We study the quantum spin-1/2 Heisenberg model in two dimensions, interacting through a nearest-neighbor antiferromagnetic exchange \(J\) and a ferromagnetic dipolar-like interaction \(J_d\), using double-time Green’s function, decoupled within the random phase approximation (RPA). We obtain the dependence of \(k_B T_c/J_d\) as a function of frustration parameter \(\delta\), where \(T_c\) is the ferromagnetic (F) transition temperature and \(\delta\) is the ratio between the strengths of the exchange and dipolar interaction (i.e., \(\delta = J/J_d\)). The transition temperature between the F and paramagnetic phases decreases with \(\delta\), as expected, but goes to zero at a finite value of this parameter, namely \(\delta = \delta_c = \pi/8\). At \(T = 0\) (quantum phase transition), we analyze the critical parameter \(\delta_c(p)\) for the general case of an exchange interaction in the form \(J_{ij} = J_d/r_{ij}^p\), where ferromagnetic and antiferromagnetic phases are present.

I. INTRODUCTION

Considerable attention during the last decade has been devoted to the investigation of systems with long-range interactions. In particular, the interest in films and quasi-two-dimensional systems has attracted attention mainly due to their technological applications as, for example, in electronics, data storage, catalysis in the case of metal-on-metal films, biotechnology, and pharmacology in the case of molecular films. The magnetic size unit and its thermal stability are essential points to be considered in order to obtain a good performance in magneto-optical recording\(^{[3]}\). The magnetic properties of these films depend on the subtle interplay between the long-range antiferromagnetic dipolar interaction, the short-range rotational invariant exchange, and the magnetic surface anisotropy. The presence of antiferromagnetic domains (AF) was observed in epitaxial thin films by the polarization-dependent X-ray magnetic linear dichroism spectra microscopy\(^{[2]}\). A possible intrinsic mechanism leading to AF domains is the competition between anisotropy and dipolar interaction\(^{[5]}\).

In two-dimensional lattices and for spins with rotational symmetry, long-range order does not occur at any finite temperature, for quantum and classical models with short-range interactions\(^{[4]}\). That is the case when only short-range exchange interactions are present, for the XY and Heisenberg models, for example. For all real systems there is a long-range dipolar interaction, with the important property that it breaks the symmetry between out-of-plane orientation of the spins and the in-plane orientation of the spins in the ordered state. The presence of dipolar interactions in systems with rotational symmetry (exchange) may stabilize long-range order at finite temperatures, for both classical and quantum models\(^{[5]}\).

The competition between long-range antiferromagnetic dipolar and short-range ferromagnetic exchange interactions in two-dimensional uniaxial (Ising) spin systems is responsible for a very rich phenomenological scenario concerning both their equilibrium statistical mechanics\(^{[6-9]}\) and non-equilibrium dynamic properties\(^{[10-13]}\). By means of Monte Carlo simulations and analytical calculations of the ground state, MacIsaac et al.\(^{[6]}\) studied the two-dimensional spin-1/2 Ising model with ferromagnetic exchange and antiferromagnetic dipolar interactions, and have shown that for \(\delta = J/J_d < 0.425\), \(J\) and \(J_d\) being the strength of exchange and dipolar interactions, respectively, the antiferromagnetic state is stable. For \(\delta > 0.425\) the AF state becomes unstable with respect to the formation of striped domain structures, i.e., to state configurations with spins aligned along a particular axis forming a ferromagnetic stripe of constant width \(h\), forming a superlattice in the direction perpendicular to the stripes. Monte Carlo results\(^{[8]}\) at low temperatures give further support to this proposal, at least for intermediate values of \(\delta\).

