_{i+1}^n \in B_{n-i}(b, \epsilon)) = 1 \) by the definition of the set \( B_{n-i}(b, \epsilon) \).

Hence, if we apply (19), (21) and (22) to (17), we can write (12) as

\[ E[S(n)] = \sum_{i=1}^{n} P(E_i^f) R(i) E[S(n-i)] + P(E_n^nc) T(n), \]  \tag{23}

hence the proof concludes.
Theorem 3.1 provides a recursion to iteratively calculate the expected wealth growth \( E[S(n)] \), when \( R(\tau) \) and \( T(\tau) \) are explicitly calculated for a TRP with \((b-\epsilon, b+\epsilon)\). Hence, if we can obtain \( P(E^{fc}_\tau) R(\tau) \) and \( P(E^{nc}_\tau) T(\tau) \) for any \( \tau \), then (12) yields a simple iteration that provides the expected wealth growth for any period \( n \). We next give the explicit definitions of the events \( E^{fc}_\tau \) and \( E^{nc}_\tau \) in order to calculate the conditional expectations \( R(\tau) \) and \( T(\tau) \). Following these definitions, we calculate \( P(E^{fc}_\tau) R(\tau) \) and \( P(E^{nc}_\tau) T(\tau) \) to evaluate the expected wealth growth \( E[S(\tau)] \), iteratively from Theorem 3.1 and find the the optimal TRP, i.e., optimal \( b \) and \( \epsilon \), by using a brute force search.

In the next section, we provide the explicit definitions for \( E^{fc}_\tau \) and \( E^{nc}_\tau \), and define the conditions for staying in the no rebalancing region or hitting one of the boundaries to find the corresponding probabilities of these events.

### B. Explicit Calculations of \( R(n) \) and \( T(n) \)

In this section, we first define the conditions for the market portfolios to cross the corresponding thresholds and calculate the probabilities for the events \( E^{fc}_\tau \) and \( E^{nc}_\tau \). We then calculate the conditional expectations \( R(n) \) and \( T(n) \) as certain multivariate Gaussian integrals. The explicit calculation of multivariate Gaussian integrals are given in Section [III-C].

To get the explicit definitions of the events \( E^{fc}_\tau \) and \( E^{nc}_\tau \), we note that we have two different boundary hitting scenarios for a TRP, i.e., starting from the initial portfolio \( b \), the portfolio can hit \( b - \epsilon \) or \( b + \epsilon \). From \( b \), the portfolio crosses \( b - \epsilon \) boundary if

\[
\frac{b \prod_{t=1}^\tau (x_1(t))}{b \prod_{t=1}^\tau (x_1(t)) + (1-b) \prod_{t=1}^\tau (x_2(t))} \leq b - \epsilon,
\]

(24)

where \( \tau \) is the first time the crossing happens without ever hitting any of the boundaries before. Since \( x_1(i), x_2(i) > 0 \) for all \( i \), (24) happens if

\[
\prod_{t=1}^\tau \frac{x_2(t)}{x_1(t)} \geq \frac{b(1-b+\epsilon)}{(1-b)(b-\epsilon)},
\]

(25)

which is equivalent to

\[
\Pi_2(\tau) \geq \gamma_1 \Pi_1(\tau),
\]

where \( \Pi_1(i) \overset{\Delta}{=} \prod_{t=1}^i x_1(t), \Pi_2(i) \overset{\Delta}{=} \prod_{t=1}^i x_2(t) \) and \( \gamma_1 \overset{\Delta}{=} \frac{b(1-b+\epsilon)}{(1-b)(b-\epsilon)}. \) Since \( x(i)'s \) have log-normal distributions, i.e., \( x(t) \sim \ln N(\mu, \sigma^2) \), \( \Pi_1(i) \) and \( \Pi_2(i) \) are log-normal, too [31]. Furthermore, to calculate
the required probabilities, we have
\[
p(\Pi_1(i), \Pi_1(k-1), \Pi_1(k)) = p(\Pi_1(i), \Pi_1(k-1)) \cdot p(\Pi_1(k)|\Pi_1(k-1), \Pi_1(i))
\]
\[
= p(\Pi_1(i)) \cdot p(\Pi_1(k-1)|\Pi_1(i)) \cdot p(\Pi_1(k-1)x_1(k)|\Pi_1(k-1), \Pi_1(i))
\]
\[
= p(\Pi_1(i)) \cdot p(\Pi_1(k-1)|\Pi_1(i)) \cdot p(\Pi_1(k)|\Pi_1(k-1)), \quad (26)
\]
where \(\forall i \in \{0,1,\ldots,k-2\}\), where (26) follows since \(x(k)\) is independent of \(\Pi_1(i)\) for \(k > i\). Hence \(\Pi_1(i)\)'s form a Markov chain such that \(\Pi_1(i) \leftrightarrow \Pi_1(k-1) \leftrightarrow \Pi_1(k) \ \forall i \in \{0,1,\ldots,k-2\}\). Following the similar steps we also obtain that \(\Pi_2(i) \leftrightarrow \Pi_2(k-1) \leftrightarrow \Pi_2(k) \ \forall i \in \{0,1,\ldots,k-2\}\). We point out that by extending the definitions \(\Pi_1\) and \(\Pi_2\) one can obtain \(\Pi_1, \Pi_2, \ldots, \Pi_m\) for the case \(m > 2\). Furthermore, taking the logarithm of both sides of (25) we have
\[
\Sigma_1^\tau \triangleq \sum_{t=1}^\tau z(t) \geq \theta_1,
\]
where \(z(t) \triangleq \ln \left(\frac{x_2(t)}{x_1(t)}\right)\) and \(\theta_1 \triangleq \ln \frac{b(1-b+\epsilon)}{(1-b)(b-\epsilon)} = \ln \gamma_1\). The partial sums of \(z(t)\)'s are defined as \(\Sigma_k^i = \sum_{t=i}^k z(t)\) for notational simplicity. Since \(x(t) \sim \mathcal{N}(\mu, \sigma^2)\), \(z(t)\)'s are Gaussian, i.e., \(z(t) \sim \mathcal{N}(\mu, \sigma^2)\), where \(\mu = \mu_2 - \mu_1\) and \(\sigma^2 = \sigma_1^2 + \sigma_2^2\), their sums, \(\Sigma_k^i\)'s, are Gaussian too. Furthermore note that, \(\Sigma_1^k = \sum_{t=1}^k z(t) = \sum_{t=1}^k \ln \left(\frac{x_2(t)}{x_1(t)}\right) = \ln \left(\prod_{t=1}^k x_2(t) x_1(t)\right) = \ln \frac{\Pi_k^i}{\Pi_1^i}\).

