Paired Cut-Wire Arrays for Enhanced Transmission of Transverse-Electric Fields through Sub-Wavelength Slits in a Thin Metallic Screen

Ilaria Gallina, Giuseppe Castaldi, Vincenzo Galdi, Senior Member, IEEE, Emiliano Di Gennaro, and Antonello Andreone, Member, IEEE

Abstract—It has recently been shown that the transmission of electromagnetic fields through sub-wavelength slits (parallel to the electric field direction) in a thin metallic screen can be greatly enhanced by covering one side of the screen with a metallic cut-wire array laid on a dielectric layer. In this Letter, we show that a richer phenomenology (which involves both electric- and magnetic-type resonances) can be attained by pairing a second cut-wire array at the other side of the screen. Via a full-wave comprehensive parametric study, we illustrate the underlying mechanisms and explore the additional degrees of freedom endowed, as well as their possible implications in the engineering of enhanced transmission phenomena.

Index Terms—Enhanced optical transmission, cut-wire arrays, slit arrays.

I. INTRODUCTION

TRIGGERED BY the seminal work by Ebbesen et al. [1], the study of extraordinary transmission phenomena through sub-wavelength apertures has emerged during the last decade as one of the most fascinating research areas in electromagnetics and optics, with a wealth of subtle physical aspects and potentially disruptive application perspectives to data storage, imaging, sensing, and lithography technologies. The reader is referred to [2] and [3] (and references therein) for recent tutorials and reviews of the well-established physical aspects and potentially disruptive application perspectives to data storage, imaging, sensing, and lithography technologies.

For the slit geometries of direct interest for the present investigation, most of the available results [2], [3] pertain to the transverse-magnetic (TM) polarization (i.e., magnetic field directed along the slits), for which the enhanced transmission is mediated by a propagating waveguide mode (with no cut-off frequency) supported by the slits. Comparatively much less effort (see, e.g., [4]–[7]) has been devoted to the transverse-electric (TE) case (i.e., electric field directed along the slits), for which the waveguide mode does instead exhibit a nonzero cut-off frequency, below which only evanescent coupling is possible. In particular, substantial (nearly 800-fold) transmission enhancements of TE fields were observed in [6] by placing a metallic cut-wire array (with the wires centered on the slits and parallel to them) on a thin dielectric substrate at the side of the screen that is directly illuminated. Such phenomenon was shown to be attributable to the excitation of an electric (dipole-like) resonance in the cut wires, whose strong field localization near the input aperture of the slit allows effective coupling of the illuminating plane-wave with the evanescent spectrum, and thus its “squeezing” through the slits [6]. Building up on these results, in this Letter, we show that richer effects (and moderately higher transmission enhancements) can be attained by pairing a second cut-wire array at the other side of the screen.

Cut-wire pairs have recently elicited attention as building blocks for (magnetic or negative-index) metamaterials (see, e.g., [8]–[11]). For the scenario of interest, we show that such structures can induce TE enhanced transmission phenomena via a richer phenomenology, whose underlying mechanisms can be tuned, by acting on the structure parameters (see, e.g., [12]–[15]), thereby providing new degrees of freedom for engineering the enhanced transmission phenomena.

II. PROBLEM GEOMETRY

The geometry of interest, obtained via two-dimensional (2-D) replication of the unit cell (of periods $\Lambda_x$ and $\Lambda_y$) illustrated in Fig. 1 is constituted by a metallic screen with infinitely long (in the $x$ direction) slits of subwavelength width $g$ [Fig. 1(b)] separated by a distance $\Lambda_y$ [Fig. 1(a)]. Generalizing the scenario in [6], in our configuration, the screen (of thickness $h_s$) is embedded in a dielectric slab of relative permittivity $\varepsilon_r$ and thickness $h_d$ [Fig. 1(b)], with a 1-D array of metallic wires (of length $l$, width $w$, and thickness $h_w$) laid at each side of the slab along the $x$ direction. The arrays are located...
The resonance phenomena in paired cut-wire arrays for enhanced transmission of TE fields through sub-wavelength slits are studied. The response of the slotted screen alone, with metallic-screen and dielectric slab regions overlaid as solid and dashed lines, respectively, at the center of each slit, with period \( \Lambda_x \) (i.e., longitudinal gap \( b = \Lambda_x - l \)), and a possible longitudinal displacement \( \Delta_x \) [Fig. 1(c)].