There are few numerical results concerning the equilibrium statistical mechanics of quantum models with competitive exchange and dipolar interactions in two-dimensional lattices\(^{[14,15]}\). The two dimensional antiferromagnetic (AF) Heisenberg model has been investigated by many authors to explain, for example, the magnetic mechanism of high \(T_c\) superconductivity\(^{[16,17]}\). Antiferromagnetic fluctuations are believed to play an important role in the superconductivity of the cuprates\(^{[17]}\), such as \(\text{La}_2\text{CuO}_4\), which is well described by a quasi-two-dimensional quantum spin-1/2 Heisenberg AF model. Chandra and Doucot\(^{[18]}\) have studied the square-lattice Heisenberg model at \(T = 0\) with next-nearest-exchange coupling and suggested that the AF order is destroyed due to the competition between the nearest and next-nearest exchange interactions. Although frustration effects are very effective to destroy the AF order in general, they may not be effective in high \(T_c\) materials, considering the extended nature of the holes which destroy the AF order. A good example of quasi-two-dimensional AF materials in which the dipolar interaction (with presence of frustration) is comparable to the exchange coupling are the so called high-\(T_c\) superconductors \(\text{RBa}_2\text{Cu}_3\text{O}_{7-x}\) (where \(R\) stands for rare earth)\(^{[19]}\).
From a theoretical point of view, the double-time Green’s function (GF) theory is both a convenient and an effective theoretical framework for interpretation and forecasting of various characteristics of matter at all temperatures. The development of approximation schemes for the GF approach has focused on decoupling their equations of motion. This decoupling is usually chosen for convenience or for reasons which are essentially ad hoc. The consistency of the basic decoupling approximation with relevant operator identities is not always assured. Several first-order decoupling have been proposed in the literature: firstly, the random phase approximation (RPA) was applied to the quantum spin-1/2 Heisenberg ferromagnetic, and Wagner theorem. The quantitative results of the phase diagram in the region obtained by RPA are in accordance with quantum Monte Carlo simulations. The consistency of the basic decoupling approximation (RPA) was applied to the quantum spin-1/2 Heisenberg model. In Sec. II, the model is presented and treated by the double-time GF technique in the RPA decoupling. In Sec. III, we analyze the phase diagram in the $T - \delta$ plane. Conclusions and remarks are summarized in Sec. IV.

II. MODEL AND GREEN’S FUNCTION METHOD

In order to study the consequences of both quantum effects and frustration, we propose here a spin model to describe the destruction of the F order, represented by the following Hamiltonian

$$H = J \sum_{<i,j>} S_i \cdot S_j - J_d \sum_{(i,j)} \frac{S_i \cdot S_j}{r_{ij}^3},$$

where $S_i = (S_i^x, S_i^y, S_i^z)$ is the spin-1/2 operator at site $i$. The first term, $J$, is the strength of the exchange interaction, and the sum is over all nearest-neighbor pairs, $<i,j>$, on a square lattice. The second term, $J_d = (g\mu_B^2)/a^3$ ($g$ is the Landé factor, $\mu_B$ the Bohr magneton, $a$ the lattice constant), represents a long-ranged dipole-dipole interaction and the sum is over all possible pairs of atoms on the square lattice. The dipolar interaction tends to align the spins in the F system at low temperatures ($T < T_c$), while the exchange interaction (antiferromagnetic, $J > 0$) tends to destroy the long-range ferromagnetic order. Consequently the ground state of a system determined by the dipolar interaction alone differs from the ground state of a system determined by the exchange interaction alone. In the absence of the dipolar interaction (i.e., $J_d = 0$), the isotropic Heisenberg model is regained and in two-dimensional lattices it does not present long-range order at $T > 0$ (i.e., $T_c = 0$). When both interactions are present the system is inherently frustrated.

The double-time Green’s function $\langle\langle A(t); B(0)\rangle\rangle$ is defined by

$$\langle\langle A(t); B(0)\rangle\rangle = -i\theta(t) \langle[A(t), B(0)]\rangle,$$

where $\theta(t)$ is the step function, $[A, B]$ is the commutator of operators $A$ and $B$, and $\langle \cdots \rangle$ denotes an average with respect to the canonical density matrix of the system at temperature $T$. The time-Fourier transform of Eq. (2), $\langle\langle A; B \rangle\rangle_E$, satisfies the following equation of motion

$$E \langle\langle A; B \rangle\rangle_E = \frac{1}{2\pi} \langle[A, B]\rangle + \langle\langle [A, H]; B \rangle\rangle_E,$$

and $\langle\langle [A, H]; B \rangle\rangle_E$ obeys an equation similar to Eq. (3), with a higher-order Green function appearing on the right side. In this way, an infinite set of coupled equations is generated. Therefore, an approximation (decoupling) is used to obtain the Green function.

