### Abstract

We have analyzed natural variation in mitochondrial form and function among a set of *Caenorhabditis briggsae* isolates known to harbor mitochondrial DNA structural variation in the form of a heteroplasmic *nad5* gene deletion (*nad5:4*) that correlates negatively with organismal fitness. We performed *in vivo* quantification of 24 mitochondrial phenotypes including reactive oxygen species level, membrane potential, and aspects of organelle morphology, and observed significant among-isolate variation in 18 traits. Although several mitochondrial phenotypes were non-linearly associated with *nad5:4* levels, most of the among-isolate phenotypic variation could be accounted for by phylogeographic clade membership. In particular, isolate-specific mitochondrial membrane potential was an excellent predictor of clade membership. We interpret this result in light of recent evidence for local adaptation to temperature in *C. briggsae*. Analysis of mitochondrial-nuclear hybrid strains provided support for both mtDNA and nuclear genetic variation as drivers of natural mitochondrial phenotype variation. This study demonstrates that multicellular eukaryotic species are capable of extensive natural variation in organellar phenotypes and highlights the potential of integrating evolutionary and cell biology perspectives.

**Introduction**

Mitochondria are organelles that harbor DNA and produce most of the energy required to sustain eukaryotic life via an electron transport chain (ETC). Proper assembly and operation of the mitochondrial ETC relies upon the coordinated functioning of both nuclear and mitochondria-encoded subunits of ETC complexes. Hence, mutations affecting ETC genes can have a variety of detrimental consequences that manifest at cellular, tissue, and whole organism levels [1,2], and have been implicated in many complex human diseases [3–6]. Proximal effects of ETC mutations include altering mitochondrial reactive oxygen species (ROS) production [7,8], membrane potential (ΔΨM) [8–11], and other aspects of mitochondrial physiology. ROS are generated by the ETC as a byproduct of oxidative phosphorylation and are of particular interest because, when present at high levels, they can damage cellular macromolecules including mitochondrial and nuclear DNA and the components of the ETC itself [12]. Because ETC genetic variation can ultimately generate variation in organismal fitness through its effects on physiology, it is likely to be a significant target of natural selection. Accordingly, selection on ETC-dependent mitochondrial traits has been implicated in the evolution and diversification of life-history traits [13,14], thermal tolerance [15–17], aging [18], reinforcement and allopatric speciation [19,20,21–24].

Despite the broad relevance of mitochondria to evolutionary processes and human health, understanding mitochondrial genotype-phenotype relationships has proven difficult [25]. One reason for this is the variable phenotypic expression of mitochondrial ETC mutations caused by variation in mitochondrial DNA (mtDNA) mutation heteroplasy [26,27]. Heteroplasy occurs when both wildtype and mutant mtDNA genomes coexist within a mitochondrion, cell, tissue, or individual, and is a common characteristic of mtDNA mutations [28]. Heteroplasy is the root cause of mitochondrial threshold effects wherein phenotypic consequences of mtDNA mutations only arise when heteroplasy level reaches some threshold [26,27]. For such reasons, we still have a limited understanding of the causes and consequences of ETC mutations *in vivo*, and virtually no such information on naturally occurring heteroplasmic ETC mutations. To date, most studies have been conducted on isolated mitochondrial fractions, chemically treated cell lines or yeast strains, or on those containing experimentally generated mutations [29]. Advances in biological imaging techniques have facilitated recent *in vivo* studies of mitochondria and are permitting unprecedented views into the dynamic structure of mitochondria and mitochondrial populations. Regular cycles of fission, fusion, and degradation are now known to maintain organelar populations and contribute to spatiotemporal variation in mitochondrial morphology [30,31]. Recent studies have identified and charac-
terized genes that control mitochondrial fission and fusion [32–36]. In addition to these loci, mutations in a number of ETC genes also result in abnormal mitochondrial morphology [37–39]. It is increasingly apparent that mitochondrial shape and function are intimately linked such that changes in morphology can affect diverse processes such as free radical signaling, energy metabolism [32,39–43], and cell cycle regulation [44]. However, the physiological causes of altered mitochondrial shape and the effects of organelar morphology on organelar function are poorly known. Further, we have no information regarding standing levels of variation in these mitochondrial traits or its evolutionary consequences.

Recently, geographically diverse isolates of *C. briggsae* nematodes have been studied with the aim of developing a model for natural population genetic and genomic studies [45–48]. Like *C. elegans*, *C. briggsae* is globally distributed and offers many of the same advantages as an experimental system [49] however, *C. briggsae* exhibits higher rates of mutation [50,51], greater molecular genetic diversity, and more extreme population subdivision than *C. elegans*. Nuclear [46] and mitochondrial [52] genetic analyses have identified four major phylogeographic clades of *C. briggsae* (the distal three of which are shown in Fig. 1), which may be adapted to local thermal regimes [53,54] and other conditions. Howe and Denver (2008) discovered that many isolates of this species contain varying levels of a large, heteroplasmic mtDNA deletion named nad5A (Fig. 1A and further described in Materials and Methods). The deletion removes nearly half of the *NADH-dehydrogenase 5* (*nad5*) gene (Fig. 1B), which encodes a central subunit of mitochondrial ET complex I. *nad5A* appears to occur via illegitimate recombination events between the *nad5* gene and an upstream pseudogene, *Ψnad5-2*, derived from *nad5*. The “Kenya” (aka Nairobi) *C. briggsae* clade does not contain the pseudogene and therefore does not experience the deletion, while other *C. briggsae* isolates exhibit *nad5A* heteroplasmy levels ranging from zero to over 50%. A number of findings suggest that *nad5A* might be detrimental for several aspects of nematode health and fitness – especially when heteroplasmic levels exceed ∼40% [47,52] as expected based on studies of *nad5* and other complex I mutants [53–56]. Together with recent work showing that *nad5A* behaves as a selfish genetic element; i.e., experiences a strong transmission bias [48], these results indicate that isolate-specific *nad5* levels are probably shaped by a combination of evolutionary forces: recurrent mutation and deletion transmission biases, genetic drift due to sampling of mitochondria during fertilization, and truncation selection.

