Generalized Entropy Regularization or:
There’s Nothing Special about Label Smoothing

Abstract
Prior work has explored directly regularizing the output distributions of probabilistic models to alleviate peaky (i.e. over-confident) predictions, a common sign of overfitting. This class of techniques, of which label smoothing is one, has a connection to entropy regularization. Despite the consistent success of label smoothing across architectures and data sets in language generation tasks, two problems remain open: (1) there is little understanding of the underlying effects entropy regularizers have on models, and (2) the full space of entropy regularization techniques is largely unexplored. We introduce a parametric family of entropy regularizers, which includes label smoothing as a special case, and use it to gain a better understanding of the relationship between the entropy of a model and its performance on language generation tasks. We also find that variance in model performance can be explained largely by the resulting entropy of the model. Lastly, we find that label smoothing provably does not allow for sparsity in an output distribution, an undesirable property for language generation models, and therefore advise the use of other entropy regularization methods in its place. Our code is available online at \url{https://github.com/rycolab/entropyRegularization}.

1 Introduction
When training large neural networks with millions of parameters, regularization of some form is needed to prevent overfitting, even when large amounts of data are used; models for language generation are no exception. In probabilistic modeling, e.g. when the final layer of the neural network is a softmax, overfitting often manifests itself in overconfident placement of most of the probability mass on a few candidates, resulting in peaky (low-entropy) probability distributions over the vocabulary. Specifically for language generation tasks, this behavior leads to the output of repetitive or frequently occurring but unrelated text, which is detrimental to the generalization abilities of the model (Chorowski and Jaitly, 2017; Holtzman et al., 2020). A natural regularizer to consider is, therefore, one that penalizes overconfidence, encouraging higher entropy in the learned distribution. Indeed, the literature has ascribed gains of $\approx 1$ BLEU point in machine translation to label smoothing, one such technique (Chen et al., 2018).

Despite the clear relationship between low entropy and overfitting, only a handful of distinct entropy regularizers have been explored. To fill this gap, we introduce \textit{generalized entropy regularization} (GER), a unified framework for understanding and exploring a broad range of entropy-inducing regularizers. GER is based on the skew-Jensen family of divergences $J_{\alpha,G}$ (Nielsen and Boltz, 2011) and thus may be generalized to any Bregman divergence through the choice of generator function $G$. For the negative entropy generator function, GER recovers label smoothing (Szegedy et al., 2015) as $\alpha \to 1$, and the confidence penalty (Pereyra et al., 2017) as $\alpha \to 0$. We provide formal properties of GER in §3, proving these special-case equivalences among other properties of GER. We then use GER to empirically examine the relationship between entropy and the evaluation metrics in two language generation tasks: neural machine translation (NMT) and abstractive summarization.

GER encompasses a large family of regularizers, which allows us to directly compare label smoothing to other forms of entropy regularization. By studying the relationship between different regularizers on the performance of natural language generation (NLG) systems, we can better understand not just \textit{when} but also \textit{why} label smoothing aids language generation tasks. Through our analysis, we gain the following insights:

- (i) With tuning of the regularizer’s coefficient, any choice of $\alpha$ can yield similar performance, i.e. there is nothing special about label smoothing. In fact, our results suggest that la-
bel smoothing ($\alpha \rightarrow 1$) makes it more difficult to tune the regularizer’s coefficient.

(ii) Label smoothing assigns infinite cost to sparse output distributions, which may be an undesirable behavior for language generation tasks.

(iii) There is a strong (quadratic) relationship between a model’s performance on the evaluation metric and its (average) entropy, offering a hint as to why these regularizers are so effective for NLG.

In summary, entropy-inducing regularizers are a boon to probabilistic NLG systems, which benefit from higher entropy output distributions. Label smoothing works because it forces the model towards a higher-entropy solution, but we recommend the confidence penalty and other entropy regularizers ($\alpha < 1$) for reasons (i) and (ii) above.

2 Preliminaries

In this work, we consider conditional probability models $p_\theta(y \mid x)$ for natural language generation; such models assign probability to a target sequence $y \in \mathcal{Y}$ given a source sequence $x$. Specifically, our target sequence $y = \langle y_1, \ldots, y_n \rangle$ of arbitrary length $n$ is a sequence of target words\footnote{Targets $y_i$ may also be characters or subwords; our experiments use byte-pair encoding (Sennrich et al., 2016)} $y_i$ from our vocabulary $Y$. The set of all complete target sequences, which are padded with distinguished beginning- and end-of-sentence symbols, BOS and EOS, is then defined as $\mathcal{Y} := \{ \text{BOS} \circ y \circ \text{EOS} \mid y \in Y^\dagger \}$. For language generation tasks, $p_\theta(y \mid x)$ is typically a neural network with parameters $\theta$; this network is trained to approximate $\hat{p}(y \mid x)$, the empirical distribution (i.e. the distribution of the data). In this work, we focus on locally normalized models; in such models $p_\theta(y \mid x)$ is factored as:

$$p_\theta(y \mid x) = p_\theta(y_1 \mid x) \cdots p_\theta(y_n \mid x, y_{<n}) \quad (1)$$

where $p_\theta(y_i \mid x, y_{<i})$ is represented by a softmax over the output of the final fully connected layer of the network. Generation is performed using greedy search, beam search or a sampling scheme. Of the candidate sequences generated, the one with the highest probability under the model $p_\theta$ is returned as the model’s prediction.