The time-harmonic response, under TE-polarized \( x \)-directed electric field) plane-wave excitation, via the finite-integration commercial software package CST Microwave Studio. In our simulations below, we assume an aluminum (electrical conductivity \( \sigma = 3.72 \times 10^7 \) S/m) screen, copper (\( \sigma = 5.8 \times 10^7 \) S/m) wires, and a lossless dielectric, unless otherwise stated. The 3-D unit cell in Fig. 1 is terminated via periodic boundary conditions in the \( x-y \) plane and with open-boundary (matched) conditions along \( z \) (with a 10 mm air layer at each side of the slab), and is discretized using an adaptive hexahedral mesh (resulting, within the parametric range of interest, in about \( 6 \times 10^4 \) cells).

### III. Representative Results

Figure 2(a) illustrates a representative normal-incidence transmittance \( (|S_{21}|^2) \) spectrum, for a configuration featuring a lossless dielectric and longitudinally symmetric \( \text{i.e., } \Delta_x = 0 \) in Fig. 1(c)] cut-wire pairs, over a frequency range (2–10 GHz) well below the cutoff frequency of the slit (15.75 GHz, taking into account the presence of the dielectric). Two sharp resonances are clearly visible at frequencies of 3.916 GHz and 4.230 GHz, with transmittance peak values which turn out to be over three orders of magnitude (1230- and 1533- times, respectively) stronger than the response attainable in the slotted screen alone. The two insets illustrate the longitudinal current mode, representative of electric-type resonance phenomena. Figures 2(b) and 2(c) show the electric field intensity distributions in the \( y-z \) plane (at the center of the wire gap), from which it is fairly evident the strong localization effect that allows the field “squeezing” through the slit, as also observed in [6]. Consistently with previous observations in the literature [9], [14], the two field distributions are rather different, with the localization most pronounced in the slit region for the electric resonance [Fig. 2(c)], and around the wire ends for the magnetic resonance [Fig. 2(b)].

We note that the presence of two transmission resonances was also observed in [4] for a configuration based only on a slit array embedded in a dielectric slab (i.e., without cut wires), and was attributed to the symmetric and anti-symmetric coupling of the surface waves supported by the slab.

Besides the moderately higher transmission enhancement, by comparison with [6], the proposed scenario features a richer phenomenology, which involves both electric- and magnetic-type resonances, typical of cut-wire-pair structures, thereby endowing further degrees of freedom in the engineering of enhanced transmission. It is therefore interesting to explore the robustness of these resonances and the possibilities of tuning them by acting on the structure parameters. In this framework, Figs. 3 compactly summarize the salient results from a comprehensive parametric study. Specifically, Fig. 3 shows the resonant frequencies and transmittances observed for oblique incidence (maintaining the TE polarization), as well as in the presence of losses (up to loss-tangent=0.01) in the dielectric substrate, and for various values of the electrical conductivity of the screen and wires. Interestingly, the resonances turn out to be rather robust up to near-grazing incidence angles and moderate values of the dielectric losses, and maintain the clear-cut electric (empty markers) or magnetic (full markers) hallmarks illustrated above. A breakdown was observed for stronger loss levels (loss-tangent=0.1, not displayed), with the merging of the two resonances into a rather wide and low-transmittance peak. On the other hand, the metal conductivity appears to yield stronger effects in the peak transmittance,
For normal incidence and lossless dielectric.

Fig. 5. As in Fig. 4, but varying the dielectric relative permittivity (a,b), slit width (c,d), screen thickness (e,f), or gap (g,h).

Going from a practically unit value (for both electric and magnetic resonances) in the ideal perfectly electric conducting (PEC) case, to values over twice smaller for the magnetic resonance in the presence of finite but relatively high conductivity values ($\sigma = 10^7$ S/m).