Here we expanded our previous work to analyze variation in *C. briggsae* mitochondrial form and function using natural and experimental hybrid populations of nematodes. This study provides an assessment of natural levels of subcellular phenotypic variation and takes a first step toward understanding how this species’ extensive ETC genetic variation may affect cellular traits in vivo. We identified traits that diagnose mitochondrial dysfunction and hypothesized that *C. briggsae* isolates with higher *nad5A* levels would exhibit mitochondrial phenotypes often associated with such dysfunction, including increased ROS, decreased ATPM, and more fragmented mitochondria. However, we found that several mitochondrial phenotypes were non-linearly associated with *nad5A* level and that much of the among-isolate phenotypic variation was best explained by phylogeographic clade membership rather than *nad5A* frequency. Analysis of mitochondrial-nuclear hybrid strains provided support for both mtDNA and nuclear genetic variation as drivers of natural mitochondrial phenotype variation.

**Materials and Methods**

**Nematode Strains and Culture Conditions**

For the current study, we used ten natural *C. briggsae* isolates and two experimental hybrid strains derived from three of those isolates (Fig. 1). The ten isolates represent three of the four major phylogeographic clades of *C. briggsae*, encompass the known range of *nad5A* heteroplasm level, and were chosen to include two isolates that do not experience the deletion and two isolates containing a putative compensatory mutation that limits *nad5A* formation [47,52]. We note here that we assayed a different strain of HK104 from that analyzed in Estes et al. (2011). Here we study the natural HK104 isolate, which has low *nad5A* (Fig. 1), while Estes et al. (2011) used an inbred HK104 line that had evolved higher *nad5A* frequency. Briefly, *nad5A* segregates among natural populations of *C. briggsae* and requires the presence of the *Ψnad5-2* pseudogene (Fig. 1B). Sequence repeats within *nad5A* and *Ψnad5-2* promote direct repeat-associated deletion events. Isolates in the Kenya clade (Fig. 1A) lack the pseudogene and are therefore spared *nad5A*. Among-isolate variation in *nad5A* heteroplasm level is also controlled by the presence of compensatory sequences within the mtDNA of certain isolates [47], which appear to place an upper bound on the proportion of *nad5A*-deletion bearing genomes able to accrue within individuals [52]. *nad5A* was recently shown to behave as a selfish genetic element that increases in frequency when *C. briggsae* isolates are maintained by single-individual bottlenecks [48]; however, *nad5A* heteroplasm level is stably maintained across generations when isolates are maintained in larger population sizes (N~100) where natural selection is more efficient (Estes, Coleman-Hulbert, Howe, and Denver, unpubl. data). Great care was taken to ensure that *C. briggsae* natural isolates did not experience population bottlenecks in the lab and *nad5A* heteroplasm levels were found to remain stable over the course of our study [47].

To test the relative contributions of mitochondrial and nuclear genomes to among-isolate phenotypic variability, we also studied two mitonuclear hybrid strains that contain the mitochondrial genome of one isolate (PB800 or HK105) upon the same (AF16) nuclear genetic background (Fig. 1C). These strains were generated through serial backcrossing of AF16 males to hermaphrodite cross-progeny for 10 generations. This process is expected to result in worms with >99.9% of their nuclear genome from AF16 and their mitochondrial genome from a separate *C. briggsae* isolate. We confirmed that each hybrid line encoded the expected mtDNA through PCR and direct sequencing of a portion of *nad5A* [52] and *COII* [61] genes. Each hybrid line was also confirmed to harbor *nad5A* levels similar to that of the original hermaphrodite mitonuclear donor parent through agarose gel analysis of PCR reactions using primers that flank the deletion region as described in Howe and Denver (2008) (Fig. 1C).

Nuclear contributions of hybrid lines were confirmed by evaluating six nuclear PCR loci, one for each of the six *C. briggsae* chromosomes, that contained single nucleotide polymorphism or large-indel variants between the two strains involved in the crosses. SNP variants were evaluated by fluorescent capillary DNA sequencing and large-indel variants were evaluated by agarose gel electrophoresis. The loci used were taken from published variants described in [62,63]. For the AF16 x HK105 hybrid lines (expected to contain AF16 nuclear DNA), 6/6 target loci contained differences between the strains and 6/6 of the loci were confirmed to contain only the AF16 sequence in the hybrid line. For the AF16 x PB800 cross (also expected to contain AF16 nuclear DNA), only 3/6 loci had diagnostic sequence differences between the two strains; the chromosome V locus employed was
identical between AF16 and PB800. However, 5/5 of the diagnostic nuclear loci confirmed the presence of the AF16 sequence only in the hybrid strain.