One way of selecting the parameters $\theta$ is to minimize the KL-divergence between the empirical distribution and the model. This yields the cross-entropy loss (plus an additive constant):

$$\mathcal{L}(\theta) = \text{KL}(\hat{p} \parallel p_\theta) \quad (2)$$

$$= H(\hat{p}, p_\theta) - H(\hat{p}) \quad (3)$$

However, fitting a model that perfectly approximates the empirical distribution is, in general, fraught with problems (Hastie et al., 2001). The goal of learning is to generalize beyond observed data. Exactly fitting the empirical distribution, often termed overfitting, is therefore not an ideal goal and for language generation models specifically, does not go hand-in-hand with the ability of a model to generate desirable text (Bengio et al., 2015). Consequently, it is advisable to minimize a regularized objective to prevent overfitting:

$$\mathcal{L}(\theta) + \beta R(\theta) \quad (4)$$

where $R(\theta)$ is a regularizer defined over the model with “strength” coefficient $\beta > 0$.

2.1 Entropy Regularization

Overfitting can manifest itself as peakiness in $p_\theta$ (Williams and Peng, 1991; Mnih et al., 2016; Pereyra et al., 2017). In other words, $p_\theta$ overconfidently places most of the probability mass on very few candidates. While this overconfidence improves training loss, it hurts generalization. Entropy regularization is one technique that directly combats such overconfidence by encouraging more entropic (less peaky) distributions.

The entropy of the model $p_\theta$ is defined as:

$$H(p_\theta) := - \sum_{y \in \mathcal{Y}} p_\theta(y) \log p_\theta(y) \quad (5)$$

where we remove dependence on $x$ for notational simplicity. However, the sum in eq. (5) over $\mathcal{Y}$ generally renders its computation intractable.\footnote{The notation used by Pereyra et al. (2017) is imprecise.} Instead, regularization is performed on the conditional distribution over $Y$ at each time step, which can be interpreted as an approximation of the true model entropy. For ease of notation, we define a higher-order function $D_f$ over our training corpus $C$ consisting of $\langle x, y \rangle$ pairs that maps a function $f$ over

$$H(p, q) := - \sum_{z \in Z} p(z) \log q(z)$$

is cross-entropy and $H(p) := H(p, p) = - \sum_{z \in Z} p(z) \log p(z)$ is the Shannon entropy, for which $\log = \log_2$ and $Z = \text{supp}(p)$.
While the loss function is often scaled as above, weighted term for the entropy of the model’s prediction $p_u(\cdot)$ from the loss function, thereby encouraging a more entropic model. This is equivalent to adding the KL divergence between the model $p_u$ and the uniform distribution:

$$L(\theta)^{CP} := L(\theta) + \beta \KL(p_u \parallel u) \quad (8)$$

While Pereyra et al. (2017) found that label smoothing performed better than the confidence penalty for NMT, they only searched coarsely over a small range of $\beta$’s for both regularizers. Our findings in §4 suggest an alternate conclusion.

## 3 Generalized Entropy Regularization

The positive effect of both label smoothing and the confidence penalty on model performance in language generation tasks motivates further exploration of entropy-promoting regularizers. To this end, we construct a parameterized family of regularizers with label smoothing and the confidence penalty as special cases. We discuss the formal properties of a subset of this family, providing upper and lower bounds for it. We show divergence only occurs in one case for this subset ($\alpha \to 1$), which directly implies that no sparse solution exists when label smoothing is used as a regularizer.

### 3.1 A Family of Entropy Regularizers

We derive a family of regularizers from the skew-Jensen divergence $J_{\alpha,G}$ (Nielsen and Boltz, 2011), which is defined below as:

$$J_{\alpha,G}(q \parallel p_u) := \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(q) + \alpha G(p_u) ight) - G((1-\alpha)q + \alpha p_u) \quad (9)$$

for a strictly convex generator function $G : \Omega \to \mathbb{R}$ and $\alpha \in (0,1)$ where $\Omega$ is a closed convex set. In this paper, we restrict $\Omega$ to be the $|Y|$-simplex. Note that $J_{\alpha,G}(q \parallel p_u) \neq J_{\alpha,G}(p_u \parallel q)$ in general, although this is true for some choices of $G$ and $\alpha$.

We define the generalized entropy regularizer as $R(\theta) = D_{J_{\alpha,G}}(u \parallel p_u)$ where $u$ is the uniform distribution $p_u(\cdot)$ from the loss function, thereby encouraging a more entropic model. This is equivalent to adding the KL divergence between the model $p_u$ and the uniform distribution:

$$L(\theta)^{CP} := L(\theta) + \beta \KL(p_u \parallel u) \quad (8)$$

While Pereyra et al. (2017) found that label smoothing performed better than the confidence penalty for NMT, they only searched coarsely over a small range of $\beta$’s for both regularizers. Our findings in §4 suggest an alternate conclusion.

### 3.1 A Family of Entropy Regularizers

We derive a family of regularizers from the skew-Jensen divergence $J_{\alpha,G}$ (Nielsen and Boltz, 2011), which is defined below as:

$$J_{\alpha,G}(q \parallel p_u) := \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(q) + \alpha G(p_u) ight) - G((1-\alpha)q + \alpha p_u) \quad (9)$$

for a strictly convex generator function $G : \Omega \to \mathbb{R}$ and $\alpha \in (0,1)$ where $\Omega$ is a closed convex set. In this paper, we restrict $\Omega$ to be the $|Y|$-simplex. Note that $J_{\alpha,G}(q \parallel p_u) \neq J_{\alpha,G}(p_u \parallel q)$ in general, although this is true for some choices of $G$ and $\alpha$.

