Utility Change Point Detection in Online Social Media: A Revealed Preference Framework
Anup Aprem and Vikram Krishnamurthy, Fellow, IEEE

Abstract—This paper deals with change detection of utility maximization behaviour in online social media. Such changes occur due to the effect of marketing, advertising, or changes in ground truth. First, we use the revealed preference framework to detect the unknown time point (change point) at which the utility function changed. We derive necessary and sufficient conditions for detecting the change point. Second, in the presence of noisy measurements, we propose a method to detect the change point and construct a decision test. Also, an optimization criteria is provided to recover the linear perturbation coefficients. Finally, using the utility function recovered in the paper, several useful insights can be gleaned from these data sets. First, the changes in ground truth affecting the utility of the agent can be detected by utility maximization behaviour in online search. Second, the recovered utility functions satisfy the single crossing property indicating strategic substitute behaviour in online search. Third, due to the large number of videos in YouTube, the utility maximization behaviour was verified through the dimensionality reduction algorithm using Johnson-Lindenstrauss transform. The results developed are illustrated on two real datasets: Yahoo! Tech Buzz dataset and Youstatanalyzer dataset. By using the results developed in the paper, several useful insights can be gleaned from these data sets. First, the changes in ground truth

I. INTRODUCTION

The interaction of humans on social media platforms mimic their interactions in the real world [1]. Hence, as in the real world, “utility maximization” underpins human interaction on social media platforms. Utility maximization is the fundamental problem humans face, wherein humans maximize utility given their limited resources of money or attention. Detection of utility maximization behaviour is therefore useful in online social media. However, a key difference for agents in online social media is the absence of economic incentives. For example, the majority of content in Facebook, YouTube and Twitter are user-generated with limited or no economic incentives. Hence, as explained in [2], incentives such as “fun” and “fame” are some of the major attributes of the utility function of online social behaviour. It is therefore difficult to analytically characterize the utility function and hence any detection of utility maximization behaviour in online social media needs to be necessarily nonparametric in nature.

Another key difference is that the utility function in online social media is “content-aware”, i.e. the quality of content affects the utility function. Due to the content-aware nature of the utility function and the availability of large amount of user generated content, data from online social media is high-dimensional. For example, utility maximization in YouTube depends on all the user generated video content available at any point of time.

The problem of nonparametric detection of utility maximizing behaviour is the central theme in the area of revealed preferences in microeconomics. This is fundamentally different to the theme used widely in the signal processing literature, where one postulates an objective function (typically convex) and then develops optimization algorithms. In contrast, the revealed preference framework, considered in this paper, is data centric: Given a dataset, $D$, consisting of probe, $p_t \in \mathbb{R}^m$, and response, $x_t \in \mathbb{R}^n$, of an agent for $T$ time instants:

$$D = \{(p_t, x_t), t = 1, 2, \ldots, T\}.$$  (1)

Revealed preference aims to answer the following question: Is the dataset $D$ in (1) consistent with utility-maximizing behaviour of an agent? A utility-maximization behaviour (or utility maximizer) is defined as follows:

**Definition 1.1.** An agent is a utility maximizer if, at each time $t$, for input probe $p_t$, the output response, $x_t$, satisfies

$$x_t = x(p_t) \in \arg\max_{x, p_t \in I_t} u(x),$$  (2)

Here, $u(x)$ denotes a locally non-satiated utility function, i.e. the budget of the agent, $p_t x \leq I_t$, imposes a budget constraint on the agent, where $p_t x$ denotes the inner product between $p_t$ and $x$.

Major contributions to the area of revealed preferences are due to Samuelson [3], Afriat [4], Varian [5], and Dievert [6] in the microeconomics literature. Afriat [4] devised a nonparametric test (called Afriat’s theorem), which provides necessary and sufficient conditions to detect utility maximizing behaviour for a dataset. For an agent satisfying utility maximization, Afriat’s theorem [4] (stated below in Theorem II.1) provides a method to reconstruct a utility function consistent with the data. The utility function, so obtained, can be used

---

1Local non-satiation means that for any point, $x$, there exists another point, $y$, within an $\varepsilon$ distance (i.e. $\|x - y\| \leq \varepsilon$), such that the point $y$ provides a higher utility than $x$ (i.e. $u(x) < u(y)$). Local non-satiation models the human preference: *more is preferred to less*.

2The utility function is a function that captures the preference of the agent. For example, if $x$ is preferred to $y$, $u(x) \geq u(y)$.
to predict future response of the agent. Varian [7] provides a comprehensive survey of revealed preference literature.

Despite being originally developed in economics, there has been some recent work on application of revealed preference to social networks and signal processing. In the signal processing literature, revealed preference framework was used for detection of malicious nodes in a social network in [8], [9] and in demand estimation in smart grids in [10], [11] analyzes social behaviour and friendship formation using revealed preference among high school friends. In online social networks, [12] uses revealed preference to obtain information about products from bidding behaviour in eBay or similar bidding networks.

A. The Problem: Utility Change Point Detection in Online Social Media.

In this paper, we consider an extension of the classical revealed preference framework of [4] to agents with “dynamic utility function”. The utility function jump changes at an unknown time instant by a linear perturbation. Given the dataset of probe and responses of an agent, the objective is to develop a nonparametric test to detect the change point and the utility functions before and after the change, which is henceforth referred to as the change point detection problem.

Such change point detection problems arise in online search in social media. The online search is currently the most popular method for information retrieval [13]. The online search process can be seen as an example of an agent maximizing the information utility, i.e. the amount of information consumed by an online agent given the limited resource on time and attention. There has been a gamut of research which links internet search behaviour to ground truths such as symptoms of illness, political election, or major sporting events [14], [15], [16], [17], [18], [19]. Detection of utility change in online search, therefore, is helpful to identify changes in ground truth and useful, for example, for early containment of diseases [15] or predicting changes in political opinion [20], [21]. Also, the intrinsic nature of the online search utility function motivates such a study under a revealed preference setting. The problem of studying agents with dynamic utility functions, with a linear perturbation change in the utility function is motivated by several reasons. First, it provides sufficient selectivity such that the non-parametric test is not trivially satisfied by all datasets but still provides enough degrees of freedom. Second, the linear perturbation can be interpreted as the change in the marginal rate of utility relative to a “base” utility function. In online social media, the linear perturbation coefficients measure the impact of marketing or the measure of severity of the change in ground truth on the utility of the agent. This is similar to the linear perturbation models used to model taste changes [22], [23], [24], [25] in microeconomics. Finally, in social networks, linear change in the utility is usually used to model the change in utility of an agent based on the interaction with the agent’s neighbours [26]. Compared to the taste change model, our model is unique in that we allow the linear perturbation to be introduced at an unknown time. To the best of our knowledge, this is the first time in the literature that change point detection problem has been studied in the revealed preference setting.