Similarly with an initial value \(b\), market portfolio crosses \(b + \epsilon\) boundary if
\[
\frac{b \prod_{t=1}^\tau x_1(t)}{b \prod_{t=1}^\tau x_1(t) + (1-b) \prod_{t=1}^\tau x_2(t)} \geq b + \epsilon, \quad (27)
\]
where \(\tau\) is the first crossing time without ever hitting any of the boundaries before. Again, since \(x_1(i), x_2(i) > 0\) for all \(i\), (27) happens if
\[
\prod_{t=1}^\tau x_2(t) x_1(t) \leq \frac{b(1-b-\epsilon)}{(1-b)(b+\epsilon)}, \quad (28)
\]
which can be written of the form
\[
\Pi_2(t) \leq \gamma_2 \Pi_1(t).
\]
Equation (28) yields
\[
\Sigma_1^\tau = \sum_{t=1}^\tau z(t) \leq \theta_2,
\]
where \(\theta_2 \triangleq \ln \frac{b(1-b-\epsilon)}{(1-b)(b+\epsilon)} = \ln \gamma_2\).

Hence, we can explicitly describe the event that the market threshold portfolio \((b-\epsilon, b+\epsilon)\) does not hit any of the thresholds for \(\tau\) consecutive periods, \(E_{\tau}^{nc}\), as the intersection of the events as
\[
E_{\tau}^{nc} \triangleq \bigcap_{i=1}^\tau \{\Sigma_1^i \in [\theta_2, \theta_1]\} = \bigcap_{i=1}^\tau \{\gamma_2 \Pi_1(i) \leq \Pi_2(i) \leq \gamma_1 \Pi_1(i)\}. \quad (29)
\]
Similarly, the event of the market threshold portfolio \((b - \epsilon, b + \epsilon)\) hitting any of the thresholds first time at the \(\tau\)-th period, \(E^\tau_{\text{fc}}\), can be defined as the intersections of the events

\[
E^\tau_{\text{fc}} = \bigcap_{i=1}^{\tau-1} \{ \Sigma_i^i \in [\theta_2, \theta_1] \} \bigcap \left[ \{ \Sigma_\tau \in [-\infty, \theta_2] \} \bigcup \{ \Sigma_\tau \in (\theta_1, \infty) \} \right]
\]

\[
= \bigcap_{i=1}^{\tau-1} \{ \gamma_2 \Pi_1(i) \leq \Pi_2(i) \leq \gamma_1 \Pi_1(i) \} \bigcap \left[ \{ \Pi_2(\tau) \geq \gamma_1 \Pi_1(\tau) \} \bigcup \{ \Pi_2(\tau) \leq \gamma_2 \Pi_1(\tau) \} \right],
\]

yielding the explicit definitions of the events \(E^\tau_{\text{fc}}\) in (30) and \(E^\tau_{\text{nc}}\) in (29). The definitions of \(E^\tau_{\text{fc}}\) and \(E^\tau_{\text{nc}}\) can be readily extended for the case \(m > 2\) by using the updated definitions of \(\Pi_1, \Pi_2, \ldots, \Pi_m\).

Since we have the quantitative definitions of the events \(E^\tau_{\text{fc}}\) and \(E^\tau_{\text{nc}}\), we can express the expected overall gain of portfolios with no hitting over \(\tau\)-period, \(T(\tau)\), as

\[
T(\tau) = E \left[ S(\tau) \left| E^\tau_{\text{fc}} \right. \right]
\]

\[
= E \left[ b \prod_{t=1}^{\tau} [x_1(t)] + (1 - b) \prod_{t=1}^{\tau} [x_2(t)] \left| E^\tau_{\text{fc}} \right. \right]
\]

\[
= E \left[ b \Pi_1(\tau) + (1 - b) \Pi_2(\tau) \left| E^\tau_{\text{fc}} \right. \right],
\]

(31)