We define the generalized entropy regularizer as $R(\theta) = D_{J_{\alpha,G}}(u \parallel p_u)$ where $u$ is the uniform distribution $p_u(\cdot)$ from the loss function, thereby encouraging a more entropic model. This is equivalent to adding the KL divergence between the model $p_u$ and the uniform distribution:

$$L(\theta)^{CP} := L(\theta) + \beta \KL(p_u \parallel u) \quad (8)$$

While Pereyra et al. (2017) found that label smoothing performed better than the confidence penalty for NMT, they only searched coarsely over a small range of $\beta$’s for both regularizers. Our findings in §4 suggest an alternate conclusion.
We prove these relationships in App. A and App. B. We use $H(\cdot)$ (see §3.1). We include entropy label smoothing and confidence penalty is equivalent to the uniform distribution and $\nabla \alpha H(p)$ for $\alpha = 0.5$ and $G(p) = ||p||^2$.

For ease, we define $\lim_{\alpha \rightarrow 0} J_\alpha(q \parallel p_\theta) = KL(p_\theta \parallel q)$ (10) $\lim_{\alpha \rightarrow 1} J_\alpha(q \parallel p_\theta) = KL(q \parallel p_\theta)$ (11) $J_{1/2}(q \parallel p_\theta) = 4 \cdot JS(q \parallel p_\theta)$ (12)

We prove these relationships in App. A and App. B. For ease, we define $J_1 := \lim_{\alpha \rightarrow 1} J_\alpha$ and $J_0 := \lim_{\alpha \rightarrow 0} J_\alpha$. We note the following two equivalences for these special cases.

**Proposition 1.** $\nabla q J_1(u \parallel p_\theta) = \nabla q H(q, p_\theta)$. In words, the gradient of the loss with GER as $\alpha \rightarrow 1$ is equivalent to the gradient of the loss augmented with label smoothing.

**Proposition 2.** $\nabla q J_0(u \parallel p_\theta) = \nabla q H(p_\theta)$. In words, the gradient of the loss with GER as $\alpha \rightarrow 0$ is equivalent to the gradient of the loss augmented with the confidence penalty.

See App. C and App. D for proofs.

---

6 Distributions other than $u$ may also be used. See §5.
7 We also experiment with $G(z) = ||z||^2$.

Figure 1: Different divergence measures between $u$, the uniform distribution and $p$, a probability distribution over a Bernoulli random variable $X$. Note that the confidence penalty is equivalent to $KL(p \parallel u) = J_0$ and label smoothing is equivalent to $KL(u \parallel p) = J_1$ (see §3.1). We include entropy label smoothing and confidence penalty is equivalent to the uniform distribution and $\nabla \alpha H(p)$ for $\alpha = 0.5$ and $G(p) = ||p||^2$.

3.2 Formal Properties of $J_\alpha$

When fitting a model $p_\theta$, we generally optimize the inclusive KL, i.e. $KL(\hat{p} \parallel p_\theta)$, so that, among other reasons, $p_\theta$ has support everywhere that $\hat{p}$ has support. However, it is unclear what relationships we want to encourage between the model $p_\theta$ and the uniform distribution $u$ during regularization as complete support of $u$ implies no word can ever have non-zero probability. Here we explore formal properties of $J_\alpha$ as a regularizer to gain insight into how, as a function of $\alpha$, these regularizers affect the learned distribution.

**Magnitude.** Figure 1 shows the different divergence measures between $u$ and $p_\theta$. We see that $J_1 = KL(u \parallel p_\theta)$ (label smoothing) is much larger than $J_0 = KL(p_\theta \parallel u)$ (confidence penalty) at values of $p_\theta$ farther from $u$. This indicates that $J_1$ would be a stronger regularizer than $J_{<1}$, i.e. penalize values of $p_\theta$ far from $u$ more heavily, given the same strength coefficient $\beta$. Note that it is not always the case that $J_{<1}(u \parallel p) \leq J_1(u \parallel p)$ for fixed $p$. We can, however, bound $J_\alpha$ from above and below by other quantities.

**Proposition 3.** The divergence $J_\alpha(u \parallel p)$ is not a monotonic function of $\alpha$ for all distributions $p$.

A proof by counter example is shown in Figure 2.

**Proposition 4.** For fixed $p$, $J_\alpha$ has bounds: $0 \leq J_\alpha(u \parallel p) \leq KL(u \parallel p) + KL(p \parallel u)$.

See App. E for a proof.

**Sparsity.** Sparsity is generally a desirable trait in probabilistic models; specifically for structured prediction, it leads to improvements in performance and interpretability (Martins et al., 2011; Niculae
We evaluate our family of entropy regularizers on when using label smoothing. \(\alpha\) which induces sparsity in an output distribution, (2016) showed the benefits of using sparsemax, \(\gamma\) with \(\alpha\), \(\beta\) and explore how this entropy af-
tive task.\(^{10}\) We additionally do a more fine-grained grid search over \(\beta\) for \(J_0\) (confidence penalty) and \(J_1\) (label smoothness) for completeness. All other model hyperparameters are held constant. We run experiments on multiple architectures and across several data sets to ensure trends are general.