We note here that we attempted to generate additional sets of mitonuclear hybrid strains by crossing other pairs of C. briggsae natural isolates; however, molecular genetic assays revealed that bi-parental inheritance of mitochondrial genotypes had occurred in these lines. In a similar study involving inter-strain crosses in C. elegans, mitochondrial DNA was observed to be strictly maternally inherited (W.K. Thomas and K. Morris, unpubl. data). Thus, our result may suggest that favorable mitonuclear epistatic interactions specific to individual C. briggsae isolates were disrupted in some hybrid strains such that paternal mitochondria were transmitted to hybrid offspring [64–67]. Such a situation might arise if hybridization in some way disrupts the autophagic degradation of paternal mitochondria that normally occurs after fertilization [68,69], for example. These strains were therefore omitted from the current analysis.

Nematodes were grown under standard laboratory conditions at 25°C on 15 mm NGM Petri plates seeded with HB101 Escherichia coli as a food source. All strains were included in each analysis. Prior to each assay, age synchronous worms were obtained through a standard bleaching protocol.

Fluorescence Microscopy
We performed confocal image analysis on young adult nematodes treated with mitochondria-targeted fluorescent dyes. Fluorescent imaging provides the distinct advantage of allowing simultaneous localization and relative quantification of mitochondrial traits (Fig. 2). Additionally, recent work indicates that ROS data obtained from fluorescent analysis and electron spin resonance yield similar results [70]. This dye-based method has received criticism for its potential to be influenced by variable feeding rates [71]. Importantly, we find no correlation between pharyngeal pumping rates [47] and maximal ROS or DY measured here (ROS \( r = 0.024, p = 0.955 \); DY \( r = 0.167, p = 0.693 \)). Also, unlike dye-based methods performed using whole-worm lysate (B. Halliwell, pers. comm.), our method does not cause the disruption and release of organellar and intracellular contents, which can lead to increased ROS via the release of free iron and ensuing Fenton reactions [72]. Prior to each assay, age synchronous worms were incubated with E. coli labeled with 10 μM concentrations of the specific fluorescent dye(s) appropriate for each experiment. Concurrently, a second age synchronous batch of worms from the same strain was incubated without dye to serve as the control. After 24 hours of exposure, young adult stage worms were washed and transferred to fresh NGM plates containing unlabeled E.coli. Worms were allowed to feed for one day.

Figure 1. Natural and experimental C. briggsae strains and description of the nad5.4 mtDNA deletion. A. Phylogenetic relationship and nad5.4 heteroplasmy level of C. briggsae isolates studied here. GL = global superclade; KE = Kenya clade; TE and TR = temperate and tropical subclades of GL; C(+) = isolates bearing compensatory \( \Psi \) nad5.4-2 allele; C(-) = isolates bearing ancestral alleles. nad5.4 heteroplasmy categories were assigned to each C. briggsae natural isolate for statistical analysis following Estes et al. (2011): High = underlined font, medium = italicized, low = regular, and zero-nad5.4 = “N/A”. Note that we assayed the natural HK104 isolate here instead of the mutation-accumulation line progenitor reported in Estes et al. (2011), which had evolved high nad5.4 levels in the lab (See Materials and Methods). B. Positions of the nad5.4 deletion (dashed line at top) and \( \Psi \) nad5.4-2 elements in the mitochondrial genome. Primers are indicated by arrows (adapted from Howe and Denver, 2008). C. Mitochondrial and nuclear parent isolates for each mitonuclear hybrid. nad5.4 heteroplasmy for each hybrid strain matches that of the maternal isolates as expected. Mitochondrial phenotypes are expected to match those of the maternal isolate if measured traits are predominantly determined by the mitochondrial genotype.

hour, which clears the digestive tract of any labeled E. coli that could interfere with accurate fluorescence measurements. Immediately prior to imaging, worms were paralyzed following the methods of Dingley et al. (2009) with a single drop of 5 M levamisole (Molecular Probes Inc., Eugene, OR, Carlsbad, CA), which immobilizes worms by preventing depolarization of skeletal muscle [73].

For each dye-based assay, images of the pharynx of each nematode were collected. The pharynx is a neuromuscular organ that nematodes use to ingest bacteria [74]. We chose to analyze pharyngeal bulbs for two reasons: 1) they are easily visualized and have high levels of dye uptake, which serves to reduce technical variation, and 2) they are mitochondria-rich but contain few lipid droplets, which are highly autofluorescent and thus interfere with accurate measurement of mitochondrial fluorescence. Images were acquired using a high resolution wide field Core DV system (Applied Precision™, Issaquah, WA) equipped with an Olympus IX71 inverted microscope mounted with a Nikon Coolsnap ES2 HQ camera (Advanced Light Microscopy Core Facility, Oregon Health and Science University, Portland, OR). Fluorescent z-stack images of the pharyngeal bulb of individual worms were captured at 60X magnification using a short arc 250W Xenon lamp. All images were captured immediately following paralysis. Images were optimized by deconvolving, and relative fluorescence values were obtained using ImageJ software (NIH, Bethesda, MD).