A related important practical issue that we also consider in this paper is the high dimensionality of data arising in online social media. As an example of high dimensional data arising in online social media, we investigate the detection of the utility maximization process inherent in one of the most common social media interactions: video sharing via YouTube. Detecting utility maximization behaviour with such high dimensional (big) data is computationally demanding.

The organization of the paper is as follows: In Sec. II, we derive necessary and sufficient conditions for change point detection, for dynamic utility maximizing agents under the revealed preference framework. In Sec. III, we study the change point detection problem in the presence of noise. Section IV address the problem of high dimensional data arising in the context of revealed preference. Section V presents numerical results. First, we compare the proposed approach with the popular CUSUM test and corresponding ROC curves are presented. Second, we illustrate the result developed on two real world datasets: Yahoo! Tech Buzz dataset and Youstantalyzer dataset.

II. UTILITY CHANGE POINT DETECTION (DETERMINISTIC CASE)

In this section, we consider agents with a dynamic utility function. For completeness, we start with Afriat’s theorem, in the classical static setting. Afriat’s Theorem is one of the big results in revealed preferences in micro-economics theory.

**Theorem II.1** (Afriat’s Theorem [4]). Given the dataset \( \mathcal{D} \) in (1), the following statements are equivalent:

1. The agent is a utility maximizer and there exists a monotonically increasing\(^4\) and concave\(^5\) utility function that satisfies (2).

2. For \( u_t \) and \( \lambda_t > 0 \) the following set of inequalities has a feasible solution:

   \[
   u_s - u_t - \lambda_t p_t^*(x_s - x_t) \leq 0 \quad \forall t, s \in \{1, 2, \ldots, T\}.
   \]

3. A monotonic and concave utility function that satisfies (2) is given by:

   \[
   u(x) = \min_{t \in \{1, 2, \ldots, T\}} \{u_t + \lambda_t p_t^*(x - x_t)\}
   \]

4. The dataset \( \mathcal{D} \) satisfies the Generalized Axiom of Revealed Preference (GARP), namely for any \( t \leq T \),

   \[
   p_t^*(x_t) \geq p_{t+1}^*(x_{t+1}) \quad \forall t \leq k - 1 \implies p_k^* x_k \leq p_{k+1}^* x_{k+1}.
   \]

\( ^4 \)YouTube has millions of videos. https://www.youtube.com/yt/press/statistics.html

\( ^5 \)To the signal processing reader unfamiliar with this theorem, it can be viewed as a set-valued system identification method for an argmax nonlinear system with a constraint on the inner product of the probe and response of a system. Afriat’s theorem has several interesting consequences including the fact that if a dataset is consistent with utility maximization, then it is rationalizable by a concave, monotone and continuous utility function. Hence, the preference of the agent represented by a concave utility function can never be refuted based on a finite dataset, see [7]. Further, we can always impose monotone and concave restrictions on the utility function with no loss of generality.

\( ^6 \)In this paper, we use monotone and local non-satiation interchangeably. Afriat’s theorem was originally stated for a non-satiated utility function.

\( ^7 \)Concavity of utility function models the human preference: “averages are better than the extremes. It is also related to the law of diminishing marginal utility, i.e. the rate of utility decreases with \( x \).
The remarkable property of Afriat’s Theorem is that it gives necessary and sufficient conditions for the dataset to satisfy utility maximization (2). The feasibility of the set of inequalities can be checked using a linear programming solver or by using Warshall’s algorithm with $O(T^3)$ computations [7] [5]. A utility function consistent with the data can be constructed using (4). The recovered utility is not unique since any monotonic transformation of (4) also satisfy Afriat’s Theorem.

A. System Model

In this paper, we consider an agent that maximizes a utility function that jump changes by a linear perturbation at a time that is unknown to the observer. The aim is to estimate the utility before and after the change, and the change point. Consider an agent that selects a response $x$ at time $t$ to maximize the utility function given by:

$$u(x, \alpha; t) = v(x) + \alpha'x \mathbb{1}\{t \geq \tau\},$$

subject to the following budget constraint $p_i'x \leq I_t$. Here, $\mathbb{1}\{\cdot\}$ denotes the indicator function. The utility function, $u(x, \alpha; t)$ consists of two components: a base utility function, $v(x)$, and a linear perturbation, $\alpha'x$, which occurs at an unknown time $\tau$. The base utility function, $v(x)$ is assumed to be monotonic and concave. We will restrict the components of the vector $\alpha$ to be (strictly) greater than 0, so that the utility function, $u$, conditioned on $\alpha$ is monotonic and concave. The objective is to derive necessary and sufficient conditions to detect the time, $\tau$ at which linear perturbation is introduced to the base utility function. Theorem II.2 summarizes the necessary and sufficient conditions to detect the change in utility function according to the model in (5) and the proof is in Appendix A.

**Theorem II.2.** The dataset $\mathcal{D}$ in (1) is consistent with the model in (5) if we can find set of scalars $\{v_t\}_{t=1,...,T}$, $\{\lambda_t > 0\}_{t=1,...,T}$, $\{\alpha_k\}_{k=1,...,m}$, such that there exists a feasible solution to the following inequalities:

$$v_t + \lambda_t p_i'(x_s - x_t) \geq v_s \quad (t < \tau)$$

(6)

$$v_t + \lambda_t p_i'(x_s - x_t) - \alpha'i(x_s - x_t) \geq v_s \quad (t \geq \tau)$$

(7)

$$\alpha_i \leq \lambda_t p_i'(\forall i, t \geq \tau)$$

(8)

where $p_i'$ is the $i^{th}$ component of the probe $p_i$.

The inequalities in (6) to (8) closely resemble the Afriat inequalities (3). The time instant $\tau$ at which the inequalities are satisfied is the time at which the linear perturbation is introduced.

B. Recovery of minimum perturbation of $\alpha$ and the base utility function

Computing the linear perturbation coefficients in (5) gives an indication of the severity of the ground truth or the effect of marketing and advertising in social media. The solution to the following convex optimization provides the minimum value of the perturbation coefficients:

$$\min ||\alpha||^2_2$$

s.t. $v_t + \lambda_t p_i'(x_s - x_t) \geq v_s \quad (t < \tau)$

(10)

$$v_t + \lambda_t p_i'(x_s - x_t) - \alpha'i(x_s - x_t) \geq v_s \quad (t \geq \tau)$$

(11)

$$\alpha_i \leq \lambda_t p_i'(\forall i, t \geq \tau)$$

(12)

(13)

where, $\beta$ and $\delta$ are arbitrary constants.