### 4.1 Neural Machine Translation

We explore performance of the regularizer \(D_{J\alpha}\) on NMT systems using three language pairs and corpora of two different sizes on the following tasks: WMT ’14 German-to-English (De-En) (Bojar et al., 2014), IWSLT’14 German-to-English (De-En) (Cettolo et al., 2012), and Multitarget Ted Talks Task (MTTT) French-to-English (Fr–En) and Japanese-to-English (Ja-En) tasks (Duh, 2018). For the larger WMT data set, we train fewer models using coarser-grained \(\alpha\) and \(\beta\) ranges. We perform experiments for both Transformers (Vaswani et al., 2017) and convolutional sequence-to-sequence models (Gehring et al., 2017).

For reproducibility and comparability, we use the data pre-processing scripts provided by fairseq (Ott et al., 2019) and follow recommended hyper-parameter settings from previous work (Vaswani et al., 2017; Gehring et al., 2017) for baseline models. We use SacreBLEU (Post, 2018) to calculate BLEU scores (Papineni et al., 2002). Specific data pre-processing steps and model hyperparameter details are provided in App. G. Decoding is performed with length-normalized grid search over \(\beta\) for \(J_0\) (confidence penalty) and \(J_1\) (label smoothness) for completeness. All other model hyperparameters are held constant. We run experiments on multiple architectures and across several data sets to ensure trends are general.

We evaluate our family of entropy regularizers on two language generation tasks: machine translation and abstractive summarization. We then analyze trends in model performance as a function of \(\alpha\) and model entropy\(^{9}\) and explore how this entropy affects other properties of language generation models. In the following experiments, each model is trained using eq. (4) where \(\mathcal{R}(\theta) = D_{J\alpha}(\hat{p} \mid p_0)\). We conduct searches over \(\alpha\) and \(\beta\) using Bayesian optimization (Snoek et al., 2012) to find the combination of regularizer \(D_{J\alpha}\) and strength coefficient \(\beta\) that lead to the best evaluation score on the respec-

\(\text{Table 2: BLEU scores and normalized entropy } H(\hat{p}_b) \text{ on the test sets for WMT’14 De-En, WMT’14 De-En, and MTTT Fr-En. Results include baseline models with no (entropy) regularization and standard label smoothing with } \gamma = 0.1 \text{ (equivalent to } \beta \approx 0.11\). We report scores from the best model found (on validation set) for \(D_{J\alpha}\), \(D_{J1}\), and \(D_{J0}\) over all \(\alpha, \beta\) pairs. BLEU standard deviation across random seeds was typically \(< 0.1\) and always \(< 0.2\).\(^{9}\) Results for MTTT Ja-En and convolutional architectures can be found in App. H.

\end{array}
\]

\(^{8}\)We have \(\alpha \approx 1\) as an exception; the standard deviation is slightly higher for larger \(\alpha\).

\(^{9}\)Model entropy is estimated as an average of the entropies of distributions at each time step during decoding. Entropy is normalized by the maximum possible entropy for the given vocabulary size \(\log |Y|\) in all figures and tables to control for the fact that languages have vocabularies of different sizes.

\(^{10}\)We only report results with generator function \(G = -H\) as results using \(G(z) = ||z||^2\) were consistently worse and often did not improve on the baseline; these results may be seen in App. H.
Figure 3: Model entropy $H(p_\theta)$ vs. BLEU on IWSLT’14 German to English (De-En) and Multitarget Ted Talks Task French to English (Fr-En) using a Transformer architecture; each point is a fully trained model, regularized with $D_{J_\alpha}$ for varying $\alpha$ and $\beta$. Label smoothing at standard $\gamma = 0.1$ and no (entropy) regularization are marked.

![Figure 3](image)

Table 3: ROUGE-L on test set for CNN/DailyMail abstractive summarization task. Note that we replicate their reported result (achieved with label smoothing).

| No Regularization | $\alpha$ | $\beta$ | $H(p)$ | ROUGE-L |
|-------------------|---------|---------|--------|--------|
| Confidence Penalty $D_{J_0}$ | 0 | 0.15 | 0.19 | 40.9 +0.4 |
| Label Smoothing $D_{J_1}$ | 1 | 0.1 | 0.2 | 40.9 +0.4 |
| GER $D_{J_{\alpha}}$ | 0.5 | 0.35 | 0.19 | 40.8 +0.3 |

Results of our experiments are shown in Table 2 and Figure 3. We see the same relation between model entropy and BLEU with both Transformer and convolutional architectures and between different language pairs. We show results for the Transformer architectures inline as they are the current standard for many NLP tasks; results for convolutional architectures are in App. H. Our results show better performance is achieved with values of $\alpha$ and $\beta$ other than those that correspond to label smoothing with $\gamma = 0.1$, which is the commonly used value for the strength coefficient (Vaswani et al., 2017; Edunov et al., 2018). Moreover, the relationship between model entropy and evaluation performance is quite strong, following the same trend for all values of $\alpha$, which suggests tuning a model for a specific entropy rather than $\alpha$, $\beta$ may be a better method in practice. We discuss trends in §4.3.