Relative Mitochondrial Oxidant Levels

ROS levels were assessed in vivo for all C. briggsae isolates following the basic approach of [8] and described further in Estes et al. (2011). Briefly, worms were incubated for 24 hours in 10 uM MitoSOX Red (Molecular Probes Inc., Eugene, OR) before imaging as outlined above. MitoSOX Red was recently shown to quantify total levels of mitochondrial oxidants, rather than superoxide specifically, when used with confocal microscopy [75]. Images of the pharynx were captured with a 1.0 second exposure time. Terminal pharyngeal bulbs were manually encircled within each image to quantify mean fluorescence intensity of the area in exposed and unexposed (control) animals from each strain. The final pharyngeal bulb intensity values were calculated as the difference between intensity values for exposed and control worms. We note here that we have previously measured ROS levels for most of the natural isolates studied here [47] and that the results presented here are the combined data from the current study and the previous study. In the current study, however, we have doubled our sample size (20 individuals) and have included additional strains in the analysis: two mito-

Figure 2. Localization of mitochondria-targeted dyes in C. briggsae nematodes. A Z-projection image of MitoTracker Red CMXRos (red objects) and MitoTracker Green FM (green objects) specific staining, and colocalization of these probes (yellow objects) within an individual (after processing to find edges of objects). Green objects are relatively depolarized mitochondria that have taken up primarily MitoTracker Green FM probe; red objects are more polarized mitochondria that have taken up mostly MitoTracker Red probe. Yellow objects likely have intermediate polarization and have taken up equivalent amounts of each probe. Scale bar = 10 μm.

doi:10.1371/journal.pone.0043837.g002
nuclear hybrid strains, one isolate with an intermediate *nad5A* frequency level, ED3034, and the natural isolate of HK104 (Fig. 1A). All other isolates performed the same in each assay with respect to ROS (t ≤1.77, p=0.090); we therefore combined the ROS data from the two assays to increase statistical power.

The efficacy of a second mitochondrial ROS detecting dye, MitoTracker Red CM-H2XRos (Molecular Probes Inc., Eugene, OR), was assessed using the same protocol as above. We initially believed that this dye would be preferable over MitoSOX Red because of its greater sensitivity to ROS [70]. However, although the fluorescent signal from MitoTracker Red CM-H2XRos-treated mitochondria was distinct, the background fluorescence generated from non-specific lipid uptake of the dye decreased the precision of the fluorescence measurement [76]. MitoSOX Red generated less background fluorescence and produced more precise images, and was therefore used for mitochondrial ROS detection.

**Relative Mitochondrial ΔΨM**

Relative ΔΨM was assessed using MitoTracker Red CMXRos, the uptake of which is dependent upon mitochondrial ΔΨM. We utilized the ROS assessment protocol (above), except that a shorter, 0.08 seconds, exposure time was used for imaging; these assays were performed concurrently with those for mitochondrial morphology (below).

**Mitochondrial Morphology**

Quantification of differences in mitochondrial morphology was achieved by co-labeling worms with MitoTracker Green FM, which is not ΔΨM-specific, and MitoTracker Red CMXRos, which accumulates exclusively within actively respiring mitochondria (Fig. 2). This allowed us to distinguish between polarized and depolarized mitochondria. Worms were prepared for imaging as above, this time with exposures of 0.08 seconds for MitoTracker Red and 0.02 seconds for MitoTracker Green.

We also confirmed that altered ΔΨM would produce the expected effects on mitochondrial morphology [32] by depleting ΔΨM with 10 μM carbonylcyanide-3-chlorophenylhydrazone (CCCP, Sigma-Aldrich, St. Louis, MO) in 15 individuals from mid-deletion isolate, ED3034 (Fig. 1A). Beginning at the L1 stage, worms were transferred daily to fresh CCCP-treated plates until they reached young adulthood. Compared to an equal number of untreated ED3034 individuals, we found that CCCP treatment reduced the size of both the total and the functional (polarized) mitochondrial population (ΔΨM: F = 6.105, p = 0.0292; ΔΨM: F = 7.607, p = 0.0134), the size of individual functional mitochondria (ΔΨM: F = 4.591, p = 0.0425), and the variance in circularity of functional mitochondria (ΔΨM: F = 7.136, p = 0.0134) – as expected if organelles are becoming increasingly fragmented. (See below and Table 1 for further explanation.)

**Mitochondrial Localization of Fluorescent Dyes and Effect of Levamisole**

We observed extensive localization of MitoTracker Green FM and Red CMXRos (Fig. 2), which points to mitochondria-specific staining by fluorescent dyes. This specificity was further confirmed by depleting ΔΨM using CCCP (as above) and directly visualizing reductions in the fluorescence intensity of all probes used, especially the membrane-potential dependent dyes (data not shown). We also tested the effect of levamisole, the drug used to paralyze worms prior to imaging, on dye fluorescence using five age synchronous individuals from isolates PB800 and 1HK105 (Fig. 1). There was no significant effect of levamisole on the mean or maximum fluorescence values of MitoTracker Red CMXRos or MitoTracker Green FM, nor was there a levamisole-by-isolate interaction. Similarly, levamisole had no effect on the maximum values of MitoSOX fluorescence (t-tests, p=0.291); however, there were significant effects of levamisole (t = 2.29, p = 0.030) and the interaction of levamisole and isolate (t = 2.13, p = 0.051) on mean MitoSOX fluorescence. Maximum fluorescence values were therefore used for all statistical analyses so that any isolate-by-probe interactions generated by levamisole were unlikely to influence our among-isolate comparisons. Furthermore, maximum measures are more consistent in fluorescence image analysis because they are unaffected by variation in pixel size and mitochondrial number or area between images.

