Abstract

Although the modulation of Ca²⁺ channel activity by extremely low-frequency electromagnetic fields (ELF-EMF) has been studied previously, few reports have addressed the effects of such fields on the activity of voltage-activated Na⁺ channels (NaV). Here, we investigated the effects of ELF-EMF on NaV activity in rat cerebellar granule cells (GCs). Our results reveal that exposing cerebellar GCs to ELF-EMF for 10–60 min significantly increased NaV currents (Iₐ) by 30–125% in a time- and intensity-dependent manner. The NaV channel steady-state activation curve, but not the steady-state inactivation curve, was significantly shifted (by 5.2 mV) towards hyperpolarization by ELF-EMF stimulation. This phenomenon is similar to the effect of intracellular application of arachidonic acid (AA) and prostaglandin E₂ (PGE₂) on Iₐ in cerebellar GCs. Increases in intracellular AA, PGE₂ and phosphorylated PKA levels in cerebellar GCs were observed following ELF-EMF exposure. Western blotting indicated that the NaV, 1.2 protein on the cerebellar GCs membrane was increased, the total expression levels of NaV, 1.2 protein were not affected after exposure to ELF-EMF. Cyclooxygenase inhibitors and PGE₂ receptor (EP) antagonists were able to eliminate this ELF-EMF-induced increase in phosphorylated PKA and Iₐ. In addition, ELF-EMF exposure significantly enhanced the activity of PLA₂ in cerebellar GCs but did not affect COX-1 or COX-2 activity. Together, these data demonstrate for the first time that neuronal Iₐ is significantly increased by ELF-EMF exposure via a cPLA₂ AA PGE₂ EP receptors PKA signaling pathway.

Introduction

A number of studies have noted that exposure to extremely low-frequency electromagnetic fields (ELF-EMF) alter animal behaviors and modulate biological effects, including changes in gene expression, regulation of cell survival and promotion of cell differentiation [1–3]. In addition, exposure to ELF-EMF induces changes in cerebral blood flow in old Alzheimer’s mice. Enzyme activity in the cytosol or at the membrane and subsequent alternations in intracellular signaling are found in lymphoma B cells and Chinese hamster lung (CHL) cells upon exposure to ELF-EMF [4–6]. ELF-EMF can also modify the physical properties of cell membranes, such as changes in the membrane permeability of carbonic anhydrase [7], stimulation of the activity of Ca²⁺-activated potassium channels via increases in Ca²⁺ concentration [3,8] and increased the expression level of Ca²⁺ channel protein [9]. However, very few studies have investigated the effects of EMF on sodium channels, in particular, the voltage-gated sodium (NaV) channels which are highly expressed in neurons.

Voltage-gated sodium channels (NaV) are one of the primary classes of ion channels responsible for driving neuronal excitability in both the central and peripheral nervous system. NaV are clinically important because they play an important role in the generation of neuronal activity and alterations in NaV are key factors in a number of pathologies [10]. Recent studies have revealed that NaV channels participate in the rising phase of the neuronal action potential and contribute to many cellular functions including apoptosis, motility and secretory membrane activity [11–13]. Moreover, the EMF exposure was recently reported to modulate neuronal excitation and neurogenesis, which may be related to NaV channel activity [8,14,15]. Thus, a thorough investigation of the influence of ELF-EMF on NaV channels and the corresponding mechanism of action could help to uncover the effects of ELF-EMF-induced biological effects on brain physiology, pathogenesis and neural development.

Cerebellar granule cells (GCs) occupy a key position in the cerebellar–cortical circuitry by forming the input layer of the major cerebellar afferent system. Cerebellar GCs grown in primary culture express tetrodotoxin (TTX)-sensitive NaV channels which are responsible for action potentials (APs) and for the code relay in the cerebellar circuitry [16,17]. Cerebellar GCs are widely used as a model for neuronal cell development and apoptosis [18–20]. We have previously shown that the Iₐ of cerebellar GCs are modulated by the lipid products ceramide and arachidonic acid (AA). Ceramide reduces the Iₐ of
cerebellar GCs by increasing calcium release through the ryanodine-sensitive Ca^{2+} receptor [21] while elevation in intracellular AA levels increases the \( I_{Na} \) of cerebellar GCs through the PGE\(_2\)-mediated activation of the cAMP/PKA pathway [22]. The present study was conducted to determine whether exposure to ELF-EMF influences the Na\(^+\) channels of cerebellar GCs and, if so, whether this effect is mediated by changes in ceramide and/or arachidonic acid. The data presented in this report demonstrate that the activity of neuronal Na\(^+\) channels is significantly increased by ELF-EMF stimulation. Notably, the effect of ELF-EMF is mediated by an increase in cPLA\(_2\) activity and subsequent changes in intracellular concentration of arachidonic acid (AA) and EP receptor-mediated activation of the cAMP/PKA signaling pathway are involved.