The expectation \(E \left[ b \Pi_1(\tau) + (1 - b) \Pi_2(\tau) \left| E^\tau_{\text{fc}} \right. \right]\) can be expressed in an integral form as

\[
E \left[ b \Pi_1(\tau) + (1 - b) \Pi_2(\tau) \left| E^\tau_{\text{fc}} \right. \right] = \int_{0}^{\infty} \int_{0}^{\infty} (b \pi_1 + (1 - b) \pi_2) \times P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \left| E^\tau_{\text{fc}} \right. \right) d\pi_2 d\pi_1
\]

(32)

by the definition of conditional expectation. To extend this for the case \(m > 2\), the double integral in the definition of \(T_\tau\) (32) is replaced by an \(m\)-dimensional integral over updated random variables \(\Pi_1, \Pi_2, \ldots, \Pi_m\). Combining (32) and (31) yields

\[
T(\tau) = \int_{0}^{\infty} \int_{0}^{\infty} (b \pi_1 + (1 - b) \pi_2) \times P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \left| E^\tau_{\text{fc}} \right. \right) d\pi_2 d\pi_1
\]

\[
= \frac{1}{P \left( E^\tau_{\text{fc}} \right)} \int_{0}^{\infty} \int_{0}^{\infty} (b \pi_1 + (1 - b) \pi_2) \times P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \left| E^\tau_{\text{nc}} \right. \right) d\pi_2 d\pi_1
\]

(33)

by Bayes’ theorem that \(P(A|B) = \frac{P(B|A)P(A)}{P(B)}\). If we write the explicit definition of \(E^\tau_{\text{nc}}\) given in (29),
then we obtain
\[
\begin{align*}
P(\mathcal{E}^{bc}_\tau) T(\tau) &= \int_0^\infty \int_0^\infty (b\pi_1 + (1 - b)\pi_2) \; P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) \; P\left[ \gamma_2 \Pi_1(1) \leq \Pi_2(1) \leq \gamma_1 \Pi_1(1) \right] \\
&\quad \ldots, \gamma_2 \Pi_1(\tau) \leq \Pi_2(\tau) \leq \gamma_1 \Pi_1(\tau) \bigg| \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \bigg] \; d\pi_2 d\pi_1 \\
&= \int_0^\infty \int_{\gamma_1 \pi_1}^{\gamma_2 \pi_1} (b\pi_1 + (1 - b)\pi_2) \; P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) \\
&\quad \times P\left[ \frac{\pi_1}{\prod_{t=2}^\tau x_1(t)} \leq \frac{\pi_2}{\prod_{t=2}^\tau x_2(t)} \leq \gamma_1 \frac{\prod_{t=3}^\tau x_1(t)}{\prod_{t=3}^\tau x_2(t)}; \frac{\prod_{t=3}^\tau x_1(t)}{\prod_{t=3}^\tau x_2(t)} \leq \frac{\pi_2}{\pi_1 \gamma_1} \leq \gamma_1 \frac{\prod_{t=3}^\tau x_1(t)}{\prod_{t=3}^\tau x_2(t)} \right] \; d\pi_2 d\pi_1
\end{align*}
\]
where (34) follows by the definitions of \(\Pi_1(i)\) and \(\Pi_2(i)\), i.e., \(\Pi_1(i) = \prod_{t=i}^{\tau} x_1(t) = \frac{\Pi_1(\tau)}{\prod_{t=i+1}^{\tau} x_1(t)}\) and \(\Pi_2(i) = \prod_{t=i}^{\tau} x_2(t) = \frac{\Pi_2(\tau)}{\prod_{t=i+1}^{\tau} x_2(t)}\). If we rearrange the inequalities in (34) to put the product terms together, which does not affect the direction of the inequality since all terms are positive, then we obtain
\[
\begin{align*}
P(\mathcal{E}^{bc}_\tau) T(\tau) &= \int_0^\infty \int_{\gamma_1 \pi_1}^{\gamma_2 \pi_1} (b\pi_1 + (1 - b)\pi_2) \; P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) \\
&\quad \times P\left[ \frac{\pi_2}{\prod_{t=3}^\tau x_1(t)} \leq \frac{\prod_{t=3}^\tau x_2(t)}{x_1(t)} \leq \frac{\pi_2}{\pi_1 \gamma_1}; \frac{\prod_{t=3}^\tau x_1(t)}{x_2(t)} \leq \frac{\pi_2}{\pi_1 \gamma_2} \right] \; d\pi_2 d\pi_1
\end{align*}
\]
which follows from the definition of \(\Sigma_k^\tau\) where \(\kappa \triangleq \ln \frac{\pi_2}{\pi_1}\). The first probability in (35) can be calculated as
\[
P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) = P(\Pi_1(\tau) = \pi_1) \; P(\Pi_2(\tau) = \pi_2) = \frac{1}{\pi_1 \sqrt{2\pi \tau \sigma_1^2}} e^{-\frac{(\ln \pi_1-\gamma_1)^2}{2\tau \sigma_1^2}} + \frac{1}{\pi_2 \sqrt{2\pi \tau \sigma_2^2}} e^{-\frac{(\ln \pi_2-\gamma_2)^2}{2\tau \sigma_2^2}}
\]
which follows since \(\Pi_1(\tau) \triangleq \prod_{t=1}^\tau x_1(t)\) and \(\Pi_2(\tau) \triangleq \prod_{t=1}^\tau x_2(t)\) and we have \(\Pi_1(\tau) \sim \ln N(\tau \mu_1, \tau \sigma_1^2)\) and \(\Pi_2(\tau) \sim \ln N(\tau \mu_2, \tau \sigma_2^2)\). The corresponding terms in (35) are written as a multi variable integral calculated in Section III-C.