We also attempted to co-label nematodes treated as above with either DAPI or Hoechst 33342 (Sigma) in order to visualize cellular nuclei, which would have allowed us to assess the intracellular distribution of mitochondria. (Appropriate GFP fusions are not yet available for *C. briggsae*.) Unfortunately, both DAPI and Hoechst noticeably interfered with the fluorescence of the above MitoTracker dyes in *C. briggsae* (Hicks, pers. obs.). Our study therefore focuses on properties of individual mitochondria and mitochondrial populations within the pharyngeal tissue.

**Image Analysis**

All image analyses were performed in ImageJ (NIH, ver. 1.43 u). Quantification of relative ROS and ΔΨM levels was achieved by manually enclosing the terminal pharyngeal bulb of each image to find the average intensity of the area as described in [8]. Mitochondrial morphology traits were quantified by processing images following [77]. Briefly, visibility of MitoTracker stained structures was improved by applying a linear stretch of the pixel intensity histogram corresponding to each slice in the z stack. This process enhances the contrast of an image by adjusting the number of low and high intensity pixels in the image based on the lowest and highest pixel values in the current image [78]. The image was then converted into a z-projection, a process that effectively removes the spaces between each slice of the z-stack creating a composite image from all slices. A 7x7 top-hat filter was then applied, followed by a median filter and a thresholding step [77]. The thresholded image was then converted to a binary image, which results in white mitochondria on a black background that can be analyzed in ImageJ.

To quantify among-isolate differences in mitochondrial form and function, we defined and measured 24 traits (Table 1). We evaluated functionality of mitochondria based on relative membrane potential (ΔΨM mean, ΔΨM max) and reactive oxygen species (ROS mean, ROS max). We also quantified various features of the mitochondrial population: the combined area of the mitochondrial population (ΔΨM, ANP, APF), the area of the ratio of non-functional mitochondria (ΔΨM/P), the number of the total mitochondrial area that is functional (APF /TP), the number of organelles (NF, NC, NP), the ratio of functional to non-functional organelles (NF/NP), and the percentage of functional mitochondria (NF/TP), as defined by uptake of MitoTracker Red CMXRos. To describe organellar shape differences we quantified the area (ANP, ANP), aspect ratio (ARF, ARN), and circularity (CF, CN) of individual mitochondria. Aspect ratio measures the ratio between the long and short axes of an ellipse fit to the object in question [78]. It has a minimal value of 1, which corresponds to a perfect circle. Circularity (sometimes referred to as formfactor in the literature) is calculated as 4Π(area/perimeter²), and will also equal 1 when the measured object is a perfect circle. As the object becomes more elongated and/or branched, circularity approaches 0 [78]. Because circularity...

Table 1. Assigned labels and descriptions of all mitochondrial traits measured for *C. briggsae* natural isolates.
Natural Variation in Mitochondrial Phenotypes

We quantified natural variation in 24 phenotypes that describe mitochondrial function and shape (Table 1) among ten distinct *C. briggsae* isolates (Fig. 1A). A majority (18 of 24) of the measured traits exhibited significant among-isolate variation. Mitochondrial ΔΨM showed the greatest among-isolate diversity, followed by mitochondrial ROS levels (Table 1; Fig. 3). Notably, mitochondria that we considered to be functional (i.e., polarized) by virtue of their having sufficient ΔΨM to permit uptake of MitoTracker Red CMXRos (Fig. 2; Materials and Methods) did not vary significantly among isolates in shape or heterogeneity in shape (Table 1). In contrast, characteristics of shape and heterogeneity in non-functional (depolarized) mitochondria often differed significantly among isolates. Traits that describe features of mitochondrial populations (i.e., all ten traits that describe the combined area or number of mitochondria), however, differed among isolates for both functional and non-functional mitochondria (Table 1).

We also found striking variation among phylogeographic clades of *C. briggsae* (Fig. 3; Table S1). Of the nine traits that best distinguished isolates with different nad5A levels (see below), all but *N*~*F/N*~ – the ratio of the number of functional to non-functional organelles – varied significantly among *C. briggae* clades, consistent with a phylogenetic effect on many mitochondrial traits. In all of these cases, among-clade variation exceeded the variation observed within clades (Table S1). To further explore among-clade phenotypic differences, we used classification tree analysis to identify which of the 24 measured mitochondrial traits best distinguished three major phylogeographic clades of *C. briggae*.
Table S2). Classification trees invariably retained only ΔΨM in the analysis. Misclassification rates were somewhat high (34%); isolate-specific ΔΨM nonetheless accounted for 20% of the total variation among clades. Further, if we allowed classification trees to continue splitting beyond the optimal number of splits (i.e., when further partitioning failed to account for a significant fraction of the total variation), analyses again used ΔΨM to further classify groups of isolates.

Possible Relationships between nad5Δ and Phenotypes

We also used classification trees to determine whether mitochondrial traits distinguished groups of C. briggsae isolates with different nad5Δ heteroplasmky levels (Fig. 1A). Classification trees invariably used ROS and ΔΨM to classify nad5Δ frequency groups (Table S2). In addition to ROS and ΔΨM levels, the phenotypes most often used to classify nad5Δ categories were the area of non-functional and functional mitochondrial populations (ANP, AFP), descriptors of non-functional mitochondrial shape (AN, ARN, C N, CNV), and the ratio of functional to non-functional mitochondria (NF/N) (Table S2). About 45% of the total phenotypic variation was accounted for, but misclassification rates were again fairly high (33% on average), meaning that these traits were imperfect predictors of nad5Δ category.