**Results**

First, we investigated the actions of extremely low frequency electromagnetic fields (ELF-EMF) on the \( I_{Na} \) of cerebellar GCs. An \( I_{Na} \) was elicited by a depolarization step to \(-20\) mV from the holding potential of \(-100\) mV. When cerebellar GCs were exposed to ELF-EMF (1 mT) for 10 min, the amplitude of the \( I_{Na} \) was increased by approximately 51.8\% + 3.8\% (n = 12, \( P < 0.05 \)) compared to cells that were not exposed to ELF-EMF (n = 8, Fig. 1A). However, the mean capacitance of recorded cells for the control group (13.05 ± 0.40 pF, \( n = 7 \)) and for the ELF-EMF treatment group (12.45 ± 0.77 pF, \( n = 6 \)) showed no significant difference (F = 0.48). The similar in capacitance indicated that the increased current density upon ELF-EMF exposure was not due to different in abnormal cell morphology. In addition, the increase in \( I_{Na} \) density induced by ELF-EMF exposure was time dependent. When cerebellar GCs were exposed to ELF-EMF for 30 min, 60 min or 90 min, the density of the \( I_{Na} \) increased by 67.1\% ± 4.38\% (n = 8, \( P < 0.05 \)), 125.6\% ± 8.26\% (n = 16, \( P < 0.05 \)), 102.4\% ± 4.1\% (n = 9, \( P < 0.05 \)), respectively, compared to controls (Fig. 1B). We also tested the effects of low-density ELF-EMF (0.4 mT) on \( I_{Na} \). The results shown in Fig. 1C indicated that, when cerebellar GCs were exposed to 0.4 mT ELF-EMF, a longer exposure time was needed to induce an increase in \( I_{Na} \) density. The density of \( I_{Na} \) was only increased by 3.62\% ± 2.38\% (n = 6) when cerebellar GCs were exposed to ELF-EMF (0.4 mT) for 6 h. Upon an increase in the length of cell exposure to ELF-EMF (0.4 mT) to 12 h, the \( I_{Na} \) density increased by 31.6\% ± 3.38\% (n = 8, \( P < 0.05 \), Fig. 1D). Because a previous study indicated that when cells are exposed to ELF-EMF over a long term, their levels of protein expression may be affected [5], which will be difficult to further identify the primary factor involved in the ELF-EMF-induced \( I_{Na} \) increase. Thus, we chose to focus on the mechanism by which a relatively short-term exposure to a 1 mT ELF-EMF induces an \( I_{Na} \) increase.

Next, we investigated the effects of ELF-EMF on the voltage-gating properties of \( I_{Na} \) channels. The activation properties of \( I_{Na} \) in cerebellar GCs following exposure to ELF-EMF were studied using the appropriate voltage protocols. \( I_{Na} \)s were evoked by a 20 ms depolarizing pulse from a holding potential of \(-100\) mV to potentials between \(-70\) and \(-20\) mV, with 5 mV steps 5 s intervals (Fig. 2A). Fig. 2B illustrated a voltage-current curve in which the maximum activation potential was changed from \(-27.3 ± 0.9\) mV to \(-32.5 ± 2.5\) mV when cerebellar GCs were exposed to ELF-EMF for 60 min (n = 13 for control and n = 12 for ELF-EMF exposure, \( P < 0.05 \)). A value for steady-state activation of \( I_{Na} \) was then obtained by normalizing the conductance as a function of the command potential; conductance was calculated as \( G_{Na} = I_{Na}/(V_{m1}/2-V_{rev}) \). The data points were fitted to the Boltzmann function \( G_{Na}/G_{Na-max} = 1/(1+exp [(V_{m1}/2-V_{rev})/k]) \). As shown in Fig. 2C, when cerebellar GCs were exposed to ELF-EMF for 60 min, the half-activation potentials changed from \(-40.93 ± 0.67\) mV to \(-46.07 ± 2.35\) mV (n = 10, \( P < 0.05 \)), with slope factors of 3.7 ± 0.1 mV and 4.6 ± 1.0 mV (n = 10). These data indicate that ELF-EMF exposure significantly shifts the voltage dependence of the steady-state activation of \( I_{Na} \) of cerebellar GCs.

Next, we studied the effects of ELF-EMF exposure on the voltage dependence of the steady-state inactivation of \( I_{Na} \) channels. \( I_{Na} \)s were elicited using 1-s conditioning pre-pulses ranging from \(-100\) to \(-40\) mV in steps of 5 mV prior to a \(-10\) mV test pulse (Fig. 2D). The steady-state inactivation curve was then fitted using the Boltzmann equation \( I_{Na}/I_{Na-max} = 1/(1+exp [(V_{Na}-V_{Na/2})/k]) \). In the 11 cells studied, the \( V_{Na/2} \) values were \(-72.7 ± 0.74\) mV (n = 6) and \(-68.2 ± 0.75\) mV (n = 5) for cells with or without ELF-EMF exposure, respectively (Fig. 2E). These data indicate that the steady-state inactivation curve of \( I_{Na} \) in cerebellar GCs did not significantly shift upon exposure to ELF-EMF.