The equations (10) to (12) correspond to the revealed preference inequalities (6) to (8). The normalization conditions (13) are required because of the ordinality of the utility function. This is because for any set of feasible values of $\{v_t\}_{t=1,...,T}$, $\{\lambda_t\}_{t=1,...,T}$, $\{\alpha_k\}_{k=1,...,m}$ satisfying the constraints in Theorem II.2 the following relation also holds

$$\beta(v_s + \delta) - \beta(v_s + \delta) - \beta\lambda t p_i'(x_s - x_t) + \beta\alpha'(x_s - x_t) \leq 0.$$  

Recall that the base utility function $v(x)$, is the utility function before the linear change.

**Corollary II.1.** The recovered base utility function is

$$\hat{v}(x) = \min_t \{v_t + \lambda_t p_i'(x - x_t)\},$$

(14)

where

$$\hat{p}_t = \begin{cases} p_t' \quad t < \tau, \\ \hat{p}_t - \alpha_i/\lambda_t \quad t \geq \tau. \end{cases}$$

(15)

In (14) and (15) $\{v_t\}$, $\{\lambda_t\}$, $\{\alpha_k\}$ are the solution of (9) to (13).

C. Comparison with classical change detection algorithms

Table I compares the revealed preference framework of our paper with classical change detection algorithms. The key difference is that the revealed preference framework considers a system with maximization of a utility function subject to linear constraints (the budget constraint). In comparison, a classical CUSUM type change detection algorithm requires knowledge of a parametrized utility function (see Sec. V-A for a numerical example when $v(x)$ is a Cobb-Douglas utility function). The revealed preference framework for change detection makes no such assumptions. The revealed preference problem is related to the supervised learning literature when the parametric class of functions for empirical risk minimization (ERM) is limited to concave and monotone functions [28], [29], [30]. The change detection problem can be thought of as a multi-class learning problem with the first class being the utility function before the change and the second class being the utility function after the change. However, this paper provides an algorithmic approach to detect change points by deriving necessary and sufficient conditions.

Clearly any positive monotonic transformation of $u(x)$ in (2) gives the same response.

The Cobb-Douglas is a widely used utility function in economics. When $m = 2$, i.e. the dimension of the probe and response is 2, the utility function can be expressed as $u(x) = x_1^2x_2^2$. The utility function is parameterized by $\alpha$ and $b$. 
satisfies utility maximization. Similarly, let \( H_1 \) denote the alternative hypothesis that the dataset does not satisfy utility maximization. There are two possible sources of error:

**Type-I errors**: Reject \( H_0 \) when \( H_0 \) is valid.

**Type-II errors**: Accept \( H_0 \) when \( H_0 \) is invalid. (18)

The following statistical test can be used to detect if an agent is seeking to maximize a utility function.

\[
\int_{\Phi^*(y)}^{+\infty} f_M(\psi) d\psi \geq \gamma, \quad H_0.
\]

In the statistical test, (19):
(i) \( \gamma \) is the “significance level” of the statistical test.
(ii) The “test statistic” \( \Phi^*(y) \), with \( y = [y_1, y_2, \ldots, y_T] \) is the solution of the following constrained optimization problem:

\[
\min \Phi
\]

subject to

\[
\begin{align*}
\lambda_t > 0 & \quad \Phi \geq 0 & \text{for} & \quad t, s \in \{1, 2, \ldots, T\}. \\
\end{align*}
\]

(iii) \( f_M \) is the pdf of the random variable \( M \) where

\[
M \equiv \max_{t, s} \left[ p_t'(w_t - w_s) \right].
\]

The probability of false alarm or Type-I error, the probability of rejecting \( H_0 \), when true, is given by \( P \{ M \geq \Phi^*(y) \} \).

Below, we derive an analytical expression for the lower bound for the false alarm probability of the statistical test in (19). The motivation comes from the following fact: Given the significance level of the statistical test in (19), a Monte Carlo (M.C.) simulation is required to compute the threshold. However, from an analytical expression for the lower bound on false alarm probability, we can obtain an upper bound of the test statistic, denoted by \( \Phi^*(y) \). Hence, for any dataset \( D_{obs} \) in (17), if the solution to the optimization problem (20) is such that \( \Phi > \Phi^*(y) \), then the dataset does not satisfy utility maximization, for the desired false alarm probability.

Theorem III.1 provides the lower bound on the false alarm probability and the proof is provided in Appendix C.

**Theorem III.1.** If the noise components have a standard Gaussian distribution, then the probability of false alarm is lower bounded by

\[
1 - \prod_t \left\{ 1 - \sqrt{\frac{2}{\pi}} \frac{\sqrt{2||p_t||^2 \exp(-\Phi^*(y)^2/4||p_t||^2)}}{\Phi^*(y) + \sqrt{\Phi^*(y)^2 + 8||p_t||^2}} \right\}.
\] (22)
The key idea is to bound $M$ in (21) by the highest order statistic of a carefully chosen set of random variables which are negatively dependent. Refer to Appendix B for the definition of negative dependence.

Figure 1 shows the comparison of the upper bound of the cdf (and correspondingly the lower bound on the false alarm probability) and the M.C. simulation of actual density of $M$. As can be seen from Fig 1 that the upper bound of the cdf (lower bound on false alarm probability) is tight at all regimes. The upper bound of the test statistic, $\Phi^*(y)$, can be obtained by setting the analytical expression in (22) to be equal to the desired false alarm probability.

B. Dynamic Revealed Preference in a noisy setting

In this section, we consider the case of dynamic utility maximizing agents, satisfying the model in (5), in the presence of noise. In Sec. III-B1, we propose a procedure to detect the unknown change point in time in presence of noise. In Sec. III-B2, similar to Sec. III-A, we formulate a hypothesis test to check whether the dataset satisfy the model in (5). As in Sec. III-A, we bound the false alarm probability and obtain a criteria for recovering the linear perturbation coefficient, corresponding to minimum false alarm probability. Once the unknown change point time and the linear perturbation coefficients have been recovered, the base utility function can be recovered similar to that in Sec. II-B.

1) Estimation of unknown change point: In the presence of noise, the inequalities in (6) to (8) may not be satisfied for any value of $\tau$. Hence, we consider the following linear programming problem, to find the minimum error or “adjustment” such that the inequalities in (6) to (8) are satisfied.

\[
\Phi_\tau = \min \Phi \\
\text{s.t. } v_s - v_t - \lambda_t p_t'(y_s - y_t) - \Phi \leq 0 \quad (t < \tau) \\
\quad v_s - v_t - \lambda_t p_t'(y_s - y_t) + \alpha'(y_s - y_t) - \Phi \leq 0 \quad (t \geq \tau) \\
\quad \alpha_s - \lambda_t p_t' \leq 0 \quad (\forall i, t \geq \tau) \\
\quad \Phi \geq 0, \quad \lambda_t > 0
\]

The solution of the linear program (23) depends on the choice of the change point variable $\tau$. When the data is measured without noise, the equations are satisfied with zero error at the correct change point. The estimated change point, $\hat{\tau}$, corresponds to time point with minimum adjustment.

\[
\hat{\tau} = \arg\min_{1 \leq \tau \leq T} \Phi_\tau
\]

The intuition for (24) is if $\tau$ is the true change point, then the perturbation $\Phi$ needs to compensate only for the noise.