Following similar steps, we can obtain the expected overall gain \(R(\tau)\) as
\[
\begin{align*}
R(\tau) &= E \left[ S(\tau) \Big| \mathcal{E}^{bc}_\tau \right] \\
&= E \left[ b \prod_{t=1}^\tau [x_1(t)] + (1 - b) \prod_{t=1}^\tau [x_2(t)] - 2c(b - b^2) \prod_{t=1}^\tau [x_1(t)] - \prod_{t=1}^\tau [x_2(t)] \bigg| \mathcal{E}^{bc}_\tau \right]. \quad (37)
\end{align*}
\]
The conditional expectation $E \left[ S(\tau) \mid E^c_\tau \right]$ can also be expressed in an integral form as

$$E \left[ S(\tau) \mid E^c_\tau \right] = \int_0^\infty \int_0^\infty S(\tau) \ P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \mid E^c_\tau \right) \ d\pi_2d\pi_1,$$

(38)

which follows from the definition of conditional expectation. Combining (38) and (37) yields

$$R(\tau) = \int_0^\infty \int_0^\infty S(\tau) \ P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \mid E^c_\tau \right) \ d\pi_2d\pi_1$$

$$= \frac{1}{P(E^c_\tau)} \int_0^\infty \int_0^\infty S(\tau) \ P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \right)$$

$$\times P \left( E^c_\tau \mid \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \right) \ d\pi_2d\pi_1,$$

(39)

where (39) follows from the Bayes’ theorem. Note that the definition of $R(\tau)$ (39) can be extended for the case $m > 2$ by replacing the double integral with an $m$-dimensional integral over the updated random variables $\Pi_1, \Pi_2, \ldots, \Pi_m$. If we replace the event $E^c_\tau$ with its explicit definition in (30), then we get

$$P \left( E^c_\tau \right) R(\tau) = \int_0^\infty \int_0^\infty (\zeta_1 \pi_1 + \zeta_2 \pi_2) \ P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \right)$$

$$\times P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \mid E^c_\tau \right) \ d\pi_2d\pi_1$$

$$+ \int_0^\infty \int_0^\infty \zeta_3 \pi_1 + \zeta_4 \pi_2 \ P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \right)$$

$$\times P \left( \Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2 \mid E^c_\tau \right) \ d\pi_2d\pi_1,$$

(40)

where $\zeta_1 \triangleq b - 2c(b - b^2)$, $\zeta_2 = 1 - b + 2c(b - b^2)$, $\zeta_3 = b + 2c(b - b^2)$ and $\zeta_4 = 1 - b - 2c(b - b^2)$.

We next calculate the first integral in (40) and the second integral follows similarly.
If we gather the product terms in (41) into the same fraction, then we obtain
\[
\int_0^\infty \int_0^\infty (\zeta_1 \pi_1 + \zeta_2 \pi_2) P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) P\left[ \frac{\pi_2}{\pi_1 \gamma_1} \leq \prod_{t=2}^\tau \frac{x_2(t)}{x_1(t)} \leq \frac{\pi_2}{\pi_1 \gamma_2} \right] d\pi_2 d\pi_1
\]
\[
\frac{\pi_2}{\pi_1 \gamma_1} \leq \prod_{t=3}^\tau \frac{x_2(t)}{x_1(t)} \leq \frac{\pi_2}{\pi_1 \gamma_2} \Rightarrow \frac{\pi_2}{\pi_1 \gamma_1} \leq \frac{x_2(\tau)}{x_1(\tau)} \leq \frac{\pi_2}{\pi_1 \gamma_2} \] (42)
\[
= \int_0^\infty \int_0^\infty (\zeta_1 \pi_1 + \zeta_2 \pi_2) P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) P\left( \Sigma_i^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_j^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^\tau \in [\kappa - \theta_1, \kappa - \theta_2] \right) d\pi_2 d\pi_1, (43)
\]
which follows from the definition of $\Sigma_i^k$, where $\kappa \triangleq \ln \frac{\pi_2}{\pi_1}$. Following similar steps that yields (43), we can calculate (40) as
\[
P\left( \mathcal{E}_r^k \right) R(\tau) = \int_0^\infty \int_0^\infty (\zeta_1 \pi_1 + \zeta_2 \pi_2) P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) P\left( \Sigma_i^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_j^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^\tau \in [\kappa - \theta_1, \kappa - \theta_2] \right) d\pi_2 d\pi_1
\]
\[
+ \int_0^\infty \int_0^{\tau^2 \pi_1} (\zeta_3 \pi_1 + \zeta_4 \pi_2) P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2) P\left( \Sigma_i^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_j^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^\tau \in [\kappa - \theta_1, \kappa - \theta_2] \right) d\pi_2 d\pi_1, (44)
\]
where the probability $P(\Pi_1(\tau) = \pi_1, \Pi_2(\tau) = \pi_2)$ can be obtained via (56). Hence to calculate $P\left( \mathcal{E}_r^c \right) T(\tau)$ and $P\left( \mathcal{E}_r^c \right) R(\tau)$, we need to calculate the probability $P\left( \Sigma_i^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_j^\tau \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^\tau \in [\kappa - \theta_1, \kappa - \theta_2] \right)$ in (45) and (44).