As a second means of testing for any association between mitochondrial phenotypes and nad5Δ frequency in C. briggsae, we examined individual relationships between all measured traits and isolate-specific nad5Δ level. A second order quadratic provided the best fit of many traits to nad5Δ percentage (Fig. 3; Table S3); however, only a minimal amount of the total variation in these traits could be attributed to nad5Δ level (low R2 values in Table S3). For instance, zero- and high-nad5Δ isolates exhibited the highest values for mitochondrial ROS and ΔΨM; however, the relationship between these traits and nad5Δ is weak (Fig. 3; Table S3). All mitochondrial traits describing non-functional organelle shape (ARN, CN, CNV) exhibited stronger non-linear (quadratic) relationships with nad5Δ level, as did both measures describing the functional mitochondrial population (AFP, NF/N) (Fig. 3; Table S3). Neither the mean area of individual non-functional mitochondria (AN) nor the combined area of these mitochondria (ANP) was significantly associated with nad5Δ percentage in this analysis. However, non-functional mitochondria (AN) were larger on average than functional mitochondria (AF) (Table 1). Overall,
Insights from Mitochondrial-nuclear Hybrid Lines

To directly test whether the observed differences among *C. briggsae* isolates were due to mtDNA variation, we examined the nine phenotypes retained in classification tree analyses on two mitochondrial-nuclear hybrid strains (e.g., Fig. 4). If among-isolate variation in mitochondrial phenotypes is primarily due to an additive mtDNA genetic contribution, we predicted a correspondence between mitochondrial-nuclear hybrid strain phenotypes and their respective mitochondrial parental strain. Consistent with this idea, we observed that hybrid strains were more similar to their mitochondrial parent strains than to their nuclear parent strains (Table S4). Considering ROS and ΔΨM only, the hybrid strains were more similar to their mitochondrial parent in each case (Fig. 4). Note that in the AF16 and PB800 pairing, the hybrid is not significantly different from the nuclear parent, but is still more similar to the mitochondrial parent. The diversity in ROS and ΔΨM phenotypes seen in the three strains studied therefore appears to be due to variation in mtDNA as opposed to among-strain nuclear variation. However, the relative contribution of each genome was less clear for measures of the mitochondrial population and mitochondrial shape. These traits rarely differed significantly among parent and hybrid strains studied here (Table S4), although a larger study may have revealed small differences. A visual inspection of these data suggested that mitochondrial morphology traits may be more affected by the nuclear genome (hybrids are more similar to the paternal isolate) or by mitochondrial-nuclear epistasis (hybrids differ from both parental isolates), than were ROS and ΔΨM (not shown).

Discussion

Evolutionary Implications

We have used in vivo techniques with *C. briggsae* nematodes to conduct the first analysis of naturally-occurring variation in mitochondrial function, morphology, and properties of mitochondrial populations. We discovered considerable variation among natural *C. briggsae* isolates for most of the measured traits. In fact, we find more variation among natural isolates of *C. briggsae* for both ROS and ΔΨM than has been measured among ETC mutant strains of *C. elegans* [8,11]. This result is partly explained by the greater phenotypic variation observed within *C. elegans* mutant strains (e.g., see among-replicate variation in Figs. 2 and 3 in [8]) than within *C. briggsae* isolates; the source of this species difference is unclear. Our findings also mirror those of previous studies revealing extensive variation in life-history and metabolic traits among the same isolates [47,52]. A good deal of this variation was related to the phylogeographic clade membership of particular isolates (Fig. 3; Table S1); this was especially true for ΔΨM (Fig. 3G; Table S2). *C. briggsae* is globally distributed [80] and both mitochondrial and nuclear genetic analyses consistently reveal the existence of distinct phylogeographic clades that are separated by latitude [52,81]. These clades have experienced different population genetic histories [46,52,81] and show some evidence for local adaptation to temperature; e.g., Tropical clade isolates appear to have higher thermal maxima [53]. Consequently, divergence in mitochondrial phenotypes measured here may reflect clade-specific phylogenetic or selective histories. It is impossible to say without further study whether the among-clade differences in mitochondrial function measured here have an adaptive significance or are a non- or maladaptive consequence of genetic drift [52]; however, it is conceivable that Tropical *C. briggsae* isolates adaptively maintain low ΔΨM. Because *C. briggsae* is ectothermic, its biology will be driven strongly by environmental temperature. At higher temperatures, biological reactions such as those controlling electron transport and the subsequent production of ROS occur at higher rates [82]. The higher temperatures experienced by Tropical clade isolates may have thus subjected them to higher ROS levels during their evolutionary history. Reducing ROS production, especially from complex I, may be achieved by lowering ΔΨM by uncoupling oxidative phosphorylation [83,84]. We may therefore hypothesize that Tropical *C. briggsae* have adaptively reduced their ΔΨM to counter increased ROS levels brought on by higher temperatures and perhaps exacerbated by nad5A-induced complex I inefficiency.