2) Recovering the linear perturbation coefficients for minimum false alarm probability: As in (18), define the null hypothesis $H_0$, that the dataset satisfies utility maximization under the model in (5), and the alternative hypothesis $H_1$ that the dataset does not satisfy utility maximization under the model in (5). Type-I errors and Type-II errors are defined, similarly, as in Sec. III-A.

Consider the following hypothesis test:

\[
\int_{\Phi^*(y)}^{+\infty} f_M(\psi) d\psi \geq \gamma \quad H_0
\]

In (25):

1) $\gamma$ is the significance level of the test.
2) The test statistic “$\Phi^*(y)$”, is the solution of the following constrained optimization problem with $\tau = \hat{\tau}$ (from Sec. III-B1).

\[
\min \Phi \\
\text{s.t. } v_s - v_t - \lambda_t p_t'(y_s - y_t) - \Phi \leq 0 \quad (t < \tau) \\
\quad v_s - v_t - \lambda_t p_t'(y_s - y_t) + \alpha'(y_s - y_t) - \Phi \leq 0 \quad (t \geq \tau) \\
\quad \alpha_s - \lambda_t p_t' \leq 0 \quad (\forall i, t \geq \tau) \\
\quad \Phi \geq 0, \quad \lambda_t > 0
\]

The optimization problem above (26) is similar to the optimization problem (23) but is introduced for simplicity of analysis of the error probability in the subsequent sections.

3) $f_M$ is the pdf of the random variable, $M$, where $M \triangleq M_1 + M_2$, where $M_1$ and $M_2$ are defined as:

\[
M_1 \triangleq \max_{s\neq t, x \neq w, t \geq \tau} \left[ p_s'(w_t - w_s) \right], \quad (28) \\
M_2 \triangleq \max_{s\neq t, x \neq w, t \geq \tau} \left[ \alpha'(w_t - w_s) / \lambda_t \right], \quad (29)
\]

where $\alpha$ and $\lambda$ are the solution of (26). The set of inequalities in (26) can be re-written using (16) as:

\[
(\alpha_s - \lambda_t p_t') \leq 0 \quad (\forall i, t \geq \tau) \\
(\lambda_t - \alpha_t') \leq \lambda_t \leq (\lambda_t - \alpha_t'/\lambda_t) \quad (t \geq \tau).
\]

Therefore for the dataset satisfying the model in (5) it should be the case that the test statistic “$\Phi^*(y) \leq M$”.

The pdf of the random variable $M$ can be computed using Monte Carlo simulation. As in Sec. III-A, we bound the probability of false alarm and obtain a criteria to recover the linear perturbation coefficients corresponding to minimum false alarm probability. Theorem III.2 provides the criteria and the proof is provided in Appendix D.

Theorem III.2. Assume that the noise components are iid zero mean unit variance Gaussian. Suppose $\tau = O(\log 1/\varepsilon)$ and $T - \tau = O(\log 1/\varepsilon)$, where $\varepsilon > 0$. Then the optimization criterion to recover $\alpha$ with minimum probability of Type-I error is to minimize $\|\alpha\|_2$ (i.e., the Euclidean norm).

The recovery of the linear perturbation coefficients and the base utility function are similar to that in Sec. II-B.
IV. DIMENSIONALITY REDUCTION IN REVEALED PREFERENCE

Classical revealed preference deals with the case \( m < T \) (recall \( m \) is the dimension of the probe vector and \( T \) is the number of observations). Below, we consider the “big data” domain: \( m \gg T \). Checking whether a dataset, \( D \), satisfies utility maximization (2) can be done by verifying whether GARP (statement 4 of Theorem II.1) is satisfied. For \( m \gg T \), the computational cost for checking GARP is dominated by the number of computations required to evaluate the inner product in GARP, given by \( m^2T \). The computational cost for computing the inner product can be reduced by embedding the \( m \)-dimensional probe and observation vector into a lower dimensional subspace, of dimension \( k \), and checking GARP on the lower dimensional subspace. We use Johnson-Lindenstrauss Lemma (JL Lemma) to achieve this.

**Lemma IV.1** (Johnson-Lindenstrauss (JL) [32]). Suppose \( x_{1}, x_{2}, \ldots, x_{n} \in \mathbb{R}^{m} \) are \( n \) arbitrary vectors. For any \( \varepsilon \in (0, \frac{1}{2}) \), there exists a mapping \( f : \mathbb{R}^{m} \rightarrow \mathbb{R}^{k} \), \( k = O(\log n/\varepsilon^2) \), such that the following conditions are satisfied:

\[
\begin{align*}
(1 - \varepsilon)||x_i||^2 &\leq ||f(x_i)||^2 \leq (1 + \varepsilon)||x_i||^2 \quad \forall i \\
(1 - \varepsilon)||x_i - x_j||^2 &\leq ||f(x_i) - f(x_j)||^2 \\
\leq (1 + \varepsilon)||x_i - x_j||^2 \quad \forall i, j.
\end{align*}
\]

To implement JL efficiently, one possible method of [33] is summarized in Theorem IV.1. This method utilizes a linear map for \( f \) and hence can be represented by a projection matrix \( R \). The key idea in [33] is to construct the projection matrix \( R \) with elements \( +1 \) or \( -1 \) so that the computing the projection involves no multiplications (only additions).

**Theorem IV.1** ([33]). Let \( A = [x_{1}, x_{2}, \ldots, x_{n}]' \) denote the \( n \times m \) data matrix. Given \( \varepsilon, \beta > 0 \), let \( R \) be a \( m \times k \) random binary matrix, with independent and equiprobable elements \(+1\) and \(+1\), where

\[
k > \frac{4 + 2\beta}{\varepsilon^2/2 - \varepsilon^3/3} \log n.
\]

The projected data matrix, \( B \) of dimension \( n \times k \), is given by \( B = \frac{1}{\sqrt{\pi}}AR \). Then with probability at least \( 1 - \delta \), where \( \delta = \frac{1}{m^2} \), the inequalities (30) and (31) holds, where \( f : \mathbb{R}^{m} \rightarrow \mathbb{R}^{k} \) maps the \( i \)th row of \( A \) to the \( i \)th row of \( B \).

The inequalities in (30) and (31) hold in a probabilistic sense (with probability \( 1 - \delta \)), with the parameter \( \beta \) controlling the corresponding probability.