Following from the definition of $\Sigma_i^k$s, we have
\[
p(\Sigma_i^k, \Sigma_j^k, \Sigma_j^k) = p(\Sigma_i^k, \Sigma_j^k) p(\Sigma_j^k | \Sigma_i^k, \Sigma_j^k)
\]
\[
= p(\Sigma_j^k) p(\Sigma_j^k | \Sigma_j^k) p(\Sigma_j^k | \Sigma_i^k, \Sigma_j^k)
\]
\[
= p(\Sigma_j^k) p(\Sigma_j^k | \Sigma_j^k) p(\Sigma_j^k | \Sigma_{i+1}^k) (45)
\]
\forall i \in \{0, 1, \ldots, k - 2\}$, where (45) follows since $z(i)$ is independent of $\Sigma_j^k$ for $j > i$. Then, $\Sigma_i^k$s form a Markov chain such that $\Sigma_j^k \leftrightarrow \Sigma_j^{k+1} \leftrightarrow \Sigma_i^k \forall i \in \{0, 1, \ldots, k - 2\}$ and $j > i$. Hence, we can write the
probability

\[
P\left(\Sigma_2^r \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_3^r \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^r \in [\kappa - \theta_1, \kappa - \theta_2]\right) = \int_{\kappa - \theta_1}^{\kappa - \theta_2} \int_{\kappa - \theta_1}^{\kappa - \theta_2} \ldots \int_{\kappa - \theta_1}^{\kappa - \theta_2} P(\Sigma_2^r = s_1, \Sigma_3^r = s_2, \ldots, \Sigma_r^r = s_r) \, ds_{r-1} \, ds_{r-2} \ldots \, ds_1
\]

\[
= \int_{\kappa - \theta_1}^{\kappa - \theta_2} \int_{\kappa - \theta_1}^{\kappa - \theta_2} \ldots \int_{\kappa - \theta_1}^{\kappa - \theta_2} P(\Sigma_2^r = s_1 | \Sigma_3^r = s_2) \, ds_{r-2} \ldots \, ds_1
\]

\[
P(\Sigma_2^r = s_2 | \Sigma_3^r = s_1) \, ds_{r-3} \ldots \, ds_1,
\]

(46)

where (46) follows by the chain rule and \(\Sigma_i\)'s form a Markov chain. We can express the conditional probabilities in (46), which are of the form \(P(\Sigma_i^r = s_{\tau-i} | \Sigma_{i+1}^r = s_{\tau-i+1})\), as

\[
P(\Sigma_i^r = s_{\tau-i+1} | \Sigma_{i+1}^r = s_{\tau-i}) = P(\Sigma_i^r = s_{\tau-i} + z(i) = s_{\tau-i+1} | \Sigma_{i+1}^r = s_{\tau-i})
\]

\[
= P(s_{\tau-i} + z(i) = s_{\tau-i+1} | \Sigma_{i+1}^r = s_{\tau-i})
\]

\[
= P(z(i) = s_{\tau-i+1} - s_{\tau-i} | \Sigma_{i+1}^r = s_{\tau-i})
\]

\[
= P(z(i) = s_{\tau-i+1} - s_{\tau-i})
\]

(47)

where (47) follows from the independence of \(z(i)\) and \(z(k)\)’s for \(i < k \leq \tau\) or the independence of \(z(i)\) and \(\Sigma_{i+1}^r = \sum_{k=i+1}^{\tau} z(k)\). If we replace (47) with the conditional probabilities in (46) and use \(P(\Sigma_r^r = s_1) = P(z(\tau) = s_1)\), then we obtain

\[
P\left(\Sigma_2^r \in [\kappa - \theta_1, \kappa - \theta_2], \Sigma_3^r \in [\kappa - \theta_1, \kappa - \theta_2], \ldots, \Sigma_r^r \in [\kappa - \theta_1, \kappa - \theta_2]\right)
\]

\[
= \int_{\kappa - \theta_1}^{\kappa - \theta_2} \int_{\kappa - \theta_1}^{\kappa - \theta_2} \ldots \int_{\kappa - \theta_1}^{\kappa - \theta_2} f_z(s_{\tau-1} - s_{\tau-2}) \, ds_{\tau-1} \, ds_{\tau-2} \ldots \, ds_1
\]

\[
= \int_{\kappa - \theta_1}^{\kappa - \theta_2} \int_{\kappa - \theta_1}^{\kappa - \theta_2} \ldots \int_{\kappa - \theta_1}^{\kappa - \theta_2} \left(\frac{1}{2\pi \sigma^2}\right)^{\frac{r}{2}} e^{-\frac{1}{2\sigma^2} \sum_{i=2}^{r} (s_i - s_{i-1} - \mu)^2 + (s_1 - \mu)^2} \, ds_{\tau-1} \, ds_{\tau-2} \ldots \, ds_1,
\]

(48)

where (48) follows since \(z(\tau)\)’s are Gaussian, \(z \sim \mathcal{N}(\mu, \sigma^2)\), i.e., \(f_z(.)\) is the normal distribution. Hence in order to iteratively calculate the expected wealth growth of a TRP, we need to calculate the multivariate Gaussian integral given in (48), which is investigated in the next section.