Although other traits appear to be influenced by both nuclear and mitochondrial genetic contributions, our data are consistent with the interpretation that much of the among-isolate variation in mitochondrial ROS and ΔΨM can be attributed to mitochondrial genome content rather than to nuclear divergence among isolates (Fig. 4; Table S4). In agreement with this finding, ROS level and ΔΨM were shown to be the best predictors among those tested of nad5A category in classification analyses (Table S2). Because mitochondrial electron transport relies upon the coordinated functioning of both mitochondrial and nuclear encoded ETC components, there is ample opportunity for epistatic interactions between mtDNA and nuclear genomes [67,85–87]. A recent analysis of recombinant inbred lines generated from reciprocal crosses between *C. briggsae* isolates AF16 and HK104 provides indirect evidence for such mitochondrial-nuclear incompatibilities [45]. In agreement with this result, we observed extensive paternal transmission of mitochondria in other sets of *C. briggsae* mitochondrial-nuclear hybrid strains (Materials and Methods). It could therefore have easily been the case that *C. briggsae* hybrids studied here bore
no similarity to either parental isolate as a result of interpopulation hybrid breakdown. This is particularly true for our hybrid strains, both of which resulted from crosses between a Tropical and a Temperate isolate (Fig. 1). That the results of our hybrid strain analyses for ROS and ΔΨM are consistent with an additive effect of the mitochondrial genome suggests that the natural isolates used to generate the hybrids have either not experienced functional divergence for the relevant ETC gene products or have purged variants that generate deleterious epistatic interactions before they had the opportunity to create fixed polymorphisms between isolates [88]. An analysis of nucleotide diversity at non-synonymous versus synonymous codon positions (πs/πu) in ten mtDNA-encoded ETC genes among 22 C. briggae natural isolates suggested that these genes are under purifying selection (πs/πu < 1 for all genes) and have not likely experienced functional divergence [52].

Patterns of diversity and divergence at nuclear-encoded ETC genes have not been analyzed in C. briggae natural isolates. In either case, our results suggest that these particular hybrid strains will be valuable for future studies of mitochondrial function.

While results of the hybrid analyses showed that ROS and ΔΨM were influenced by mtDNA content, analyses of the natural C. briggae isolates suggested that at least a portion of the among-isolate phenotypic variation may be associated with nad5A heteroplasm level or other factors in linkage disequilibrium with nad5A (Fig. 3; Table S3). In particular, several traits exhibited non-linear relationships with isolate-specific nad5A level, a pattern in agreement with previous findings for these isolates [47]; however, the patterns are in most cases quite weak (Table S3; Fig. 3). Our results for highest-deletion isolate HK105 are of special note, however, since this isolate exhibits the highest ROS levels (Figs. 3 and 4) and the lowest reproductive fitness (Fig. 2A in Estes et al. 2011). It may be that HK105 (>50% deletion bearing genomes) has reached a threshold beyond which nad5A elicits deleterious effects; i.e., high ROS levels associated with extreme ETC dysfunction [26].

Congruent with this idea, HK105 also had the largest ratio of functional to non-functional organelles (Fig. 3H) and the smallest area of depolarized mitochondria (Fig. 3B) compared to other isolates. One interpretation of these data is that mitochondria with nad5A loads beyond ~50% are unable to rescue functionality through mitochondrial fusion [89,90] and the ensuing mitochondrial degradation of highly impaired organelles increases the ratio of functional to non-functional organelles. A direct test of this hypothesis awaits development of techniques for simultaneously genotyping and phenotyping individual mitochondria.

It has been proposed that lowering mitochondrial ΔΨM may slow the rate of ROS production and help to alleviate oxidative stress – and perhaps extend lifespan [11,83,84]. Based on such studies and on the fact that ROS and ΔΨM were most important for classifying our C. briggae natural isolates into nad5A categories (Table S2), we expected that a statistical relationship between these traits might emerge, but observed no such correlation (Figs. 3G, 3I). A caveat that prohibits further interpretation of this result is that ROS and ΔΨM levels were necessarily measured on different individual nematodes; estimates of each trait were therefore obtained from different sets of mitochondria (Materials and Methods). Conversely, ΔΨM and morphology assays were conducted on the same individuals. Unfortunately, to our knowledge, all ROS and ΔΨM probes utilize nearly identical fluorescent spectra, making simultaneous in vivo quantification of both traits impossible. It is noteworthy, however, that the results of our studies differ from those of Lemire et al. (2009), which showed that reduced ΔΨM was associated with increased lifespan across four classes of C. elegans longevity mutants. We find no obvious relationship between isolate-specific ΔΨM and lifespan measured in a previous study [47]. In particular, the long-lived PB800 isolate [47] was observed here to have a high ΔΨM (Fig. 2G). Further study would be required to understand why this isolate deviates from the strong pattern seen in C. elegans experimental strains. A possible explanation may lie in the nuclear genetic differences among the C. briggae isolates used here; in contrast, Lemire (2009) studied C. elegans mutants on an otherwise common nuclear background.