Checking the GARP conditions (statement 4 of Theorem II.1) depends only on the relative value of the inner product between the probe and response vectors. Hence, we can scale both the probe and response vector such that their norms are less that one. In this case, as a consequence of preservation of the norms of the vector, the Johnson-Lindenstrauss embedding also preserves the inner product.

**Corollary IV.1.** Let \( x_{i}, x_{j} \in \mathbb{R}^{m} \) and \( ||x_{i}|| \leq 1, ||x_{j}|| \leq 1 \) be such that (31) is satisfied with probability at least \( 1 - \delta \). Then,

\[
\mathbb{P}(\langle x'_{i}, x_{j} \rangle - f(x_{i})f(x_{j}) \geq \varepsilon) \leq \delta.
\]

The proof is available, for example, in [34]. The JL embedding of the vectors preserves the inner product to within a \( \varepsilon \) fraction of the original value.

Therefore, to check for utility maximization behaviour, we first project the high dimensional probe and response vector to a lower dimension using JL (using Theorem IV.1). The inner products in the lower dimensional space is then used for checking the GARP condition for detecting utility maximization giving \( \frac{m}{T} \) savings in computation.

V. NUMERICAL RESULTS

The aim of this section is three fold. First, we illustrate the change point detection algorithm in Sec. III and show how the revealed preference framework considered in this paper is fundamentally different from classical change detection algorithms. Second, we show that the theory developed in Sec. II and Sec. III, for utility change point detection, can successfully predict the change in ground truths through online search behaviour. Also, the recovered utility functions satisfy the single crossing condition indicating strategic substitution behaviour\(^{10}\) in online search. Third, we show user behaviour in YouTube satisfies utility maximization. To reduce the computational cost associated with checking the utility maximization behaviour, we use dimensionality reduction techniques discussed in Sec. IV. In addition, in Sec. V-C, we provide an algorithm to predict total traffic in YouTube.

A. Detection of unknown change point in the presence of noise

In this section, we present simulation results on change point detection in the presence of noise. For the simulation study, assume that the probe and response vector is of dimension 2, i.e., \( m = 2 \). Assume that the system follows the model given by (33). The base utility function \( v(x) \) is a Cobb-Douglas utility function with parameter \( a_1 \) and \( a_2 \).

\[
\begin{align*}
v(x) &= x_1^{a_1}x_2^{a_2} \\
u(x) &= \begin{cases} v(x) & t < \tau \\
v(x) + \alpha'x & t \geq \tau\end{cases}
\end{align*}
\]

Let the response be measured in noise as defined in (16).

Fig. 2a shows the simulation results for \( \Phi_\tau \), in (23) as a function of \( \tau \). The estimated change point (\( \hat{\tau} \)) is the point at which \( \Phi_\tau \) attains minimum. Fig. 2b compares the ROC plot for the revealed preference framework and the CUSUM algorithm for change detection. The details of the CUSUM algorithm for change detection are provided in Appendix G. The CUSUM algorithm is used as a reference for comparing the performance of the revealed preference framework presented in this paper. The CUSUM algorithm in Appendix G makes two critical assumptions: (i) Knowledge of the utility function before change

\(^{10}\)The substitution behaviour in economics is the idea that consumers, constrained by a budget will substitute more expensive items with less costly alternatives.
(ii) Knowledge of the linear perturbation coefficients, and hence the utility function after the change. The only unknown is the change point at which the utility changed. However, if the linear perturbation coefficients are also unknown, then the CUSUM algorithm in Appendix G can be modified to search over $\mathbb{R}_{t+}^{m}$ and select the parameter with the highest likelihood. The critical assumption is the knowledge of the utility function before the change point. One heuristic solution is to estimate the utility function using some initial data, assuming no change point, utilizing the Afriat’s Theorem and then applying the CUSUM algorithm. Such a procedure is clearly suboptimal. In comparison, the revealed preference procedure in Sec. III-B makes no assumption about the base utility function or the linear perturbation coefficients. As can be gleaned from Fig. 2b, the performance of the revealed preference algorithm is comparable to the CUSUM algorithm, given the non-parametric assumptions.

**B. Yahoo! Buzz Game**

In this section, we present an example of a real dataset of online search process. The objective is to investigate the utility maximization of the online search process and to detect change points at which the utility has changed. The change points give useful information on when the ground truths have changed.

The dataset that we use in our study is the Yahoo! Buzz Game Transactions from the Webscope datasets\textsuperscript{11} available from Yahoo! Labs. In 2005, Yahoo! along with O’Reilly Media started a fantasy market where the trending technologies at that point where pitted against each other. For example, in the browser market there were “Internet Explorer”, “Firefox”, “Opera”, “Mozilla”, “Camino”, “Konqueror”, and “Safari”. The players in the game have access to the “buzz”, which is the online search index, measured by the number of people searching on the Yahoo! search engine for the technology. The objective of the game is to use the buzz and trade stocks accordingly. The interested reader is referred to \textsuperscript{35} for an overview of the Buzz game. An empirical study of the dataset \textsuperscript{36} reveal that most of the traders in the Buzz game follow utility maximization behaviour. Hence, the dataset falls within the revealed preference framework, if we consider the buzz as the probe and the “trading price\textsuperscript{12}” as the response to the utility maximizing behaviour.

We consider a subset of the dataset containing only the “WIRELESS” market which contained two main competing technologies: “WIFI” and “WIMAX”. Figure 3 shows the buzz and the “trading price” of the technologies starting from April 1 to April 29. The buzz is published by Yahoo! at the start of each day and the “trading price” was computed as the average of the trading price of the stock for each day.

Chose the probe and response vector for this dataset as follows

$$p_t = [\text{Buzz(WIFI)} \quad \text{Buzz(WIMAX)}]$$

$$x_t = [\text{Trading price(WIFI)} \quad \text{Trading price(WIMAX)}].$$

\textsuperscript{11}Yahoo! Webscope dataset: A2 - Yahoo! Buzz Game Transactions with Buzz Scores, version 1.0 http://research.yahoo.com/Academic_Relations

\textsuperscript{12}The trading price is indicative of the value of the stock.

Checking the GARP condition or the Afriat inequalities (3), we find that the dataset does not satisfy utility maximization for the entire duration from April 1 to April 29. However, we find that the dataset satisfies utility maximization from April 1 to April 17. Using the inequalities (6) to (8), that we derived in Sec II, for the model in (5), we see that utility has changed in Sec II, for the model in (5), we see that utility has changed.