The correlation function $\langle BA(t)\rangle$ is obtained by the spectral representation theory, which gives

$$\langle BA(t)\rangle = \int_{-\infty}^{\infty} J(w)e^{-iwt}dw =$$

$$\int_{-\infty}^{\infty} \frac{i \{G(w + i\varepsilon) - G(w - i\varepsilon)\} e^{-iwt}dw}{e^{\beta w} - 1},$$

where $G(E) = \langle\langle A; B \rangle\rangle_E$ and $\varepsilon \rightarrow 0$. Note that Eq. (4) is the required spectral representation for the time correlation function, where $J(w)$ is the spectral intensity of the function $\langle BA(t)\rangle$ (in fact, its Fourier transform).

With $A = S_i^+ \text{ and } B = S_i^-$, where the spin operators are defined by the usual commutation rules, we obtain from Eq. (3):

$$E \langle\langle S_i^+ S_i^- \rangle\rangle_E = \frac{m}{\pi} \delta_{gl} + 2 \sum_{j \neq l} J_{jl} \{\langle\langle S_j^+ S_l^- \rangle\rangle_E - \langle\langle S_l^+ S_j^- \rangle\rangle_E\},$$

where $m = \langle S_i^z \rangle$ is the magnetization per spin, $J$ for nearest-neighbor sites and $J_{jl} = J/a_{jl}$ for the dipolar interaction (with $\delta = J/J_d$).

The key problem of a first-order decoupling procedure is essentially to express the Green’s function...
\( \langle \langle S^+_a S^+_b ; S^+_i \rangle \rangle_E \) in terms of lower-order Green’s functions, which enables one to solve the infinite chain of equations of motion in an approximate way, and that can be expressed in the following form:

\[
\langle \langle S^+_a S^+_b ; S^+_i \rangle \rangle_E \approx m \langle \langle S^+_b ; S^+_i \rangle \rangle_E .
\]

Using the decoupling (6) in Eq. (5), we obtain

\[
EG_{gl}(E) = \frac{m}{\pi} \delta_{gl} + 2m \sum_{j \neq l} J_{jg} \{ G_{gl}(E) - G_{jl}(E) \}
\]

where \( G_{gl}(E) \equiv \langle \langle S^+_g ; S^+_l \rangle \rangle_E \).

The method of calculation we use is the same as Nakano and Takahashi\[23\], and we shall not reproduce the details. Following their notation, we obtain from Eq. (7) the Fourier transform of the Green’s function \( G_K(E) = \mathcal{F}\{ G_{gl}(E) \} \), defined by

\[
G_K(E) = \sum_{g,l} G_{gl}(E)e^{-ik \cdot (r_g - r_l)},
\]

and, in this way, we find

\[
G_K(E) = \frac{m}{\pi(E - E_k)},
\]

where the magnon energy \( E_k \) is

\[
E_k = 2m(J_o - J_k),
\]

with

\[
J_k = \sum_{(g,l)} J_{gl} e^{-ik \cdot (r_g - r_l)}.
\]

Using the low-\( k \) expression in two dimensions (as in Ref. 23) for \( p = 3 \) (the ferromagnetic interaction is assumed to decay with the distance between spins, \( r, \) as \( J(r) = J/r^p \)) we obtain:

\[
E_k = 2mJ_d k(\pi^2/8 - \delta k).
\]