Our analyses of mitochondrial phenotypes also identified traits that diagnose mitochondrial functionality. Apart from ROS, ΔΨM, and ΔFP (combined area of the functional mitochondrial population), traits retained in classification trees all described some aspect of depolarized mitochondria (Table S2). In other words, descriptors of depolarized mitochondria provided more information about the nad5A frequency class to which natural isolates belonged than did descriptors of functional mitochondria. For example, although isolates did not differ in any aspect of functional mitochondrial shape (Table 1), traits describing non-functional mitochondrial shape (ARn, CNn, and CNNn) were retained in classification trees; these traits also showed especially obvious non-linear relationships to nad5A frequency (Fig. 3D–F). In particular, depolarized mitochondria tended to be larger (Fig. 3D) and more variable with respect to circularity (Fig. 3F) (and consequently less circular, Fig. 3E) in zero- and high-nad5A strains. Furthermore, although some traits describing the average number and combined area of the functional mitochondrial population were found to be (mostly non-linearly) related to nad5A frequency in our regression analyses (Table S3), traits describing individual functional mitochondria were never found to be associated with nad5A level in any analysis. Taken together, our results suggest that isolates with different nad5A levels are more variable with respect to their depolarized mitochondrial populations than to their polarized mitochondrial populations. Furthermore, we found that functionality (based on ΔΨM) is strongly associated with elongated organelles, whereas non-functionality is associated with circular (i.e., fragmented) organelles. This result is in agreement with previous findings [33,38,41,90] and with the idea that damaged mitochondria lose ΔΨM and undergo fragmentation early in the cellular apoptosis process [32].

**Conclusions and Outlook**

We have reported a novel analysis of subcellular processes in C. briggae that, to our knowledge, provides the first explicit treatment of within-species natural variation in form and function of an organelle. Through the use of mitochondrial-nuclear hybrid lines, we demonstrated that mtDNA genotype is a strong driver of a portion of this natural variation. We also found evidence for complex associations between mitochondrial nad5A frequency and mitochondrial functioning (ROS and ΔΨM) and morphology traits. Although our study represents a major step forward in understanding natural variation in subcellular processes in vivo, additional work is required to move beyond correlational associations between mitochondrial genotypes and phenotypes to a direct determination of the genetic underpinnings of subcellular variation. Achieving this goal in our system would necessitate the simultaneous genotyping (e.g., through mitochondrial mRNA or DNA labeling) and phenotyping of individual mitochondria, which is not possible currently.

More generally, our study indicates that evolutionary approaches hold promise for advancing our knowledge of mitochondrial population dynamics and other cell-level processes. Although there is a long history of evolutionary analysis providing key insights into DNA-level genetic processes and organismal phenotypes, phenomena at more intermediate levels of biological organization (e.g., cellular, subcellular) have largely been overlooked by...
evolutionary biologists during the last century. Likewise, cell biology research rarely considers natural within-species variation. Evolutionary cell biology is an emerging and essentially untapped research area in need of both theoretical and empirical work. With regard to mitochondria, outstanding questions in this discipline include what is the role of mitochondrial fission and fusion in purging deleterious heteroplasmic mtDNA mutations, how do epistatic interactions between nuclear and mtDNA subunits of ETC genes affect mitochondrial form and function and organis- 

nal fitness, and how do we analyze the mode and strength of selection on mitochondrial form and function? Together with the many other advantages to the C. briggsae system, its amenability to in vivo physiological studies and abundant abundant, among- isolate mtDNA variation suggest that this species will be a valuable natural model system for addressing such questions.

Supporting Information

Table S1 Effect of phylogenetic clade (df = 2) and strain nested within clade (df = 7) for mitochondrial form and function traits. The F-ratio and degrees of freedom for nested analyses of variance for each trait are shown with *, **, and *** denoting p<0.05, 0.01, 0.001, respectively. Subscripts N and F indicate whether the measure refers to Non-functional or Functional mitochondria. Subscript P denotes that the measure refers to the entire mitochondrial population, rather than individual mitochondria. Subscript V denotes measures of average individual variance in that trait. (XLSX)

Table S2 Results of classification tree analysis. ROS and AVM traits reflect average maximum fluorescence values. Misclassification rate and R² are the mean values from five separate runs of the classification tree using identical parameters (see text). (Top) The three phylogenetic clades of C. briggsae (Fig. 1) were used as grouping variables during tree construction. (Bottom) Four categories based on isolate-specific nad5A heteroplasmy level (Fig. 1) were used as grouping variables. (XLSX)

Table S3 Assigned labels of all mitochondrial traits measured for C. briggsae natural isolates. The test statistic and adjusted r² values for the best fit regression of each phenotype to nad5A frequency are given for each trait. Bold font identifies the nine traits retained in the classification tree analysis when using categories based on isolate-specific nad5A % (see Table S3). Italicized values indicate that a linear regression provided the best fit to nad5A %, while standard text denotes a quadratic relationship to nad5A %. *, **, and *** denote p<0.05, 0.01, 0.001, respectively. Subscripts N, F, and T indicate whether the measure refers to Non-functional, Functional, or Total mitochondria. Subscript P and V denote that the measure refers to the entire mitochondrial population (not individual mitochondria), or the average individual variance in that trait, respectively. (XLSX)

Table S4 Comparison of mitonuclear hybrid strains to parent strains. The difference between the means of each pair of mitonuclear hybrids and their parental isolates are shown. Bolded traits exhibit significant differences among hybrid and parent strains. * , **, and *** denote p<0.05, 0.01, and 0.001 respectively (Tukey HSD, α = 0.05). AF = AF16, PB = PB800, HK = HK105. (XLSX)

Acknowledgments

We are deeply indebted to A. Snyder [Advanced Light Microscopy Core, Oregon Health and Science University] for generous technical advice on confocal imaging and analysis. Thanks also to Y. Pan for advice on classification tree analyses, M. Sedensky and P. Morgan for helpful discussion and advice, and N. Al-Musaffir, A. Coleman-Hubbert, J. Groovy, and S. Smith for lab assistance.