Also, by minimizing the 2-norm of the linear perturbation, which we derived in Sec. III, and using the optimization problem, postulated in Sec. II-B, we find that the recovered linear coefficients which correspond to minimum perturbation

\textsuperscript{13}http://www.dailywireless.org/2005/04/17/intel-shipping-wimax-silicon/
Fig. 3: Buzz scores and trading price for WIFI and WIMAX in the WIRELESS market from April 1 to April 29. The change point was estimated as April 18. This corresponds to a new WIFI product announcement. The change can also be observed due to the sudden peak of interest in WIFI around April 18.

is $\alpha = [0 \ 5.9]$. This is inline with what we expect, a positive change in the WIMAX utility, due to the change in ground truth. Furthermore, the recovered utility function, $v(x)$, is shown in Fig. 4a and the indifference curve (contour plot) of the base utility is shown in Fig. 4b. The recovered base utility function in Fig. 4a satisfy the single crossing condition indicating strategic substitute behaviour in online search. The substitute behaviour in online search can also be noticed from the indifference curve in Fig. 4b. This is due to the fact that WIFI and WIMAX were competing technologies for the problem of providing wireless local area network.

C. Youstatanalyzer Database

We now analyze the utility maximizing behaviour of users engaged in the popular online platform for videos, YouTube. YouTube is an example of a content-aware utility maximization, where the utility depends on the quality of the video present at any point. We measure the quality of the video using two measurable metrics: the number of subscribers and the number of views. The YouTube database that we use for our study is the Youstatanalyzer database\(^{15}\). The Youstatanalyzer database is built using the Youstatanalyzer tool [37], which collects statistics of YouTube videos using web scrapping technology. The database is particularly suited for our study of dimensionality reduction in revealed preference, since the entire database contains statistics of 1000K videos.

From the database, we aggregated the statistics of all popular videos existing from start of 08 July, 2012 to end of 07 Sept, 2013, having at least 2 subscribers. The entire duration was divided into 15 time periods, corresponding to each month of the duration, giving us a total of 15 observations ($T = 15$). The entire duration need to be split into sub-time periods since the statistics of all the videos are not sampled each day. For the revealed preference analysis, each of the dimension of the probe and the response is associated with a unique video ID. The probe for the revealed preference analysis is the number of subscribers and the response is the number of views during the time period. The objective is to investigate utility maximizing behaviour between the number

14Utility function, $U(x_1, x_2)$, satisfy the single crossing condition if $\forall x_1^1 > x_1, x_2^1 > x_2$, we have $U(x_1^1, x_2) - U(x_1, x_2) \geq 0 \implies U(x_1^1, x_2^1) - U(x_1, x_2^1) \geq 0$. The single crossing condition is an ordinal condition and therefore compatible with Afriat’s test.

15http://www.congas-project.eu/sites/www.congas-project.eu/files/Dataset/youstatanalyzer1000k.json.gz
of people subscribed to a particular video and the number of views that the video received. Formally, the probe and the response is chosen as follows:

\[ p_t = \frac{1}{\#\text{Subscriber(Video1)}, \ldots, 1/\#\text{Subscriber(VideoN)}} \]

\[ x_t = \#\text{Views(Video1)}, \ldots, \#\text{Views(VideoN)} \]

The motivation for this definition is that as the number of subscribers to a video increases, the number of views also increase [38]. The inner product of the probe and the response vector gives the sum of the “view focus” of all videos [39]. Also, a recent study shows that 90% of the YouTube views are due to 20% of the videos uploaded [40]. Hence, if we restrict attention to popular videos, the view focus tend to remain constant during a time period which correspond to the linear constraint in the revealed preference setting.

The number of videos satisfying the above requirements is 7605, and therefore, the dimension of the probe and response, \( m = 7605 \). The number of inner product computations required for checking the GARP conditions is given by \( mt^2 \).

Hence, we apply Johnson-Lindenstrauss lemma to the data using the “database friendly” transform that we presented in Sec IV. We choose \( \varepsilon = 0.1 \), so that the inner product are within 90% of the accuracy. Also, we choose \( \beta = 0.65 \), such that the above condition on the inner products hold with probability at least 0.9. Substituting the values of \( T, \varepsilon \) and \( \beta \) in (32) we find that the dimension of the embedded subspace is \( k = 3800 \).

From the simulations, we see that the GARP is satisfied with probability 0.9, which is inline with what we expect. For this example, the number of inner product computations required to compute GARP condition in the lower dimensional subspace is given by \( kT^2 \), which is less than the number of computations required to compute the GARP in the original space by a factor of 2. Note from Lemma IV.1 and Theorem IV.1 that the dimension of the embedding is independent of the dimension of the probe and the response and hence higher computational savings can be obtained when the dimension of the probe and the response are higher.

The utility function obtained in the lower dimension is useful for visualization, and gives a sparse representation of the original utility function. Below, we use the utility function obtained in the lower dimension to predict total traffic to YouTube when the number of subscribers to a particular video changes or when popular YouTube users (people with large number of subscribers) upload new videos. The above approach of predicting total number of views complements the findings in [38], where the authors claim that individual views to YouTube video or channel cannot be predicted. This predicted total traffic serves as an useful benchmark for allocating server resources without compromising the user experience.

**Predicting total traffic in YouTube:** Based on the utility function recovered in the lower dimension, one can predict the total traffic in YouTube. As before, let \( p_t \in \mathbb{R}^m \) and \( x_t \in \mathbb{R}^m \) be the number of subscribers and the number of views at time \( t \), respectively. Let \( \tilde{p}_t \in \mathbb{R}^k \) and \( \tilde{x}_t \in \mathbb{R}^k \) be the lower dimensional embedding of \( p_t \) and \( x_t \), respectively. The total traffic, or the number of views, at time \( t \), is given by \( T_t = \sum_{i=1}^m x_i \).

We can estimate the total traffic using the lower dimension utility function. Given \( p \), the number of subscribers at time \( t + 1 \), let \( \tilde{p} \) denote the lower dimensional embedding of \( p \). The corresponding value of \( \tilde{x} \) that rationalizes the data can be obtained by solving the following optimization problem:

\[ \tilde{x} = \arg \max \min_{\{\tilde{p}^t \leq T \} \in \{i,2, \ldots, t \}} \{ u_i + \lambda_i \tilde{p}_i^t (x - \tilde{x}_i) \} \]

The values of \( \{ u_i, \lambda_i \} \) are such that the GARP condition (3) is satisfied for the dataset \( \{ \{\tilde{p}_i, \tilde{x}_i \}_{i=1,2, \ldots, t} \} \). The budget \( I \), is assumed to be known or estimated independently of the above optimization problem. The estimated traffic due to the probe \( \tilde{p} \) is given by \( \tilde{T} = \sum_{i=1}^k \tilde{x}_i \).