Our previous study showed that elevation in arachidonic acid (AA) concentration increased \( I_{Na} \) through prostaglandin E\(_2\) (PGE\(_2\))-mediated activation of the cAMP/PKA pathway [22]. In the present study, the effect of ELF-EMF exposure on \( I_{Na} \) and the \( I_{Na} \) steady-state inactivation curve was similar to the effect of AA on \( I_{Na} \). We therefore tested whether cAMP/PKA activation was involved in the increase in \( I_{Na} \) in cerebellar GCs subjected to ELF-EMF exposure. The results in Fig. 3A showed that H-89, a selective PKA antagonist, significantly attenuated the increase in \( I_{Na} \) elicited by ELF-EMF exposure. Incubating cerebellar GCs with 10 \( \mu \)M H-89 for 60 minutes decreased the evoked \( I_{Na} \) by 42.7\% ± 4.0\% (n = 9, \( P < 0.05 \)). There was, however, only 12.4\% ± 6.4\% (n = 14) in \( I_{Na} \) after exposure to ELF-EMF in the presence of H-89. Hence, H-89 suppressed the induction of the \( I_{Na} \) activity after ELF-EMF exposure. Similarly, administration of 10 \( \mu \)M dibutyl cAMP (db-cAMP, an embrane-permeable cAMP analog) produced a significant increase of \( I_{Na} \) by 47.2\% ± 6.6\% (n = 7, \( P < 0.05 \)). Notably, exposure to ELF-EMF did not further potentiate the effect of db-cAMP on \( I_{Na} \) (54.8 ± 8.9\%, n = 20). Hence, these data support our conclusion that cAMP/PKA pathway is involved in the effect of ELF-EMFs on \( I_{Na} \).

In addition, we determined the intracellular levels of phosphorylated PKA (pPKA) by immunoblot assays and found significant increase in phospho-PKA after ELF-EMF exposure. These data indicate that when the cells were exposed to ELF-EMF, the intracellular levels of pPKA were increased by 38.6\% ± 3.76\% (n = 4, \( P < 0.05 \)), 42.4\% ± 4.32\% (n = 4, \( P < 0.05 \)), 30.4\% ± 1.5\% (n = 4, \( P < 0.05 \)) and 17.8 ± 2.14\% (n = 4, \( P < 0.05 \)), respectively (Fig. 3C). These data suggest that PKA activation is associated with the ELF-EMF-induced increase in \( I_{Na} \) in cerebellar GCs.

Previous study indicated that \( I_{Na} \) activities can be modulated by the cAMP/PKA pathways upon phosphorylation of the \( \alpha \)-subunits of Nav\(_{m} \) channels [23]. Besides increases in the modification of steady-state activation propriety, exposure to ELF-EMF might also elicit insertion of additional Nav channels into the membrane, which might then further account for the ELF-EMF-induced up-regulation of \( I_{Na} \). To investigate whether ELF-EMF induced insertion of new Nav channels on the membrane, we first ascertained that Nav\(_{m} \) 1.2 \( \alpha \)-subunits plays a significant role in Nav\(_{m} \) channel of cerebellar GCs as reported previously [17]. As shown in Fig. 4A, the expression of Nav\(_{m} \) 1.2 was significantly reduced by siRNA. Similarly, the current amplitude of \( I_{Na} \) was also significantly reduced. The current amplitude of \( I_{Na} \) recorded from
the control group was 1400.32 ± 162.15 pA (n = 7), and it was reduced to 207.89 ± 95.55 pA (n = 5, P < 0.05) after knocking down the NaV 1.2 gene (Fig. 4B).

Next, we determined the levels of NaV 1.2 protein on the membrane surface using biotinylation assay. The data obtained from four independent experiments showed that the NaV 1.2 protein on the cerebellar GCs membrane (NaV 1.2 M) was increased by 21.8% ± 3.3% after exposed to ELF-EMF for 60 min (Fig. 4C). The total expression levels of NaV 1.2 protein (NaV 1.2 T), however, was not affected after exposure to ELF-EMF (Fig. 4D). These data indicate that exposure to ELF-EMF activates PKA, which then modulates INa, in part, by insertion of new NaV channels into the membrane.

It is well known that the cellular effects of PGE2 are mediated through a family of G-protein-coupled receptors designated EP1, EP2, EP3 and EP4 [24,25]. Of these, EP2 and EP4 are involved in activation of the cAMP/PKA pathway [26]. Our previous study demonstrated that all four types of EP receptors mRNA are found in cerebellar GCs [22]. Because EP2 and EP4 receptors can activate the PKA pathway, we used EP2 and EP4 receptor antagonists (AH6809 and AH23848, respectively) to investigate whether EP receptors played a role in the activation of PKA after exposure to ELF-EMF. As shown in Fig. 5A and 5B, in the presence of 20 μM AH6809 or 20 μM AH23848, 60 minutes of ELF-EMF exposure only increased INa by 9.54% ± 4.7% (n = 6) and 5.52% ± 4.71% (n = 5), respectively. In the absence of the EP receptor antagonists, exposure to ELF-EMF increased INa to 125.6% ± 8.26% (n = 16, P < 0.05). Similarly, blocking EP2 and EP4 receptors using AH6809 or AH23848 significantly reduced the ELF-EMF exposure-induced increase in pPKA levels. The results in Fig. 5C showed that in the presence of 20 μM AH6809 or 20 μM AH23848, 60 min of ELF-EMF exposure only increased intracellular levels of pPKA by 7.25% ± 1.67% or 6.5% ± 2.8% (n = 4), respectively.

Because EP receptors, which stimulate the cAMP/PKA signaling pathway, are activated by PGE2, we next studied the release of PGE2 from cerebellar GCs following exposure to ELF-EMF using a direct rat PGE2 ELISA kit. As shown in Fig. 6A, the amount of PGE2 released from control cerebellar GCs was 64.36 ± 1.88 pmol. Following exposure to ELF-EMF...
for 10 min, 30 min, 60 min or 90 min, the PGE2 content obtained from three independent experiments was significantly increased by 9.6% ± 5.3%, 23.9% ± 4.8%, 20.9% ± 6.2% and 19.2% ± 5.9%, respectively (n = 3, P < 0.05). We also assessed the levels of intracellular AA, which can be metabolically converted to PGE2, using a direct rat AA ELISA kit to address whether the increase in PGE2 after ELF-EMF exposure was the result of an increase in intracellular AA. The results in Fig. 6B showed that the intracellular AA levels were significantly increased following exposure to ELF-EMF. When cerebellar GCs were exposed to ELF-EMF for 10 min, 30 min, 60 min or 90 min, the intracellular AA levels measured in three independent experiments were significantly increased by 9.25% ± 5.45%, 25.21% ± 1.26%, 43.8% ± 1.23% and 17.64% ± 7.4%, respectively (n = 4, P < 0.05).

AA is converted to prostaglandins by either the cyclooxygenase, the lipoxygenase or the monooxygenase pathways [27]. In particular, cyclooxygenase-2 (COX-2) is reported to play a key role in the release of PGE2 [28]. To test that the increase in INa after ELF-EMF exposure was due to an increase in intracellular AA, we investigated the effect of the selective COX-2 inhibitors flufenamica acid (FA) and nilmunic acid (NA). Administration of 10 µM FA or 20 µM NA alone reduced the INa amplitude of cerebellar GCs by 23.6% ± 1.2% (n = 4) and 14.7% ± 2.3% (n = 8), respectively. In the presence of 10 µM FA or 20 µM NA, the increase in INa induced by ELF-EMF exposure was abolished (Fig. 6C and 6D). The INa density in cerebellar GCs exposed to ELF-EMF for 60 min was increased by only 14.3% ± 3.4% (n = 8) or 6.3% ± 2.7% (n = 10), respectively, which were significantly different from those derived from cerebellar GCs exposed to ELF-EMF alone (125.6% ± 8.2%, n = 16).

To ascertain the role of COX in mediating the effects of ELF-EMF on cerebellar GCs, we determined the activities of both COX-1 and COX-2 using selective COX-1 and COX-2 ELISA kits. When cerebellar GCs were exposed to ELF-EMF for lengths of time ranging from 10 min to 90 min, the intracellular activity of COX-1 was increased from 5.0% ± 1.2% to 6.3% ± 2.3% (n = 4, P < 0.05).

\[ \text{AA} \rightarrow \text{prostaglandin} \]

Given that cytosolic phospholipase A2 (cPLA2) also plays an important role in producing intracellular AA [29], we measured the activity of intracellular cPLA2 in cerebellar GCs before and after ELF-EMF exposure using an ELISA kit and immunocytochemistry. As shown in Fig. 7C, ELF-EMF exposure significantly
enhanced cPLA2 activity, especially in the first 10 min to 30 min after exposure. Data obtained from four independent experiments indicated that exposing cerebellar GCs to ELF-EMF for 10 min, 30 min, 60 min or 90 min significantly increased cPLA2 activity by 19.78±6.93%, 15.25±2.7%, 5.92±1.61% and 1.76±2.0%, respectively (n=4, P<0.05). The effects of ELF-EMF exposure on intracellular cPLA2 levels in cerebellar GCs were confirmed by immunostaining. As shown in Fig. 7D, a low level of cPLA2 labeling was detected in cerebellar GCs without exposure to ELF-EMF (Fig. 7D, left). After exposure to ELF-EMF, cerebellar GCs showed a significant increase in staining for cPLA2 (Fig. 7D, right), indicating that ELF-EMF exposure significantly increased intracellular cPLA2 levels. A model depicting the possible mechanisms involved in the modulation of \( I_{Na} \) by ELF-EMF exposure in cerebellar GCs is shown in Fig. 8.

**Discussion**

Although ELF-EMF exposure has been previously reported to modulate the activity of ion channels, few studies to date have measured the effects of EMF exposure on neuronal \( I_{Na} \). Here, we report for the first time that ELF-EMF exposure enhances \( I_{Na} \) in cerebellar GCs. In particular, exposure of cerebellar GCs to ELF-EMF influences the activity of PLA2, thus stimulating the production of intracellular AA, which is then converted to PGE2. PGE2 then enters the extracellular space and binds to EP receptors, activating the cAMP/PKA pathway and accounts for the induction of \( I_{Na} \).

ELF-EMF Increases $I_{\text{Na}}$ in Rat Cerebellar GCs and Alters NaV Channel Kinetics

Although several ion channels, such as $\text{Ca}^{2+}$ and $\text{Ca}^{2+}$-activated $K^+$ channels [8,9], are known to be modulated by EMF, the effects of EMF on NaV channels are poorly understood. Arthur D. Rosen’s studies in GH3 cells indicated that there was a slight shift in the current-voltage relationship and a less than 5% reduction in peak current during 125 mT static magnetic field exposure [30]. The authors speculated that a physical deformation in the liquid crystal membrane may be associated with these changes [30]. However, the changes observed in the steady-state activation characteristics of NaV channel kinetics during exposure to ELF-EMF in our study are due to an AA metabolite-induced increase in $I_{\text{Na}}$, a result that is similar to those obtained previously [22]. Interestingly, the effects of ELF-EMF on carbonic anhydrase entrapped in liposomes seem to exclude the role of protein molecules but in favor of a direct action on charged lipids of the membrane [7]. Moreover, in experiments using $\text{Ca}^{2+}$-activated $K^+$ channels in dorsal root ganglion-isolated neurons, Marchionni et al. did not observe modifications in single-channel behavior that suggested a direct action of EMF on membrane proteins [9], consistent with the hypothesis that ELF-EMF-stimulated enhancement of $I_{\text{Na}}$ in rat cerebellar GCs is not related directly to physical changes within the membrane and that an AA metabolism-related pathway might be involved. The discrepancy of these two reports may be due to the use of different cell type and different form of EMF source.

The time course for the effects of ELF-EMF on the activity of NaV in this study is noteworthy. In previous studies, the effects of exposure to EMF differed significantly based on whether the exposure occurred for minutes, hours or days. Here, we demonstrate that exposure to ELF-EMF induced similar effects on $I_{\text{Na}}$ in rat cerebellar GCs regardless the condition is 1 mT stimulation for a short time or 0.4 mT stimulation for a longer time. Notably, it is generally believed that short-term changes induced by EMF are mediated by modifications in enzyme activity in the cytosol or the membrane [4,31,32] while the long-term exposure to EMF may induce changes in nuclear functions such as gene transcription and cell cycle regulation [33,34]. Moreover, a

doi:10.1371/journal.pone.0054376.g005
previous study in cerebellar GCs indicated that a five-day EMF exposure contributes to premature expression of GluRs, and leads to more rapid cellular maturation [35]. To avoid the influence of multiple factors due to long-term EMF exposure, we performed all our experiments at 1 mT EMF exposure for a short time, which we believe is well-suited to access the effect of ELF-EMF on intracellular signaling pathways.

**ELF-EMF Exposure Enhances INa via PGE2-mediated Activation of the cAMP/PKA Pathway**

It has been reported that the cAMP/PKA pathway can modulate NaV activity. In particular, the α-subunits of NaV channels are preferred substrates for phosphorylation by cAMP/PKA [36]. Either activation or inhibition of NaV channels has been reported, which is probably due to the difference in cell model used [37,38]. Our previous study demonstrated that intracellular application of AA increases the activity of NaV via the activation of the cAMP/PKA pathway in cerebellar GCs [22]. Consistent with the previous findings, we observed that the PKA signaling plays an important role in the increase in INa after exposure to ELF-EMF. In light of our findings that ELF-EMF activates PKA signaling (Fig. 3), modifies steady state properties of the NaV (Fig. 2) and increases insertion of NaV into the membrane (Fig. 4), we speculate that the effect of ELF-EMFs on INa is likely exerted at multiple levels. In addition to the changes in voltage-gating property and insertion of additional NaV channels into the membrane, exposure to ELF-EMFs may also modulate the single channel properties by phosphorylation of channel protein. Recording of single-channel activity, however, is of technically challenging and requires specialized set up for such precise measurement. Nonetheless, the possible regulation of NaV channels upon PKA phosphorylation warrants future investigations.

Previous studies by Sibylle Thumm et al. reported that ELF-EMF (20 Hz, 7–8 mT) exposure for 60 min resulted in an increase in PKA activity in human skin fibroblasts and rat embryonic osteoblasts [39]. The underlying mechanism by which PKA was activated by ELF-EMF exposure, however, was not known. In synovial fibroblasts of an osteoarthritis patient, ELF-EMF exposure-induced changes in cAMP levels were associated with a selective increase in adenosine receptor expression [33]. Similarly, our results indicate that exposure to ELF-EMF induces an increase in PKA activity and that treatment with EP2 and EP4 antagonists abolished this effect. Moreover, we observed that, along with EP receptor activation, PGE2 levels were also increased following ELF-EMF exposure. Our data indicate that the effects of ELF-EMF exposure on PKA activity might not reflect a direct effect on this enzyme. Rather, PKA activation is mediated by elevations of...
PGE$_2$, which then binds to the EP receptors to modulate PKA activity.

Increases in Intracellular PLA$_2$ Activity and AA Levels are Critical Steps in the ELF-EMF-mediated Enhancement of $I_{\text{Na}}$

It is well known that intracellular PGE$_2$ is derived from AA via the cyclooxygenase (COX) pathway, which includes COX-1 and COX-2 [28], and COX-2 has been reported to be the most abundant COX isozyme in neurons [40]. In our study, intracellular PGE$_2$ and AA levels were increased in cerebellar GCs following ELF-EMF exposure. Neither COX-1 nor COX-2 activity was significantly enhanced by ELF-EMF exposure. Inhibiting COX activity with specific inhibitors, however, eliminated the ELF-EMF exposure-induced increase in $I_{\text{Na}}$. Hence, an alternative pathway is likely involved for the increase in intracellular PGE$_2$ levels after ELF-EMF exposure.

In brain tissue, AA is mainly released downstream of cPLA$_2$. In this study, our results showed that intracellular AA levels in cerebellar GCs were significantly increased after EMF exposure.

cPLA$_2$ activity, which is important for rapid AA release in neurons, was also significantly enhanced by exposure to ELF-EMF, suggesting that the increases in cPLA$_2$ activity and AA levels are critical steps in the ELF-EMF-induced enhancement of $I_{\text{Na}}$. Using a cell-free PLA$_2$ assay, Song et al. failed to observe changes in PLA$_2$, including cPLA$_2$ and sPLA$_2$, following exposure to ELF-EMF (60 Hz, 0.1 or 1 mT) for 4 or 6 h [41]. The difference in these findings compared to our results in cerebellar GCs could be due to the use of a cell-free PLA$_2$ assay as cell membranes play an important role in mediating the effects of EMF on enzymatic activity [31]. Despite there is evidence for the involvement of cPLA$_2$ activity in the responses to a wide variety of stimuli such as oxidative stress and inflammatory factors [42,43], the relevant mechanism of ELF-EMF exposure-induced cPLA$_2$ activation remains unclear.

Physiological Implications

The effects of ELF-EMF on nerve cells have been extensively studied in various organisms [8,35]. Although the reported results are variable or contradictory due to differences in the experimental conditions and in the density and/or duration of EMF exposure...
exposure, EMF has recently been reported to modulate of neuronal excitatory functions and neurogenesis [8,14,15]. In addition, recent studies have revealed an important role for cPLA2 in the modulation of neuronal excitatory functions [29]. The findings from our molecular-level analysis of the macroscopic effects on $I_{Na}$ produced by exposure to ELF-EMF provide evidence for an important effect of EMF on neuronal excitation in the CNS. We also observed that the effects of ELF-EMF exposure on cerebellar GCs peaked and then declined with extended exposure time. Notably, this phenomenon was observed for $I_{Na}$ and also for enzyme activities. The observed effects is likely due to the cells reach equilibrium through self-regulation after the initial ELF-EMF exposure and its effect on cPLA2 and $I_{Na}$. Nonetheless, the modulatory effects on neuronal excitatory caused by exposure to ELF-EMF are complicated and varied. Therefore, further exploration is required to comprehensively analyze the physiological and/or pathological effects of ELF-EMF exposure on $I_{Na}$ along with the resulting neuronal consequences.

Materials and Methods

Ethics Statement

This study was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol was approved by the Committee on the Ethics of Animal Experiments of the Fudan University (Permit Number: 20090614-001). All surgery was performed under sodium pentobarbital anesthesia, and all efforts were made to minimize suffering.

Primary Cell Culture

Cells were derived from cerebellum of 7-day-old Sprague–Dawley rat pups as described previously [44]. Isolated cells were then plated onto 35-mm-diameter Petri dishes coated with poly-L-lysine (1 mg/ml) at a density of 2.5–6105/cm2. Cultured cells were incubated at 37°C with 5% CO2 in Dulbecco’s Modified Eagle’s Medium (DMEM) supplemented with 10% fetal calf serum, glutamine (5 mM), insulin (5 μg/ml), KCl (25 mM), and 1% antibiotic–antimycotic solution. All experiments were carried out with cerebellar GCs during 6–8 days in culture (DIC).

Electromagnetic Field Production

The system used to expose cerebellar GCs cells to electromagnetic fields was the same used in previous studies, with some revisions [I-ONE, Shanghai, China] [33,45,46]. Briefly, a 50 Hz magnetic field was generated by a pair of Helmholtz coils placed in opposition to each other. The coils were powered by a generator system that produced the input voltage of the pulse, and the magnetic flux densities could be regulated within the range of 0 to 1.0 mT. The device was powered by an AC power generator, and
the EMF frequency and density were monitored by an EMF sensor that was connected to a digital multimeter. The geometry of the system assured a uniform field for the exposed cultured cells. The surfaces of the culture plates were parallel to the force lines of the alternating magnetic field in the solenoid. Air and culture medium temperatures were continuously monitored for the duration of experiments. The maximum temperature increase recorded in the cultures that were exposed to ELF-EMF (compared to non-exposed cultures) was 0.4 ± 0.1°C. To identify any possible influence of this increase on our results, we compared data obtained from cerebellar GCs cultured in different CO2 incubators at temperature settings of 37.0 and 37.4°C, and the results are consistent. The incubator was kept closed all throughout the EMF or non-EMF experiments to make sure that the conditions were the same as for the exposed groups but without EMF.

**Patch-clamp Recordings**

Whole-cell currents of granule neurons were recorded using a conventional patch-clamp technique. In 6–8 DIC cerebellar granule cells, transient Ina are largely unclamped because of an event generated at a site electronically distant from the soma and prone to escape from clamp control, presumably the axon [47]. Therefore, we choose those cells that relatively isolated and only record currents without unclamped spike. Prior to current recordings, the culture medium was replaced with a bath solution containing (in mM): NaCl 145, KCl 2.5, HEPES 10, MgCl2 1 and glucose 10 (pH adjusted to 7.4 using NaOH). Soft glass recording pipettes were filled with an internal solution containing (in mM): NaCl 145, KCl 2.5, HEPES 10, MgCl2 1 and glucose 10 (pH adjusted to 7.4 using NaOH). The pipette resistance was 5–6 MΩ after filling with the internal solution. Whole cell series resistances of 6–8 MΩ were routinely compensated by more than 70%. All recordings were performed at room temperature (23–25°C).

**Intracellular AA Assay**

Intracellular AA levels in cerebellar GCs were measured as previously described [48], with minor modifications. Briefly, 1 x 10⁵ cells were plated in 35-mm dishes and grown to confluence. The cells were washed with 1 mL of bath solution and cerebellar GCs were exposed to 1 mT ELF-EMF for 10 min, 30 min, 60 min or 90 min. The media were then removed, and the cells were diluted with PBS (pH 7.2–7.4) until the cell concentration reached 1 million cells/mL. Following repeated freeze-thaw cycles, which result in cell damage and the release of intracellular components, the supernatant was collected by centrifugation for 20 min at 2000–3000 rpm and assayed for COX-1, COX-2 and PLA2 activities. The data represent the means of several experiments, as indicated in the figure legends.

**Phosphorylated Protein Kinase A Assay**

The cells were lysed in HEPES-NP40 lysis buffer (20 mM HEPES, 150 mM NaCl, 0.5% NP-40, 10% glycerol, 2 mM EDTA, 100 mM Na3VO4, 50 mM NaF, pH 7.5, and 1% proteinase inhibitor cocktail) on ice for 30 min. After centrifugation, the supernatant was mixed with 2× sodium dodecyl sulfate loading buffer and boiled for 3 min. The proteins were separated on a 10% polyacrylamide gel, transferred to polyvinylidene difluoride membranes (Millipore, MA, USA), blocked with 10% nonfat milk and incubated at 4°C overnight with a rabbit polyclonal antibody against the phosphorylated form of the PKA catalytic subunits (1:1000; Santa Cruz Biotechnology Inc., CA, USA) or a rabbit monoclonal antibody against GAPDH (1:1000; Sigma). After extensive washing with TBST, the membrane was incubated with horseradish peroxidase-conjugated anti-mouse or anti-rabbit IgG (1:10,000) (KangChen Bio-Tech, China) for 2 h at room temperature. Chemiluminescent signals were generated using a SuperSignal West Pico trial kit (Pierce, USA) and detected using a ChemiDoc XRS System (Bio-Rad Laboratories, Inc., CA, USA). The protein measurements were normalized to GAPDH and control/GAPDH as 1.0.

**Biotinylation Assay**

Cell surface proteins were biotinylated according to the product instruction and previously described [49]. Briefly, the neurons were incubated with 0.25 mg/mL of Sulfo-NHS-SS-biotin (Thermo scientific, Rockford, USA) for 45 min at 4°C, and then the reaction is blocked with 50 mM Tris (pH 8.0) for 20 min at 4°C. Cells were lysed in HEPES-NP40 lysis buffer. Biotinylated proteins were pulled down with Streptavidin Agrose Beads (Thermo scientific, Rockford, USA) overnight at 4°C and washed for 4 times with lysis buffer. The bound proteins were eluted by the sample buffer and analyzed by western blotting.

**Immunocytochemistry**

To detect changes in cPLA2 in cerebellar GCs following exposure to ELF-EMF, an immunocytochemical assay was performed using the following procedure. Isolated cortical neurons plated on coverslips were washed three times with 0.01 M PBS and then fixed with 4% PFA for 30 minutes, rinsed three times with PBS and pre-incubated for 1 hour in 6% normal donkey serum (v/v) in PBS plus 0.1% Triton X-100 at room temperature. The cells were then incubated with a rabbit anti-cPLA2 antibody (1:100 dilution, Santa Cruz Biotechnology Inc., CA, USA) for 2 hours in a humidified air chamber. After incubation, the cells were rinsed three times with PBS and then further incubated with a secondary donkey anti-rabbit IgG tagged with FITC (1:100 dilution) according to the manufacturer’s instructions. Briefly, 1 x 10⁵ cells were plated in 35-mm dishes and grown to confluence. The cells were washed with 1 mL of bath solution and were exposed to 1 mT ELF-EMF for 10 min, 30 min, 60 min or 90 min. The media was then removed, and the cells were diluted with PBS (pH 7.2–7.4) until the cell concentration reached 1 million cells/mL. Following repeated freeze-thaw cycles, which result in cell damage and the release of intracellular components, the supernatant was collected by centrifugation for 20 min at 2000–3000 rpm and assayed for COX-1, COX-2 and PLA2 activities. The data represent the means of several experiments, as indicated in the figure legends.
dilution, Jackson ImmunoResearch Laboratories, West Grove, PA) for 30 minutes at room temperature. The coverslips were then rinsed twice in PBS and mounted onto glass slides. For labeling of the Na+, 1.2 subunit, specific mouse monoclonal antibodies (from UC Davis/NINDS/NIMH NeuroMab Facility) were used as the primary antibody (at a working dilution of 1: 200). TRITC conjugated goat anti-mouse immunoglobulin G (1: 200 dilution, from Jackson ImmunoResearch Laboratories, West Grove, PA) was used as the secondary antibody.

siRNA design
Gene specific siRNA duplexes were designed to be homologous to NaV1.2 mRNA consensus sequence (GenBank accession number X03639). Primers for loop and 3’P-dT extensions contained 19-nt siRNA were commercially obtained (Invitrogen). The sense strand of the siRNA (5’-GGATATGGTTCCGAAAAT-3’), homologous to nt 165–198 of the NaV mRNA sequence, was chosen according to the recommendations by others (http://www.dharmacon.com/DesignCenter/DesignCenterPage.aspx). Restriction site Sac I was added to the 3’ tail of resulting molecule to facilitate ligating to Lentivector Lox 3.7.

Data Acquisition and Analysis
All currents were recorded using an Axopatch 200 B amplifier (Axon Instruments, Foster City, CA, USA) that was operated in voltage-clamp mode. A Pentium computer was connected to the recording equipment with a Digidata 1300 analog-to-digital (A/D) interface. The current was digitally sampled at 100 μs (10 kHz), and the current signals were filtered using a 5-kHz, five-pole Bessel filter. The currents were corrected online for leak and residual capacitance transients using a P/4 protocol. Data acquisition and analysis were performed using pClamp 8.01 software (Axon Instruments, Foster City, CA, USA) and/or Origin6.1 (MicroCal, Northampton, MA, USA). Statistical analysis was performed using Student’s t-test with non-paired or paired comparisons as relevant. The values are given as the means ± S.E.M., with n representing the number of cells tested. A value of P<0.05 was considered a significant statistical difference between groups. When multiple comparisons were made, the data were analyzed by a one-way ANOVA.

Chemicals
All drugs used were purchased from Sigma-Aldrich (St. Louis, MO, USA) except for the fetal calf serum. The DMEM culture medium and antibiotic–antimycotic solution were obtained from Gibco Life Technologies (Grand Island, NY, USA). The arachidonic acid, 3,5,8,11,14-eicosatetraynoic acid, flufenamic acid, phorbol-12-myristate-13-acetate, AH6809 and AH23848 were first dissolved in DMSO and then diluted in extracellular solution to a final DMSO concentration of <0.2%, which by itself, did not affect INa.