Using Eqs. (4), (8) and (9), we obtain the correlation function \( \langle S^- S^+ \rangle \); for spin \( S = 1/2 \) we have \( \langle S^- S^+ \rangle = 1/2 - m \) and, therefore, the magnetization is written in the form:

\[
m = \frac{1}{2} \left[ \frac{1}{N} \sum_k \coth(\beta E_k/2) \right]^{-1}.
\]

III. RESULTS AND DISCUSSION

In the limit \( m \to 0 \), we find, from Eqs. (12) and (13), the critical temperature \( (T_c) \), which is given by:

\[
\frac{k_B T_c}{J_d} = \left[ \frac{2}{N} \sum_k \frac{1}{k(\pi^2/8 - \delta k)} \right]^{-1}.
\]

FIG. 1: Dependence of the reduced critical temperature \( k_B T_c/J_d \) on the parameter \( \delta \) for the quantum spin-1/2 Heisenberg model with ferromagnetic and dipolar interactions with \( p = 3 \). The insert is the behavior of \( \delta_c(p) \) as a function of the parameter \( p \).

In the thermodynamic limit \( (N \to \infty) \) one must replace the sum \( \frac{1}{N} \sum_k \psi(k) \) by an integral \( \frac{1}{(2\pi)^d} \int_{\text{BZ}} \psi(k) d^d k \) in the \( d \)-dimensional \( k \)-space, where \( \text{BZ} \) denotes the first Brillouin zone. Then, the integral (14) is obtained by using the expansion (12), and the critical temperature is given by

\[
\frac{k_B T_c}{J_d} = \frac{4\pi \delta}{\ln \left( \frac{\delta_c}{\delta} \right)}.
\]

Note that the critical temperature vanishes at \( \delta_c \), which, within the present approximation, is given by \( \delta_c = \pi/8 \approx 0.39 \).

Numerical results for \( T_c \) are shown in Fig. 1. The parameter \( \delta \) is a measure of the strength of the frustration; therefore, long-range order decreases as \( \delta \) increases. Consequently, \( T_c(\delta) \) goes to zero at the critical value \( \delta = \delta_c = \pi/8 \). When the interactions have the general form \( J_d/r^p \), the existence of a finite-temperature phase transition occurs for \( 2 < p < 4 \) in two dimensions. By numerically performing the sum in Eq. \( (13) \) for \( 2 < p < 4 \) (see Ref. 23 for the general dispersion relation), we obtain the critical parameter \( \delta_c(p) \) as a function of \( p \) at \( T = 0 \) (see the insert of Figure 1), where above the curve the ordered phase is antiferromagnetic, while below it the long-range order is ferromagnetic. We note that \( \delta_c(p) \) increases as \( p \) decreases, and that \( p \) approaches \( 2 \) we have a divergence \( (T_c \ also diverge) in \( \delta_c(p = 2) \) and around \( p \approx 3.6 \) a minimum point appears. The point \( p = 4 \) corresponds the to Kosterlitz-
finite value at $p = 4$ is approximately 0.793. For $p > 4$, the critical frustration parameter, $\delta_c(p)$, is zero, as physically expected.

IV. CONCLUSIONS

We study the phase diagram of the quantum spin-$1/2$ Heisenberg model with competing interactions (i.e., presence of AF exchange and dipolar interactions). The influence of the frustration is analyzed through the variation of the parameter $\delta = J/J_d$. We observe that $T_c(\delta)$ is null when we reach the critical value $\delta_c = \pi/8$. We also analyzed the case of the general dependence of the long-range interaction in the form $J_{ij} = J_d/r^p_{ij}$, and verified that $T_c$ tends to zero at the critical parameter $\delta_c(p)$. The dependence of $\delta_c(p)$ on $p$ ($2 < p < 4$) presents a divergence at $p = 2$ ($p \leq 2$ being the non-extensive regime) and a minimum point around $p \approx 3.6$, with finite value at $p = 4$ (Kosterlitz-Thouless transition). Although quantitative results are not expected to be very precise, within the approximation we applied, we believe that we obtain reliable qualitative results for the whole range of the parameters of the Hamiltonian. In particular, our results agree with previous ones, when available.