**VI. Conclusion**

This paper derived a revealed preference based approach for change point detection in the utility function. The main result (Theorem II.2) provided necessary and sufficient conditions for the existence of the change point at which the utility function jump changes by a linear perturbation. In addition, in the presence of noise, we provided a procedure for detecting the unknown change point and a hypothesis test for testing the dataset for dynamic utility maximization. The results were applied on the Yahoo! Tech Buzz dataset and the estimated change point corresponds to the change in ground truth.

The application of results developed in this paper provided novel insights into the utility maximizing behaviour of agents in online social media. Extension of the current work could involve analytically characterizing the GARP failure rate due to dimensionality reduction, or considering multiple change points, or considering higher order perturbation functions.

**Acknowledgment**

The authors would like to thank William Hoiles\textsuperscript{16} for valuable discussions and the datasets.

**Appendix**

**A. Proof of Theorem II.2**

**Necessary Condition:** Assume that the data has been generated by the model in (5). An optimal interior point solution to the problem must satisfy:

\[ \nabla_{x_i} v(x_i) = \lambda_i p_i \quad (t < \tau) \]

\[ \nabla_{x_i} v(x_i) + a_i = \lambda_i p_i \quad (t \geq \tau) \]

At time \( t \), the concavity of the utility function implies:

\[ u(x_t, \alpha, t) + \nabla_{x_i} u(x_t, \alpha, t)'(x_s - x_t) \geq u(x_s, \alpha, t) \quad \forall s. \]

Substituting the first order conditions (35), (36) into (37), yields

\[ v(x_t) + \lambda_i p_i' (x_s - x_t) \geq v(x_s) \quad (t < \tau) \]

\[ v(x_t) + \lambda_i p_i' (x_s - x_t) - \alpha'(x_s - x_t) \geq v(x_s) \quad (t \geq \tau) \]

Denoting \( v(x_t) = v_t \) yields the set of inequalities (6), (7), (8) holds since the utility function \( v(x) \) is monotonic increasing.

\textsuperscript{16}ECE Department, University of British Columbia
Sufficient Condition: We first construct a piecewise linear utility function $\mathcal{V}(x)$ from the lower envelope of the $T$ overestimates, to approximate the function $v(x)$ defined in (5),

$$\mathcal{V}(x) = \min_t \{ v_t + \lambda_t \tilde{p}_t(x - x_t) \}, \tag{40}$$

where each coordinate of $\tilde{p}_t$ is defined as,

$$\tilde{p}_t = \begin{cases} \frac{p_t}{1 - \alpha_i / \lambda_t} & 0 \leq t < \tau \\ \frac{p_t}{\lambda_t} & t \geq \tau \end{cases} \tag{41}$$

To verify that the construction in (40) is indeed correct, consider an arbitrary response, $\hat{x}$, such that $p'_t \hat{x} \leq p'_t x_t$. We need to show $\mathcal{V}(\hat{x}) = v_t$.

First, we show that $\mathcal{V}(x_t) = v_t \forall t$ as follows.

$$\mathcal{V}(x_t) = v_m + \lambda_m p'_m(x_t - x_m),$$

for some $m$. If, $m \geq \tau$,

$$\mathcal{V}(x_t) = v_m + \lambda_m p'_m(x_t - x_m) = v_m + \lambda_m p'_m(x_t - x_m) - \alpha' (x_t - x_m) \leq v_t + \lambda_t p'_t(x_t - x_t) = v_t$$

If the inequality is true, then it would violate (39). Using similar technique, we obtain, if $m < \tau$, $\mathcal{V}(x_t) = v_t$. Hence, $\mathcal{V}(x_t) = v_t$.

Next, we show $\mathcal{V}(\hat{x}) + \alpha' \hat{x} \leq \mathcal{V}(x_t) + \alpha' x_t$. If, $t \geq \tau$,

$$\mathcal{V}(\hat{x}) + \alpha' \hat{x} \leq v_t + \lambda_t p'_t(\hat{x} - x_t) + \alpha' \hat{x} = v_t + \lambda_t p'_t(\hat{x} - x_t) - \alpha' (\hat{x} - x_t) + \alpha' \hat{x} = v_t + \lambda_t p'_t(\hat{x} - x_t) + \alpha' x_t \leq v_t + \alpha' x_t = \mathcal{V}(x_t) + \alpha' x_t$$

The inequality holds, similarly, for the case $t < \tau$. Therefore, we can construct a utility function that rationalizes the data based on the model in (5).

The variable $M$ in (21) is the highest order statistic of the set of random variables $\mathcal{M}$ defined as:

$$\mathcal{M} \triangleq \{ (p'_t(w_t - w_s)) : s, t = \{1, 2, \ldots, T\}, s \neq t \} \tag{42}$$

Define, $\xi \subset \mathcal{M}$ as

$$\xi = \{ p'_t(w_1 - w_2), p'_t(w_2 - w_3), \ldots, p'_T(w_T - w_1) \}. \tag{43}$$

Lemma A.1. If the noise components are i.i.d zero mean unit variance Gaussian distribution, then the set of random variables in $\xi$ are negatively dependent.

**Proof:** Each of the random variables in the set $\xi$, (defined in (43), is Gaussian and hence, to show negative dependence of random variables in $\xi$, it is sufficient to show that these variables are negatively correlated [41], [42]. Any element in $\xi$, $p'_t(w_i - w_{i+1})$, is correlated with either:

1. Element of the form $p'_i(w_{i+1} - w_{i+2})$:

$$\mathbb{E} \{ (p'_i(w_{i+1}) - (w_{i+2})) \} = -p'_i p_{i+1} < 0.$$  

2. Element of the form $p'_k(w_k - w_{k+1})$, $k \notin \{i, i+1\}$:

$$\mathbb{E} \{ (p'_i(w_i - w_{i+1})) (p'_k(w_k - w_{k+1})) \} = 0.$$  

Hence the random variables in $\xi$ (43) are negatively correlated and hence, negatively dependent, as defined in Def. A.1. 

**C. Proof of Theorem III.1**

For any subset of the random variables, $\xi$,

$$\xi \subset \mathcal{M} = \{ (p'_i(w_i - w_s)) : s, t = \{1, 2, \ldots, T\}, s \neq t \}$$

Choosing the set $\xi$ to be set defined in (43). Also, from Lemma A.1 the random variables in $\xi$ are negatively dependent, as defined in Def. A.1. Hence,

$$\leq \prod_i \mathbb{P} \{ \xi_i \leq x \}$$

Each of the term in $\xi$, $(p'_i(w_i - w_{i+1}))$ is distributed as $\mathcal{N}(0, 2\|p_i\|^2)$. Using standard lower bound for the tail of the Gaussian distribution, we have

$$\leq \prod_i \left( 1 - \sqrt{\frac{2}{\pi} \frac{\sqrt{2\|p_i\|^2}}{x + \sqrt{x^2 + 8\|p_i\|^2}}} \exp(-x^2/4\|p_i\|^2) \right)$$

The false alarm probability is given by $1 - \mathbb{P} \{ M \leq \Phi^*(y) \}$. Substituting the upper bound for $\mathbb{P} \{ M \leq \Phi^*(y) \}$, we get a lower bound for the false alarm probability.