4.2 Abstractive Summarization

We fine-tune BART (Lewis et al., 2019) on the CNN/DailyMail abstractive summarization task (Hermann et al., 2015) with regularizer $D_{J_{\alpha}}$. Data pre-processing and other hyperparameter settings follow Lewis et al. (2019). Results in Table 3 show that optimal values of ROUGE-L, the evaluation metric, can be achieved by regularizing with $D_{J_{\alpha}}$ for different values of $\alpha$. Notably, the entropy is virtually the same for the models that achieve top performance, demonstrating the closer relationship of performance with model entropy than with $\alpha$, discussed further in §4.3.

4.3 Significance of $\alpha$ and Model Entropy

We look at the strength of the relationship between the evaluation metrics and both $\alpha$ and the model’s entropy. Figure 3 shows a quadratic relationship between model entropy and BLEU. On the other hand, the relationship between $\alpha$ (coloring of points) and BLEU is not an obvious one; the best performing models are regularized with various values of $\alpha$.

As correlation only tells us about linear relationships, we report mutual information to measure the strength of the relationship between $\alpha$, model entropy, and BLEU. Mutual information shows the proportion of entropy of a variable that is “explained” by another and is often used as a generalized correlation measure i.e. for nonlinear relationships (Song et al., 2012). We see in Figure 4 that model entropy has a much stronger relationship with BLEU than $\alpha$. Indeed, the normalized mutual information (NMI) between $\alpha$ and BLEU is $\approx 0.05$ compared to $\approx 0.25$ between model entropy and BLEU—implying that any flavor of entropy regularization can lead to similar performance.

While the relationship between $\alpha$ and BLEU is weak, it is still statistically significant. Some evidence of this exists in Figure 3 where a closer examination reveals that each level of $\alpha$ has a
similar quadratic trend, albeit with a different offset. Specifically, the performance of models trained with $D_{J_a}$ for $\alpha \in [0.75, 1]$ (which includes label smoothing) starts to degrade at lower levels of entropy than models trained with $D_{J_a}$ for $\alpha \in [0, 0.25]$ (confidence penalty). As quantitative validation of this observation, we (i) run a conditional independence test to see whether BLEU and $\alpha$ are conditionally independent given model entropy and (ii) look at the range of $\beta$ for which $D_{J_a}$ leads to good performance for different $\alpha$.

**Conditional Independence.** Conditional independence of $\alpha$ and BLEU implies that the value of $\alpha$ does not supply any additional information about the value BLEU given model entropy, i.e. $\alpha$ does not matter when using the regularizer $D_{J_a}$. We use a Monte Carlo permutation test where the null hypothesis is that no relationship between $\alpha$ and BLEU exists.\footnote{The underlying distributions of random variables are assumed to be Gaussian. See Legendre (2000) for more details.} However, this test rejects the null hypothesis with $p$-value < 0.05, supporting the alternate hypothesis that $\alpha$ and BLEU are not conditionally independent.

**Tuning $\beta$.** On the tasks for which we trained > 60 models, we take the subset of models for which performance is within $\approx 1\% (< 0.4$ BLEU) of the best overall model. We then look at the range of $\beta$ used with the regularizer $D_{J_a}$ for these models. The range of $\beta$ that meets the above criterion is much larger for $\alpha$ close to 0 than for $\alpha$ close to 1 (see Figure 5). We contend this implies that $D_{J_a}$ is easier to tune (i.e. it is more robust) for $\alpha \approx 0$ while for $\alpha \approx 1$, $D_{J_a}$ is relatively sensitive to $\beta$.

| $\epsilon^{-10}$ | $\epsilon^{-15}$ |
|------------------|------------------|
| Label Smoothing $D_{J_0}$ | 38% ± 0.01% | 0.0% ± 5e-5% |
| Confidence Penalty $D_{J_0}$ | 54% ± 5e-3% | 0.7% ± 4e-4% |

Table 4: Percentage of words with $< \epsilon$ probability mass at different values of $\epsilon$ (below which we consider as functionally 0) for models trained with $D_{J_0}$ and $D_{J_a}$.

To control for entropy, all models used in the calculation have entropy within the same 1%.

### 4.4 Sparsity

We take a subset of models trained with regularizers $D_{J_0}$ and $D_{J_1}$ and examine the sparsity of $p_e$. Results in Table 4 support our formal analysis regarding the sparsity of $D_{J_0}$ and $D_{J_1}$ in §3.2; $D_{J_1}$ steeply penalizes sparsity while $D_{J_a}$ for $\alpha < 1$ allows words to be assigned probability $\approx 0$.

### 4.5 Sequence Likelihood

We look at how the probability of the reference solution changes with model entropy. Previously, Müller et al. (2019) found that training with label smoothing rather than hard targets resulted in worse log-likelihoods for the reference sequence. However, this observation has not been put in the appropriate context; since the most probable sequence (relative to $p_e$) is returned, a more relevant calculation would be that of the overall ranking of the reference sequence or of the log-likelihood of the reference sequence relative to the most probable sequence. Since the former is typically impossible to calculate exactly due to the size of $\mathcal{Y}$, we approximate it by looking at the average rank of each word in the reference sequence.
In Figure 6, we see that higher entropy models, i.e. models with more entropy regularization, generally rank the reference sequence lower than low entropy models. Despite this, we know that models with entropy regularization still tend to perform better in terms of downstream evaluation metrics (see Figure 3), a phenomenon similar to that seen by Müller et al. (2019). Another behavior that Figure 6 exhibits is the tendency for the reference sequence to be ranked relatively low across all models, supporting findings seen in Ott et al. (2018).

In Figure 8, we see that while lower entropy models will place more probability mass on the reference sequence, the reference sequence is still far from the most probable. For models with higher entropy, the ratio of log-likelihoods of the reference sequence to the highest-probability sequence is larger, showing that in this context, higher entropy correlates with higher relative log-likelihood.

4.6 Decoding

In language generation tasks, estimated distributions are fed to decoding algorithms to create sequence predictions. To fully understand how model entropy affects performance for these tasks, we must explore the potential interactions between model entropy and the decoding strategy.

Chorowski and Jaitly (2017) saw that with label smoothing, prediction accuracy improved and so using a wider beam during beam search did not give further improvements; however, our results suggest otherwise. As shown in Figure 7, the trend in BLEU vs. model entropy stays remarkably constant for beam search as the beam width is varied, including for greedy decoding (beam size of 1). Perhaps unsurprisingly though, higher entropy is detrimental to the performance of decoding with random sampling (with temperature $T = 1$). However, this phenomenon could potentially be remedied by decreasing the temperature during decoding, a common practice for avoiding sampling from the tail of the distribution (Kirkpatrick et al., 1983).

5 Discussion

Our experiments show entropy regularization has a number of beneficial effects on natural language generation models. Foremost, we observe that low-entropy predictions, which are more aligned with the empirical distribution (Figure 8), lead to worst performance on evaluation metrics than the higher entropy predictions produced by more regularized models (Figure 3). Further, our findings show that closely approximating the empirical distribution appears to be at ends with a well calibrated model, i.e. a model $p_{θ}(y \mid x)$ that matches the true, underlying probabilities $p(y \mid x)$.

Namely, Figure 8 demonstrates an increase in the log-likelihood of the reference sequence relative to the highest probability sequence for higher entropy models.

Decoding. Overconfident predictions inhibit the ability to recover after a poor choice of words during decoding; Chorowski and Jaitly (2017) suggest that higher-entropy models $p_{θ}$, like the ones resulting from regularization with label smoothing, would alleviate this problem. Results throughout this paper support this hypothesis not just for la-

12 This is different than the empirical distribution $p̃(y \mid x)$. 
Figure 8: Average word probability of the reference and the most probable (for beam search with $k = 5$) sequences plotted against model entropy on test set for IWSLT ’14 (De-En). The black line is a smoothed estimate of their ratio.

Bel smoothing, but for the $D_{Ja}$ family of entropy regularizers as well.

Choosing the baseline distribution. Throughout this work, we use the uniform distribution $u$ as our baseline distribution for the regularizer $D_{Ja}$. However, one could also use some other distribution defined over the vocabulary such as the unigram (Chorowski and Jaitly, 2017) or a function of word embedding distance with the target word (Kumar and Tsvetkov, 2019; Li et al., 2020). Both have proven to be more effective than $u$ when used with label smoothing and the confidence penalty. However, using distributions other than $u$ with $D_{Ja}$ leads to indirect forms of entropy regularization. Specifically, the mathematical relationship to entropy regularization becomes more convoluted. Therefore, we leave the application of GER to other distributions as a topic for future work.

6 Related Work

Entropy regularization has a long history in reinforcement learning (Williams and Peng, 1991; Mnih et al., 2016; Fox et al., 2016; Haarnoja et al., 2018) where it has provided substantial improvements in exploration. Such methods have since been adapted for supervised learning where they have proven to be more effective than $u$ when used with label smoothing and the confidence penalty. More recently, interpolating between exclusive and inclusive KL divergences has been explored in NMT by Xiao et al. (2019). However, this method was used for the objective function (i.e. between $\tilde{p}$ and $p_\theta$) and not as a regularization technique (i.e. between a baseline distribution $q$ and $p_\theta$). Li et al. (2020) construct a baseline distribution $q$ as a function of word embedding distances to use in place of the uniform distribution $u$ in the label smoothing equation. This work is complementary to ours, as $q$ can similarly be used in place of $u$ with GER. Finally, our work is closest to that of Müller et al. (2019), which attempts to find the circumstances under which label smoothing has a positive effect on model performance. However, they do not explore entropy regularization on the whole nor do they attempt to provide an explanation for why label smoothing works. We attempt to answer the “why” question through a quantitative analysis of label smoothing and empirical exploration of the relationship between model entropy and performance.

7 Conclusion

We discuss the properties of generalized entropy regularization and provide empirical results on two language generation tasks. We find entropy regularization leads to improvements over baseline systems on evaluation metrics for all values of the parameter $\alpha$ with our regularizer $D_{Ja}$. Theoretical and empirical evidence show label smoothing adds undesirable constraints to the model and is the hardest to tune of the regularizers tested. We therefore advocate the use of alternate forms of entropy regularization for language generation tasks.

For reference, we repeat eq. (9), the definition of the skew Jensen divergence for some strictly convex function $G : \Omega \to \mathbb{R}$ and probability distributions $p, q$:

$$ J_{\alpha,G}(p \parallel q) := \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - \nabla G((1-\alpha)p + \alpha q) \right) $$

We can rewrite the $\alpha$-Jensen divergence with convex generator function $G$ in terms of the Bregman divergence

$$ J_{\alpha,G}(p \parallel q) = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - G((1-\alpha)p + \alpha q) \right) $$

$$ = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - G((1-\alpha)p + \alpha q) - \alpha(1-\alpha)\langle p-q, \nabla G((1-\alpha)p + \alpha q) \rangle \right) $$

$$ = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - G((1-\alpha)p + \alpha q) - \alpha(1-\alpha)\langle q-p, \nabla G((1-\alpha)p + \alpha q) \rangle \right) $$

$$ = 0, \text{ note } p-q \text{ in first inner product and } q-p \text{ in second} $$

$$ = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - G((1-\alpha)p + \alpha q) - (1-\alpha)\langle p - ((1-\alpha)p + \alpha q), \nabla G((1-\alpha)p + \alpha q) \rangle \right) $$

$$ - \alpha \langle q - ((1-\alpha)p + \alpha q), \nabla G((1-\alpha)p + \alpha q) \rangle \right) $$

$$ = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) - G((1-\alpha)p + \alpha q) - \langle p - ((1-\alpha)p + \alpha q), \nabla G((1-\alpha)p + \alpha q) \rangle \right) $$

$$ + \alpha \langle G(q) - G((1-\alpha)p + \alpha q) - \langle q - ((1-\alpha)p + \alpha q), \nabla G((1-\alpha)p + \alpha q) \rangle \rangle $$

regroup terms based on multiplier (either $\alpha$ or $1-\alpha$) so we can rewrite equation as two Bregman divergences

$$ = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)D_G(p, (1-\alpha)p + \alpha q) + \alpha D_G(q, (1-\alpha)p + \alpha q) \right) $$

We look at the behavior of $D_{1,\alpha,G}(p \parallel q)$ as $\alpha \to \{0, 1\}$

$$ \lim_{\alpha \to 0} \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)D_G(p, (1-\alpha)p + \alpha q) + \alpha D_G(q, (1-\alpha)p + \alpha q) \right) $$

$$ = \lim_{\alpha \to 0} \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)D_G(p, p) + \alpha D_G(q, p) \right) $$

$$ = \lim_{\alpha \to 0} \frac{1}{\alpha(1-\alpha)} D_G(q, p) $$

$$ = D_G(q, p) $$
If we expand $D_G(q, p)$ using our generator function $G(p) = \sum_i p(i) \log p(i)$, we get

$$D_G(q, p)\]

$$= \sum_i q(i) \log q(i) - \sum_i p(i) \log p(i) - \langle q - p, \log p \rangle$$

$$= \sum_i q(i) \log q(i) - \sum_i p(i) \log p(i) + \sum_i p(i) \log p(i) - \sum_i q(i) \log p(i)$$

$$= 0 \text{ since } q, p \text{ are both probability distributions summing to 1}$$

$$= \sum_i q(i) \log q(i) - \sum_i q(i) \log p(i)$$

$$= \text{KL}(q \mid \mid p)$$

Similarly, we can show $\lim_{\alpha \to 1} J_\alpha = \text{KL}(p \mid \mid q)$

**B  $\alpha$-Jensen to Jensen–Shannon**

The proof that the $\alpha$-Jensen divergence is proportional to the Jensen–Shannon divergence is quite straightforward. If we evaluate $J_\alpha(p \mid \mid q)$ at $G = x \log x$ and $\alpha = \frac{1}{2}$

$$J_\alpha(p \mid \mid q) = \frac{1}{\alpha(1-\alpha)} \left( (1-\alpha)G(p) + \alpha G(q) - G((1-\alpha)p + \alpha q) \right)$$

$$= 4 \cdot \left( \frac{1}{2} G(p) + \frac{1}{2} G(q) - G(\frac{1}{2}p + \frac{1}{2}q) \right)$$

$$= 4 \cdot \left( \frac{1}{2} p \log(p) + \frac{1}{2} q \log(q) - \frac{p+q}{2} \log(\frac{p+q}{2}) \right)$$

$$= 4 \cdot \left( \frac{1}{2} (p \log(p) - p \log(\frac{p+q}{2})) + \frac{1}{2} (q \log(q) - q \log(\frac{p+q}{2})) \right)$$

$$= 4 \cdot \left( \frac{1}{2} \text{KL}(p \mid \mid \frac{p+q}{2}) + \frac{1}{2} \text{KL}(p \mid \mid \frac{p+q}{2}) \right)$$

$$= 4 \cdot \text{JS}(p \mid \mid q)$$

**C  Label Smoothing**

For the case that $\alpha \to 1$, $p = u$, and $q = p_\theta$, we have

$$\lim_{\alpha \to 1} J_\alpha(u \mid \mid p_\theta(\cdot \mid x)) = \text{KL}(u \mid \mid p_\theta)$$

$$= \sum_{y \in Y} u(y) \log \frac{u(y)}{p_\theta(y \mid x)}$$

$$= \sum_{y \in Y} u(y) \log u(y) - \sum_{y \in Y} u(y) \log p_\theta(y \mid x)$$

$$= \log |Y| \sum_{y \in Y} u(y) \log p_\theta(y \mid x)$$

$$= \sum_{y \in Y} u(y) \log p_\theta(y \mid x) + N$$
When $J_1(u \parallel p_\theta(\cdot \mid x))$ is used as a regularizer for maximum likelihood training, we get the loss function

$$
L(\theta) = \text{KL} (\tilde{p}(\cdot \mid x) || p_\theta(\cdot \mid x)) + \beta \cdot \text{KL} (u(\cdot) || p_\theta(\cdot \mid x))
$$

$$
= -\sum_{y \in Y} \left( \tilde{p}(y \mid x) + \beta \cdot u(y) \right) \log p_\theta(y \mid x) + N
$$

where $N$ is constant with respect to $\theta$.

**D Classical Entropy Regularization**

For the case that $\alpha \to 0$, $p = u$, and $q = p_\theta$, we have

$$
\lim_{\alpha \to 0} J_\alpha(q \parallel p_\theta(\cdot \mid x)) = \text{KL}(p_\theta \parallel u)
$$

$$
= \sum_{y \in Y} p_u(y \mid x) \log \frac{p_\theta(y \mid x)}{u(y)}
$$

$$
= \sum_{y \in Y} p_u(y \mid x) \log p_\theta(y \mid x) - \sum_{y \in Y} p_u(y \mid x) \log u(y)
$$

$$
= -H(p_\theta(y \mid x)) - \log \frac{1}{|Y|} \sum_{y \in Y} p_u(y \mid x)
$$

$$
= -H(p_\theta(y \mid x)) - \log \frac{1}{|Y|}
$$

When $J_0(u \parallel p_\theta(\cdot \mid x))$ is used as a regularizer for maximum likelihood training, we get the loss function

$$
L(\theta) = \text{KL} (\tilde{p}(\cdot \mid x) || p_\theta(\cdot \mid x)) + \beta \cdot \text{KL} (p_\theta(\cdot \mid x) || u(\cdot))
$$

$$
= \text{KL} (\tilde{p}(\cdot \mid x) || p_\theta(\cdot \mid x)) - \beta \cdot H(p_\theta(y \mid x)) + \beta \cdot N
$$

**E Bounds of $J_\alpha$**

**Upper bound of $J_\alpha$:**

First note that $\text{KL}(p \parallel q)$ is convex in $q$ when $\text{supp}(p) \subseteq \text{supp}(q)$, which must be true since $(1 - \alpha)u + \alpha p$ has support everywhere both $p$ and $u$ do for $\alpha \in (0, 1)$. Therefore for $\alpha \in (0, 1)$

$$
\text{KL}(p \parallel (1 - \alpha)u + \alpha p) \leq (1 - \alpha)\text{KL}(p \parallel u) + \alpha \text{KL}(p \parallel u)
$$

$$
= (1 - \alpha)\text{KL}(p \parallel u)
$$

similarly,

$$
\text{KL}(u \parallel (1 - \alpha)u + \alpha p) \leq \alpha \text{KL}(u \parallel p)
$$

We then have:
\[ J(\alpha(u \parallel p)) = \frac{\alpha}{\alpha(1 - \alpha)} KL(p \parallel (1 - \alpha)u + \alpha p) + \frac{1 - \alpha}{\alpha(1 - \alpha)} KL(u \parallel (1 - \alpha)u + \alpha p) \]
\[
\leq \frac{\alpha(1 - \alpha)}{\alpha(1 - \alpha)} KL(p \parallel u) + \frac{\alpha(1 - \alpha)}{\alpha(1 - \alpha)} KL(u \parallel p)
\]
\[ = KL(p \parallel u) + KL(u \parallel p) \]

**Lower bound of** \( J_\alpha \):

The bound from below is trivial given the definition of \( J_\alpha \), however, it can more easily be seen by expressing \( J_\alpha \) as the sum of KL divergences as above:

\[ J_\alpha(u \parallel p) = \frac{\alpha}{\alpha(1 - \alpha)} KL(p \parallel (1 - \alpha)u + \alpha p) + \frac{1 - \alpha}{\alpha(1 - \alpha)} KL(u \parallel (1 - \alpha)u + \alpha p) \]

Since \( \alpha > 0 \) and necessarily \( KL(\cdot \parallel \cdot) \geq 0 \), the lower bound \( 0 \leq J_\alpha(u \parallel p) \) follows.

**F No Sparse Solution for** \( J_1 \)

*Proof.* By definition, for any distribution \( p \) over a vocabulary \( Y \):

\[ J_1(u \parallel p) = -\frac{1}{|Y|} \sum_{y \in Y} \log p(y) + \log |Y| \]

(13)

Thus, if \( p_y(y \mid x) \to 0 \) for some \( y \in Y \) and some \( x \in X \), we have \( J_1(u \parallel p) = KL(u \parallel p_y) \to \infty \). This means that label smoothing enforces \( p_y \) has support everywhere \( u > 0 \), i.e. over all words \( y \in Y \). For any \( \alpha < 1 \), \( J_\alpha \) allows for sparse solutions since \( \lim_{x \to 0} x \log x = 0 \). \( \square \)

**G Data Pre-Processing and Hyperparameter Settings**

For training with convolutional architectures we set hyperparameters, e.g. dropout, learning rate, etc., following Gehring et al. (2017). On IWSLT’14 and MTIT tasks, we follow the recommended Transformer settings for IWSLT’14 in fairseq.\(^{13}\) Hyperparameters for models trained on the WMT task are set following version 3 of the Tensor2Tensor toolkit (Vaswani et al., 2018). We use byte-pair encoding (BPE; Sennrich et al. 2016) for all languages. Vocabulary sizes for WMT and IWSLT’14 are set from recommendations for the respective tasks in fairseq; for the MTTT tasks, vocabulary sizes are tuned on models with standard label smoothing regularization.

Similarly, the CNN/DailyMail data set is pre-processed and uses BPE following the same steps as (Lewis et al., 2019). Hyperparameters are the same as for their model fine-tuned on CNN/DailyMail. Details are available on the fairseq website.\(^{14}\)