C. Multivariate Gaussian Integrals

In order to complete calculation of the iterative equation in (12), we next evaluate the definite multivariate Gaussian integral given in (48) on the multidimensional \([\kappa - \theta_1, \kappa - \theta_2]^n\) space. We emphasize that the corresponding multivariate integral cannot be calculated using common diagonalizing methods [32]. Although, in (48), the coefficient matrix of the multivariate integral is symmetric positive-definite,
A Pseudo-code of QMC Algorithm for MVN Integrals:

1. get $\Sigma$, $a$, $b$, $N$, $M$ and $\alpha$

2. compute lower triangular Cholesky factor $L$ for $\Sigma$, permuting $a$ and $b$, and rows and columns of $\Sigma$ for variable prioritization.

3. initialize $P = 0$, $N = 0$, $V = 0$, and $q = \sqrt[p]{p}$ with $p = (2, 3, 5, \ldots, p_k)$ where $p_j$ is the $j$-th prime.

4. for $i = 1, 2, \ldots, M$ do
   
   $I_i = 0$ and generate uniform random $\Delta \in [0, 1]^k$ shift vector.

   for $j = 1, 2, \ldots, N$ do
     
     $w = [2jq + \Delta] - 1$.
     
     $d_1 = \Phi \left( \frac{w}{\sqrt{q}} \right)$, $e_1 = \Phi \left( \frac{p}{\sqrt{q}} \right)$ and $f_1 = e_1 - d_1$.

     for $m = 2, 3, \ldots, k$ do
       
       $y_{m-1} = \Phi^{-1}(d_{m-1} + w_{m-1}(e_{m-1} - d_{m-1}))$.
       
       $d_m = \Phi \left( \frac{a_{m-m} - \sum_{n=1}^{m-1} l_{n,m} y_n}{l_{m,m}} \right)$.
       
       $e_m = \Phi \left( \frac{b_{m-m} - \sum_{n=1}^{m-1} l_{n,m} y_n}{l_{m,m}} \right)$.
       
       $f_m = (e_m - d_m) f_{m-1}$.
     endfor

   $I_i = I_i + (f_m - I_i)/j$.

endfor

$\sigma = (I_i - t)/i$, $P = P + \sigma$, $V = (i - 2)V/i + \sigma^2$ and $E = \alpha\sqrt{V}$

endfor

5. output $P \approx \Phi_k(a, b, \Sigma)$ with error estimate $E$.

Fig. 3: A randomized QMC algorithm proposed in [33] to compute MVN probabilities for hyper-rectangular regions.

Common diagonalizing methods cannot be directly applied since the integral bounds after a straightforward change of variables depend on $y_i$. However, (48) can be represented as certain error functions of Gaussian distributions.

We note that the multivariate Gaussian integral given in (48) is the “non-central multivariate normal integral” or non-central MVN integral [33] and general MVN integrals are in the form [33]

$$\Phi_k(a, b, \Sigma) = \frac{1}{\sqrt{|\Sigma| \sqrt{2\pi}^k}} \int_{a_1}^{b_1} \int_{a_2}^{b_2} \cdots \int_{a_k}^{b_k} e^{-\frac{1}{2}x^T \Sigma^{-1} x} \, dx_k \cdots dx_2 dx_1, \quad (49)$$

where $\Sigma$ is a symmetric, positive definite covariance matrix. In our case, (48) is a non-central MVN integral which can be written in the form (49), where $k = \tau - 1$ and the inverse of the covariance matrix is given by
\[ \Sigma^{-1} = \begin{bmatrix} 2 & -1 \\ -1 & 2 & -1 \\ & \ddots & \ddots & \ddots \\ -1 & 2 & -1 \\ -1 & 2 \end{bmatrix} \]

which is a symmetric positive definite matrix with \(|\Sigma| = 1\), the lower bound vector is of the form, \(a = [a_1, \ldots, a_{\tau-1}]^T\),

\[
a = \begin{bmatrix} \kappa - \theta_1 - \mu \\ \kappa - \theta_1 - 2\mu \\ \vdots \\ \kappa - \theta_1 - (\tau - 1)\mu \end{bmatrix}
\]

and the upper bound vector is given by, \(b = [b_1, \ldots, b_{\tau-1}]^T\),

\[
b = \begin{bmatrix} \kappa - \theta_2 - \mu \\ \kappa - \theta_2 - 2\mu \\ \vdots \\ \kappa - \theta_2 - (\tau - 1)\mu \end{bmatrix}
\]

where \(-k\mu\) terms in the lower and the upper bounds follow from the non-central property of (48). We emphasize that the MVN integral in (49) cannot be calculated in a closed form [33] and most of the results on this integral correspond to either special cases or coarse approximations [33], [34]. Hence, in this paper, we use the randomized QMC algorithm, provided in Fig. 3 [33] for completeness, to compute MVN probabilities over hyper rectangular regions. Here, the algorithm uses a periodization and randomized QMC rule [35], where the output error estimate \(E\) in Fig. 3 is the usual Monte Carlo standard error based on \(N\) samples of the randomly shifted QMC rule, and scaled by the confidence factor \(\alpha\).

We observe in our simulations that the algorithm in Fig. 3 produce satisfactory results on the historical data [15]. We emphasize that different algorithms can be used instead of the Quasi-Monte Carlo (QMC) algorithm to calculate the multivariable integrals in (48), however, the derivations still hold.