Figure 4 illustrates the effects induced by varying a single wire parameter (length $l$, width $w$, thickness $h_w$, or longitudinal gap $b$) with respect to the reference configuration in Fig. 2. Within the parametric ranges considered, the response is still characterized by two clear-cut electric- and magnetic-type resonances, with the frequency and transmittance values pertaining to the magnetic resonances always lower than their electric counterparts. Moreover, it can be observed that both resonant frequencies are mostly sensitive to the wire length [Fig. 4(a)], and very weakly dependent on the other parameters (dielectric relative permittivity $\varepsilon$, slit width $s$, thickness $h_w$, or period $\Lambda$).

Qualitatively similar considerations can be drawn from Fig. 5 which illustrates the effects of varying some other structural parameters (dielectric relative permittivity $\varepsilon$, slit width $s$, screen thickness $h_s$, and period $\Lambda$). In this case, the only parameter that turns out to yield sensible variations in the resonant frequencies is the dielectric relative permittivity [Fig. 5(a)], while all parameters seem to affect (in mild to moderate forms) the transmittance values [Figs. 5(b), 5(d), 5(f), and 5(h)]. More complex are the effects induced by varying the wire longitudinal displacement $\Delta l$ and the dielectric slab thickness $h_d$, as illustrated in Fig. 6. In these cases, the clear-cut electric or magnetic hallmarks are not always preserved, and some hybrid forms (indicated as half-empty markers) show up in certain parametric ranges. In particular, by increasing the dielectric slab thickness (and, hence, the electrical spacing between the arrays), the two resonances tend to merge into a hybrid form in which only the top wire is significantly excited, with progressively lower transmittance values [Figs. 6(c) and 6(d)]. In such regime, the behavior is not very different from the single wire structure in $\bar{G}$, and the progressively lower transmittance values can be easily explained taking into account that increasing the slab thickness results in a weaker evanescent coupling.

Conversely, by varying the wire longitudinal displacement $\Delta l$, an interesting crossing phenomenon is observed [Figs. 6(a) and 6(b)], i.e., a merging followed by an inversion in the frequency locations of the electric and magnetic resonances, with a transition region characterized by hybrid resonances (some of which with relatively low transmittances). Such behavior is generally much more complex than the one illustrated above, and also includes situations where the current amplitudes on the wire pair are moderately different (for which a prevailing electric or magnetic behavior could still be attributed). As a representative example, Fig. 7 shows the transmittance spectrum and resonant features pertaining to a longitudinal displacement $\Delta l = 2.25$ mm. In the transmittance response, one can still observe two peaks with significantly different amplitudes. From the current distributions on the wires (shown in the insets) and the field maps [Figs. 7(b) and 7(c)], it can be observed that the lower-amplitude resonance is associated with a weak (and anti-symmetric) excitation of both wires, which results in a rather inefficient coupling, whereas the much more efficient coupling of the other resonance is mainly attributable to the strong excitation of the top wire.

The above parametric studies indicate the possibility of jointly or separately tuning the two resonances by acting on the...
provides the highest transmission enhancements. Transverse wire displacement may also be used as a design parameter, top cut-wire array (i.e., only one resonance, as in [6]), whose design based on the same structure featuring only the typical response is also shown as a reference.

In conclusion, we have demonstrated the potentials of paired cut-wire arrays for enhancing the transmission of TE fields through subwavelength slits in a thin metallic screen. We have shown that such enhanced transmission phenomena originate from the excitation of electric- and magnetic-type resonances supported by the cut-wire pairs. The associated resonance frequencies can be tuned by acting on the structure parameters (mainly, the wire length and longitudinal displacement, and the dielectric substrate electrical thickness), and their distance can be adjusted over a moderately wide bandwidth (nearly 10% in the examples above). Besides the inherent basic interest in the additional mechanisms attainable, we have shown the possibility of (jointly or separately) tuning the electric- and magnetic-type resonances, with possible application to passband-type designs, which may open up new perspectives in the engineering of enhanced transmission phenomena.

Current and future research is aimed at the experimental validation via prototype fabrication (in printed-circuit-board technology) and characterization, as well as at the exploration of electronic tuning mechanisms.