**D. Proof of Theorem III.2**

The proof of Theorem III.2 relies on two lemmas: Lemma A.2 and Lemma A.3 which are stated below. Lemma A.2 states that for “sufficient” number of observations the random variables are “almost” positive.

---

17 In microeconomic theory, $x_t$ is said to be “revealed preferred” to $\hat{x}$. Since $x_t$ was chosen as response for the probe $p_t$, the utility at $x_t$ should be higher than the utility at $\hat{x}$.
Lemma A.2. Assume that the noise components are i.i.d zero mean unit variance Gaussian random variables. For $\varepsilon > 0$, $T = O(\log 1/\varepsilon)$ and $T - \tau = O(\log 1/\varepsilon)$, we have:

\[
P\{M_1 \leq 0\} < \varepsilon,
P\{M_2 \leq 0\} < \varepsilon
\]

Define, auxiliary random variables, $\hat{M}_1$ and $\hat{M}_2$, which corresponds to the truncated distributions of $M_1$ and $M_2$ as shown below:

\[
f_{\hat{M}_i}(x) = f_{M_i}(x) \mathbb{I}\{x \geq 0\} + P(M_i < 0) \delta(x) \quad \text{for } i = 1, 2,
\]

where, $\delta(x)$ is the delta function. Then, Lemma A.3 states that the expectation of the auxiliary random variables $\hat{M}_i; i = 1, 2$, are close to the expectation of the original random variables, $M_i; i = 1, 2$.

Lemma A.3. Assume that the noise components are i.i.d zero mean unit variance Gaussian random variables. For $\varepsilon > 0$, $T = O(\log 1/\varepsilon)$ and $T - \tau = O(\log 1/\varepsilon)$, we have:

\[
|E\hat{M}_1 - EM_1| < 2\varepsilon,
|E\hat{M}_2 - EM_2| < 2\varepsilon.
\]

The proof of Lemma A.2 and Lemma A.3 are provided in Appendix E and Appendix F, respectively.

Proof (Theorem III.2): For $\Phi^*(y) > 0$, the probability of Type-I error is given by $P\{M \geq \Phi^*(y)\}$.

\[
P\{M \geq \Phi^*(y)\} = P\{M_1 + M_2 \geq \Phi^*(y)\}
\]

If $\tau = O(1/\varepsilon)$, by Lemma A.2 and Lemma A.3, the truncated distribution have a small probability of being less than 0 and the expectation of the truncated distribution is close to the original distribution. Hence,

\[
E\hat{M}_1 + \hat{M}_2 \geq \Phi^*(y)
\]

By Markov inequality,

\[
\frac{E\{\hat{M}_1 + \hat{M}_2\}}{\Phi^*(y)} \leq \frac{E\{\hat{M}_1\}}{\Phi^*(y)} + \frac{E\{\hat{M}_2\}}{\Phi^*(y)}
\]

Since, $\hat{M}_2$ is a positive random variable,

\[
E\hat{M}_1 = \int_{0}^{\infty} \frac{P\{M_2 > z\}dz}{\Phi^*(y)} + \int_{0}^{\infty} \frac{\sum_{t \geq \tau, \tau \neq t} P\{\alpha(w_t - w_s)/\lambda_t > z\}dz}{\Phi^*(y)}
\]

\[
\leq \frac{E\{\hat{M}_1\}}{\Phi^*(y)} + \frac{\sum_{t \geq \tau, \tau \neq t} \exp(-z^2/4\|\alpha\|^2)dz}{\Phi^*(y)}
\]

Hence, the probability of Type-I error, is minimized by minimizing $\|\alpha\|^2$.

E. Proof of Lemma A.2

\[
P\{M_1 \leq 0\} = P\left\{\max_{s \neq t} (p_s(w_t - w_s)) \leq 0\right\}
\]

Choosing the set $\xi \subset \mathcal{M}$ as defined in (43) and since the set $\xi$ are negative dependent from Lemma A.1,

\[
\leq \prod_i P\{\xi_i \leq 0\}
\]

Each of the term if $\xi_i = (p_t(w_t - w_{t+1}))$ is distributed as $N(0, 2\|p_t\|^2)$. Let $N(0, \sigma^2)$ is the cdf of Gaussian random variable with mean $\mu$ and variance $\sigma^2$. Noting that $N(0, \sigma^2)(0) = 1/2$, we have the following

\[
\prod_i F_N(0, 2\|p_t\|^2)(0) = \prod_i \frac{1}{2} = \frac{1}{2^T} < \varepsilon.
\]

The proof for the second part is similar by an appropriate choice of a negative dependent set, $\xi$ and is hence omitted.

F. Proof of Lemma A.3

From the definition of the random variable $\hat{M}_1$ in (44),

\[
E\{\hat{M}_1\} = \int_{0}^{\infty} xf_{M_1}(x)dx + P(M_1 < 0)
\]

\[
< \int_{0}^{\infty} xf_{M_1}(x)dx + \varepsilon,
\]

where the inequality in (45) follows from Lemma A.2. The expectation of $M_1$ is given by

\[
E\{M_1\} = E\{M_1 \mathbb{I}\{x \geq 0\}\} + E\{M_1 \mathbb{I}\{x \leq 0\}\}
\]

To continue with the proof, we derive a lower bound on $E\{M_1 \mathbb{I}\{x \leq 0\}\}$, the second term in (46).

The following upper bound follows trivially,

\[
E\{M_1 \mathbb{I}\{x \leq 0\}\} \leq 0.
\]

For computing the lower bound, we proceed by integration by parts

\[
E\{M_1 \mathbb{I}\{x \leq 0\}\} = \int_{-\infty}^{0} xf_{M_1}(x)dx = -\int_{-\infty}^{0} P\{M_1 \leq x\} dx.
\]

Choosing the negative dependent subset $\xi \subset \mathcal{M}$ defined in (43), and noting that each $\xi_i$ is distributed as $N(0, 2\|p_t\|^2)$ and using analytical expression for bounds of the cdf of the Gaussian density, we obtain

\[
\geq -\int_{-\infty}^{0} \prod_i P\{\xi_i \leq x\} dx \geq -\varepsilon
\]

From (45) and (48) we get the first part of the Lemma A.3. The proof for the second part is similar and hence omitted.
G. CUSUM algorithm for Utility change point detection

Algorithm 1 CUSUM algorithm for Utility change point detection

1: Initialize:
