Abstract
Photocurrent measurements have been performed on a quantum cascade detector structure under strong magnetic field applied parallel to the growth axis. The photocurrent shows oscillations as a function of \( B \). In order to describe that behavior, we have developed a rate equation model. The interpretation of the experimental data supports the idea that an elastic scattering contribution plays a central role in the behavior of those structures. We present a calculation of electron lifetime versus magnetic field which suggests that impurities scattering in the active region is the limiting factor. These experiments lead to a better understanding of these complex structures and give key parameters to optimize them further.

Introduction
The quantum cascade detector (QCD) [1] recently proposed and realized in both the mid-infrared [2] and the THz [3,4] range is a photovoltaic version of the quantum well infrared photodetector [5]. Their band structure are designed as quantum cascade lasers without any applied bias voltage [1,3]. QCD are totally passive systems and show a response only to photon excitation. As such, the QCD structure is designed to generate an electronic displacement under illumination through a cascade of quantum levels without the need of an applied bias voltage.

In a semiconductor quantum well structure, magnetic field applied along the growth direction breaks the 2D in-plane continuum into discrete Landau levels (LLs). This experimental technique has been used to evaluate the different contributions of scattering mechanism in complex quantum cascade structures [5-9].

We present in this article experimental photocurrent measurements under magnetic field applied along the growth direction. We develop a simple model of transport under illumination in a QCD. Through a comparison between experimental and calculation results, we evidence the mechanism limiting the response of the QCD.

Experimental setup and sample
The QCD under study is a GaAs/Al\(_{0.34}\)Ga\(_{0.66}\)As heterostructure with a detection wavelength of 8 \( \mu \)m as described in ref. [9]. It consists of 40 identical periods of 7 coupled GaAs quantum wells. Figure 1 recalls the principle of the device.

QCDs are mounted inside an insert at the center of a superconducting coil where a magnetic field \( B \) up to 16 T can be applied parallel to the growth axis. Light is emitted by a globar source from an FTIR spectrometer and guided to the sample. The experiment consists in measuring the current under illumination (\( I_{\text{light}} \)) without any applied voltage at 80 K while the magnetic field is swept from 0 to 16 T.

Results
Experimental result is illustrated on Figure 2a. The photocurrent shows oscillations as a function of the magnetic field, superimposed on a continuous decreasing background which is removed from the experimental data in Figure 2b. Minima of current are located at \( B = 10.1, 11.4, 13.0, \) and 15.3 T and are in agreement with crossing of LL \(|\text{up}, 0\rangle\) and LLs \(|\text{down}, p\rangle\) represented on Figure 2c. It leads to the conclusion that an elastic scattering mechanism is dominant in this structure and mainly involves the levels \(|\text{up}\rangle\) and \(|\text{down}\rangle\).
Discussion

We propose a model of transport in one period based on a rate equation approach. We assume that electrons are in the upper detector state $|\text{up}\rangle$ through absorption of a photon. Current as a function of lifetimes involved in this structure can be written:

$$J_q = \alpha N_{\text{down}} \left( \frac{\tau_{\text{up-down}}}{\tau_{\text{up-down}} + \tau_{\text{up-c}}} \right) = \alpha N_{\text{down}} \text{QE}. \quad (1)$$

The parameters $\alpha$ and $N_{\text{down}}$ are, respectively, the absorption factor and sheet density of $|\text{down}\rangle$ and are constant. The subscribe $c$ stands for the whole cascade. The quantum efficiency QE is the ratio of the lifetime $\tau_{\text{up-down}}$ divided by $\tau_{\text{up-down}} + \tau_{\text{up-c}}$ and corresponds to the fraction of electrons on the level $|\text{up}\rangle$ that contributes to the photocurrent. In our model we suppose that any incident photon generates an absorption between the levels $|\text{down}\rangle$ and $|\text{up}\rangle$.

We present in Table 1 the calculated scattering rates of the different processes at $B = 0$ T. For interface roughness, we used a Gaussian autocorrelation of the roughness, with an average height of $\Delta = 2.8 \, \text{Å}$ and a correlation length of $\Delta = 60 \, \text{Å}$. LO phonon emission scattering rate has been calculated as in ref. [10]. In our structure impurities scattering is the most efficient process [11]. Usually in GaAs quantum cascade structures this mechanism is neglected because the doped layers are not in the active region. In order to take into account the main scattering process we calculate ionized impurities scattering as a function of magnetic field. The details of the calculation are presented elsewhere [12].

Figure 3 represents a comparison between experimental data and electron-ionized impurities scattering time as a function of magnetic field. Figure 3b, c shows the two lifetimes involved in Equation 1 as a function of $B$ calculated with electron-ionized impurities scattering. Figure 3d shows the calculation of the related quantum efficiency.

The oscillating behavior at high magnetic field ($B > 9$T) is a result of the electronic transfer from $|\text{up}\rangle$ to $|\text{down}\rangle$. This transfer leads to minima in the current which fit well with $\tau_{\text{up-down}}$ and QE. The long period oscillating behavior of $\tau_{\text{up-c}}$ as a function of $B$ enhances the peak at $B = 14$ T in QE in agreement with

**Figure 2 Experimental result and LL fan chart**

(a) Current under illumination as a function of $B$ at 80 K and at zero bias. (b) $I_{\text{light}}$ as a function of $B$ where the decreasing background as been subtracted. (c) Fan chart of $|\text{up}, 0\rangle$ and $|\text{down}, p\rangle$ as a function of $B$ taking into account the band non-parabolicity.

| Scattering mechanism       | $1/\tau_{\text{up-down}}$ | $1/\tau_{\text{up-c}}$ |
|----------------------------|-----------------------------|--------------------------|
| LO phonon emission         | $7.0 \times 10^{11}$        | $7.2 \times 10^{11}$     |
| Interface roughness        | $6.0 \times 10^{11}$        | $8.6 \times 10^{12}$     |
| Impurity scattering        | $1.8 \times 10^{13}$        | $5.2 \times 10^{13}$     |

Calculations are performed using different scattering processes for an electron in the $|\text{up}\rangle$ subband at $B = 0$ T.
The series of peaks at $\tau_{\text{up-down}}$ under magnetic field between $|\text{up}\rangle$ and $|\text{down}\rangle$ levels. These peaks are enhanced from the active region, where they are enhancing performance. An optimized structure should take these values into account by shifting the impurities in another location of the structure in order to minimize $\tau_{\text{up-down}}^\text{imp}$.

The Laboratoire Pierre Aigrain is a “Unité Mixte de Recherche” between École Normale Supérieure, the CNRS, the University Paris 6 and the University Paris 7.

**Experimental data.** QE, which describes the performance of the detector, is oscillating between 74 and 85% under $B$. By extrapolating, at $B = 0$T, QE is equal to 75%, a value that should be increased to improve the detector performance. An optimized structure should take these results into account by shifting the impurities from the active region, where they are enhancing $\tau_{\text{up-down}}^\text{imp}$, to a position where they would only enhance $\tau_{\text{up-down}}^\text{imp}$. The series of peaks at $B < 9$T corresponds to a characteristic energy of 37 meV. This energy is attributed to transitions in the cascade involving an elastic scattering mechanism.

**Conclusion**

In conclusion, we observe oscillations of the photocurrent in a mid-infrared QCD as a function of $B$. These oscillations are due to electron-ionized impurities scattering. This mechanism is dominant in this structure because impurities are located in the active region. In order to improve further this efficiency, we suggest to shift the impurities in another location of the structure in order to minimize $\tau_{\text{up-down}}^\text{imp}$.

**Abbreviations**

LLs: Landau levels; QCD: quantum cascade detector.

**Acknowledgements**

This study has been supported by a grant of the Agence Nationale pour la Recherche (ANR).

**Authors’ contributions**

FRI, NPL and LAV performed magneto-transport experiment, analysed the data and drafted the manuscript. YG, FC and RF participated in the analysis of the data. AB, LD and VB designed the band diagram of the structure and performed analysis. MC and XM have grown the sample by molecular beam epitaxy. All authors read and approved the final manuscript.

**Competing interests**

The authors declare that they have no competing interests.