IV. MAXIMUM-LIKELIHOOD ESTIMATION OF PARAMETERS OF THE LOG-NORMAL DISTRIBUTION

In this section, we give the MLEs for the mean and variance of the log-normal distribution using the sequence of price relative vectors, which are used sequentially in the Simulations section to evaluate the optimal TRPs. Since the investor observes the sequence of price relatives sequentially, he or she needs
to estimate $\mu$ and $\sigma$ at each investment period to find the maximizing $b$ and $\epsilon$. Without loss of generality we provide the MLE for $x_1(t)$, where the MLE for $x_2(t)$ directly follows.

For these derivations, we assume that we observed a sequence of price relative vectors of length $N$, i.e., $(x_1(1), x_1(2), \ldots, x_1(N))$. Note that the sample data need not to belong to $N$ consecutive periods such that the sequential representation is chosen for ease of presentation. Then, we find the parameters $\mu_1$ and $\sigma_1^2$ that maximize the log-likelihood function

$$\ln L(\mu_1, \sigma_1^2 \mid x_1(1), x_1(2), \ldots, x_1(N)) = \ln f(x_1(1), x_1(2), \ldots, x_1(N) \mid \mu_1, \sigma_1^2) = \sum_{i=1}^{N} \ln f(x_1(i) \mid \mu_1, \sigma_1^2),$$

where $f(x \mid \mu_1, \sigma_1^2) = \frac{1}{x\sqrt{2\pi\sigma_1^2}} e^{-\frac{(\ln x - \mu_1)^2}{2\sigma_1^2}}$. The log-likelihood function in (50) can also be written as

$$\ln L(\mu_1, \sigma_1^2 \mid x_1(1), x_1(2), \ldots, x_1(N)) = \sum_{i=1}^{N} \ln \frac{1}{x_1(i)\sqrt{2\pi\sigma_1^2}} e^{-\frac{(\ln x_1(i) - \mu_1)^2}{2\sigma_1^2}}.$$

We start with maximizing the log-likelihood function $\ln L$ with respect to $\mu_1$, i.e., find the estimator $\hat{\mu}_1$ that satisfies $\frac{\partial \ln L}{\partial \mu_1} = 0$. If we take the partial derivative of the expression in (50) with respect to $\mu_1$, then we obtain

$$\frac{\partial \ln L}{\partial \mu_1} = \sum_{i=1}^{N} \frac{\ln x_1(i) - \mu_1}{\sigma_1^2}.$$

Hence $\mu_1$, which satisfies $\frac{\partial \mathcal{L}}{\partial \mu_1} = 0$, or the ML estimator $\hat{\mu}_1$ of $\mu_1$, can be found as

$$\hat{\mu}_1 = \frac{1}{N} \sum_{i=1}^{N} \ln x_1(i). \quad (51)$$

To find the ML estimator of the variance $\sigma_1^2$, we find $\hat{\sigma}_1^2$ that satisfies $\frac{\partial \ln L}{\partial \sigma_1^2} = 0$. Since $\mu_1$ that satisfies $\frac{\partial \mathcal{L}}{\partial \mu_1} = 0$ in (51) does not depend on $\sigma_1^2$, we can use it in (50). Let us define $\bar{x}_1 = \sum_{i=1}^{N} \frac{\ln x_1(i)}{N}$ for notational clarity. By replacing $\bar{x}_1$ with $\mu_1$ in (51) and taking the partial derivative of the expression with respect to $\sigma_1^2$, we obtain

$$\frac{\partial \ln L}{\partial \sigma_1^2} = -\frac{N}{2\sigma_1^2} + \frac{1}{2(\sigma_1^2)^2} \sum_{i=1}^{N} (\ln x_1(i) - \bar{x}_1)^2.$$

Hence

$$\hat{\sigma}_1^2 = \frac{1}{N} \sum_{i=1}^{N} (\ln x_1(i) - \bar{x}_1)^2. \quad (52)$$
Following similar steps, the ML estimators for $x_2(t)$ yield

$$
\hat{\mu}_2 = \frac{1}{N} \sum_{i=1}^{N} \ln x_2(i),
$$

and

$$
\hat{\sigma}_2^2 = \frac{1}{N} \sum_{i=1}^{N} (\ln x_2(i) - \bar{x}_2)^2,
$$

where $\bar{x}_2 = \frac{1}{N} \sum_{i=1}^{N} \ln x_2(i)$. Note that the ML estimators $\hat{\mu}_1$, $\hat{\sigma}_1^2$, $\hat{\mu}_2$ and $\hat{\sigma}_2^2$ are consistent [36], i.e., they converge to the true values as the size of the data set goes to infinity, i.e., $N \to \infty$ [31].

V. SIMULATIONS

In this section, we illustrate the performance our algorithm under different scenarios. We first use TRPs over simulated data of two stocks, where each stock is generated from a log-normal distribution. We then continue to test the performance over the historical “Ford - MEI Corporation” stock pair chosen for its volatility [12] from the New York Stock Exchange. As the final set of experiments, we use our algorithm over the historical data set from [10] and illustrate the average performance. In all these trials, we compare the performance of our algorithm with portfolio selection strategies from [10], [15], [27].

In the first example, each stock is generated from a log-normal distribution such that $x_1(t) \sim \ln \mathcal{N}(0.006, 0.05)$ and $x_2(t) \sim \ln \mathcal{N}(0.003, 0.05)$, where the mean and variance values are arbitrarily selected. We observe that the results do not depend on a particular choice of model parameters as long as they resemble real life markets. We simulate the performance over 1100 investment periods. Since the mean and variance parameters are not known by the investor, we use the ML estimators from Section IV, which are then used to determine the target portfolio $b$ and the threshold value $\epsilon$. We start by calculating the ML estimators using the initial 200 samples and find the target portfolio $b = [b_1, b_2]^T$ and the threshold $\epsilon$ that maximize the expected wealth growth by a brute-force search. Then, we use the corresponding $b$ and $\epsilon$ during the following 200 samples. In similar lines, we calculate and use the optimal TRP for a total of 900 days, where $b$ and $\epsilon$ are estimated over every window of 200 samples and used in the following window of 200 samples. We choose a window of size 200 samples to get reliable estimates for the means and variances based on the size of the overall data. In Fig. 4 we show the performances of: this sequential TRP algorithm “TRP”, the Cover’s universal portfolio selection algorithm [10] “Cover”, the Iyengar’s universal portfolio algorithm [27] “Iyengar” and a semiconstant rebalanced portfolio (SCR) algorithm [15] “SCR”, where the parameters are chosen as suggested in [15]. As seen in Fig. 4 the TRP with the parameters sequentially calculated using the ML estimators is the best rebalancing strategy.
Fig. 4: Performance of various portfolio investment algorithms on a Log-normally simulated two-stock market. (a) Wealth growth under hefty transaction cost (c=0.025). (b) Wealth growth under moderate transaction cost (c=0.01).

among the others as expected from our derivations. In Fig. 4a and Fig. 4b, we present results for a mild transaction cost $c = 0.01$ and a hefty transaction cost $c = 0.025$, respectively, where $c$ is the fraction paid in commission for each transaction, i.e., $c = 0.01$ is a 1% commission. We observe that the performance of the TRP algorithm is better than the other algorithms for these transaction costs. However, the relative gain is larger for the large transaction cost since the TRP approach, with the optimal parameters chosen as in this paper, can hedge more effectively against the transaction costs.

As the next example, we apply our algorithm to historical data from [10] from the New York Stock
Exchange collected over a 22-year period. We first apply algorithms on the “Ford - MEI Corporation” pair as shown in Fig. 5, which are chosen because of their volatility [12]. In Fig. 5, we plot the wealth growth of: the sequential TRP algorithm with the optimal parameters sequentially calculated, the Cover’s universal portfolio, the Iyengar’s universal portfolio and the SCRP algorithm with the suggested parameters in [15]. We use the ML estimators to choose the optimal TRP as in the first set of experiments, however, since the historical data contains 5651 days we use a window of size 1000 days. Hence, the performance results are shown over 4651 days. As seen from Fig. 5, the proposed TRP algorithm significantly outperforms
Fig. 6: Performance of various portfolio investment algorithms on Ford - MEI Corporation pair. (a) Wealth growth under hefty transaction cost ($c=0.025$). (b) Wealth growth under moderate transaction cost ($c=0.01$).

Other algorithms for this data set. Similar to the simulated data case, we investigate the performance of the TRP algorithm under different transaction costs, i.e., a moderate transaction cost $c = 0.01$ in Fig. 5b and a hefty transaction cost $c = 0.025$ in Fig. 5a. Comparing the results from the Fig. 5a and Fig. 5b, we conclude that the TRP with the optimal sequential parameter selection can better handle the transaction costs when the stocks are volatile for this experiment.

Finally, to remove any bias on a particular stock pair, we show the average performance of the TRP algorithm over randomly selected stock pairs from the historical data set from [10]. The total set includes
34 different stocks, where the Iroquois stock is removed due to its peculiar behavior. We first randomly select pairs of stocks and invest using: the sequential TRP algorithm with the sequential ML estimators, the Cover’s universal portfolio algorithm, the Iyengar’s universal portfolio algorithm and the SCRP algorithm. The sequential selection of the optimal TRP parameters are performed similar to the previous case, i.e., we use ML estimators on an investment block of 1000 days and use the calculated optimal TRP in the next block of 1000 days. For each stock pair, we simulate the performance of the algorithms over 4651 days. In Fig. 6 we present the wealth achieved by these algorithms, where the results are averaged over 10 independent trials. We present the achieved wealth over random sets of stock pairs under a moderate transaction cost $c = 0.01$ in Fig. 6b and a hefty transaction cost $c = 0.025$ in Fig. 6a. As seen from the figures, the TRP algorithm with the ML estimators readily outperforms the other strategies under different transaction costs on this historical data set.

VI. CONCLUSION

In this paper, we studied an important financial application, the portfolio selection problem, from a signal processing perspective. We investigated the portfolio selection problem in i.i.d. discrete time markets having a finite number of assets, when the market levies proportional transaction fees for both buying and selling stocks. We introduced algorithms based on threshold rebalanced portfolios that achieve the maximal growth rate when the sequence of price relatives have the log-normal distribution from the well-known Black-Scholes model [8]. Under this setup, we provide an iterative relation that efficiently and recursively calculates the expected wealth in any i.i.d. market over any investment period. The terms in this recursion are evaluated by a certain multivariate Gaussian integral. We then use a randomized algorithm to calculate the given integral and obtain the expected growth. This expected growth is then optimized by a brute force method to yield the optimal target portfolio and the threshold to maximize the expected wealth over any investment period. We also provide a maximum-likelihood estimator to estimate the parameters of the log-normal distribution from the sequence of price relative vectors. As predicted from our derivations, we significantly improve the achieved wealth over portfolio selection algorithms from the literature on the historical data set from [10].
