Abstract

The aim of the study was to investigate the Internal Jugular Veins dynamics using contrast enhanced ultrasonography in Multiple Sclerosis patients, clinically isolated syndrome patients and healthy controls. Contrast enhanced ultrasonography imaging of the Internal Jugular Vein was performed in fifty-eight patients with Multiple Sclerosis, seven clinically isolated syndrome patients and in thirteen healthy controls. Time-intensity curves were quantified using a semi-automated method and compared with clinical disease outcomes. Wash-out parameters were calculated and six Time-intensity curves shapes were created. Significantly reduction of wash-out rate in Internal Jugular Venes was detected in Multiple Sclerosis patients compared to healthy controls (22.2% (2.7%–65.9%) vs. 33.4% (16.2%–76.8%); P<0.005). Internal Jugular Vein enhancement was heterogeneous in patients with Multiple Sclerosis and consisted of slow wash-out Time-intensity curves shapes, compared with almost only one type of Time-intensity curves shape in control subjects that correspond to fast enhancement and fast wash-out. The vein wash-in parameters were similar in Multiple Sclerosis group compared with controls. A significant correlation was found between Internal Jugular Vein wash-out and level of disability (R = −0.402, p<0.05). Contrast enhanced ultrasonography of the Internal Jugular Vein with time intensity curve analysis revealed alterations of cerebral venous outflow in Multiple Sclerosis patients, however mechanisms that determine this condition remains unclear.

Introduction

The most widely accepted hypothesis is that MS is an inflammatory and degenerative autoimmune disease that leads to destruction of CNS myelin, with multifactorial pathogenesis [1]. The early course of disease is characterized by episodes of neurological dysfunction that usually recover. However, over time the pathological changes become dominated by widespread microglial activation associated with extensive and chronic neurodegeneration, the clinical correlate of which is progressive accumulation of disability. Antimyelin T-cell-mediated inflammatory responses are believed to have a crucial role in the development of focal lesions [2], however, the underlying mechanism of the widespread axonal degeneration is not yet fully understood.

Abnormalities of cerebral hemodynamics in MS have been investigated by using single photon emission tomography, PET and perfusion MR imaging [3–5]. These studies have demonstrated widespread hypoperfusion in focal lesions, and in both the grey and white matter in patients with MS and all clinical phenotypes [4–5] and in the very early stage of the disease [6]. These findings are consistent with earlier histopathologic studies reporting vascular occlusive changes in MS, characterized by thrombosis of small veins and capillaries, vein wall hyalinization, and intravascular fibrin deposits [7–8]. Dawson described MS lesions as plaques mostly centered on small periventricular veins [9]. Recent studies, using high field MRI and susceptibility-weighted imaging have shown the perivascular inflammation pattern in MS by sensitively visualizing the small venous vessels in the periventricular and deep white matter [10]. Moreover MS patients showed a reduced visibility of cerebral veins that is inversely correlated with the periventricular and whole-brain T2-lesion load [11], low cerebral venous blood flow, low cerebral blood volume and higher MTT compared with healthy controls [12–13].

Compared with the cerebral arterial system, the cerebral venous system has been less well described and studied and this might lead to an underestimation of cerebral venous disorders. Unlike the carotid artery, the vascular wall of the IJV is much more flexible with a variable lumen diameter and this makes more difficult to perform a quantitative study of blood flow. The internal jugular veins (IJVs) are the main pathway for venous outflow in the supine position, while in the upright posture the IJVs collapse and venous outflow occurs mainly through secondary veins such as the vertebral, epidural, and deep cervical veins, which compose the vertebral venous plexus [14–15]. The hemodynamic of the IJVs...
Ultrasound studies and may reflect cerebral venous drainage conditions and appear to influence intracranial hemodynamic, perfusion of the brain [16] and the dynamics of Cerebrospinal fluid system [17]. The insufficient cerebral venous drainage could cause a variety of unclassified central nervous symptoms such as headaches, visual disturbances, or amnestic dysfunctions [19]. Several studies have found a relationship between IJV drainage abnormalities and certain neurological diseases of undetermined aetiology [19–20] including leukoaraiosis [21] dementia [22] and normal-pressure hydrocephalus [17] and, recently, MS [23–24].

US contrast agents are true intravascular agents that, unlike the diffusible agents commonly used in MR imaging and CT, remain entirely within the vascular space and possess intravascular rheological characteristics similar to those of red blood cells [25]. Dynamic contrast-enhanced US imaging is the time-dependent registration of changes in ultrasonic signal intensity during and after intravenous injection of a contrast agent. The dependence of enhancement by time can be shown in a time-intensity curve (TIC) where the average signal from a Region of Interest (ROI) is plotted as a function of time. The integration of modern ultrasonographic equipment with dedicated signal-processing systems overcomes the operator-dependent analysis of the ultrasonic signal. From a TIC can be obtained some temporal and amplitude parameters, such as tissue and vascular uptake, transit times, and wash-out of the contrast agent.

The present study describes a new and simple approach to cerebral venous outflow analysis, based on the use of ultrasound contrast agent imaging with time intensity curve analysis. The analysis of IJV drainage patterns in HC and MS patients in horizontal body position was presented.

**Materials and Methods**

**Patients**

This study was approved by the institutional ethics committee for biomedical activities "Carlo Romano" Medical School University Federico II, Naples - Italy, and informed written consent was obtained from all subjects. Fifty-eight consecutive patients affected by clinically defined MS diagnosed according to the revised McDonald criteria [26], seven patients with Clinically Isolated Syndrome (CIS), and thirteen age- and sex-matched healthy controls were enrolled into the study.

Clinical assessment was done on the same week of the ultrasound study, and disability was graded by using Kurtzke’s Expanded Disability Status Scale (EDSS) [27] and Multiple Sclerosis Severity Score (MSSS) [28].

Inclusion criteria for patients with MS were age 18–60 years and an EDSS between 0 and 6.5. Exclusion criteria were presence of relapse and steroid treatment in the 30 days preceding study entry for all patients, pregnancy or preexisting medical conditions known to be associated with brain pathology. ECG was performed and fasting venous blood sample was drawn for routine laboratory examination including blood clotting and screening for thrombo-phlic status.

**Ultrasonic studies**

Extracranial Duplex sonography was performed with Philips iU22 ultrasound instrument (Bothell WA, U.S.A.) with a 9–3 MHz, linear-array probe, to exclude carotid artery and/or IJV stenosis.

For contrast-enhanced perfusion imaging, the following settings were used: mechanical index, 0.06; acoustic output, 90%; gray map, one; and frame rate, 13 Hz. An area of the neck where the IJV and thyroid gland appeared in the same transverse plane was located by using color Doppler and designated for analysis. After 10 minutes with the subject at rest in supine position, a bolus of 2.4 mL of an echo-contrast enhancer (SonoVue; Bracco, Italy) was manually injected into the left antecubital vein using a 22-gauge catheter at 2 mL/sec. The injection was followed immediately by a 10-mL saline bolus injected at 5 mL/sec. A 1-minute B-mode cine loop was then acquired. Then, after 10 minutes, a second intravenous bolus of 2.4 mL of SonoVue was repeated for the evaluation of contralateral side. Electrocardiography was used to monitor the heart rate during the test.

A trained sonographer (M.M.) with more than 20 years of ultrasound experience performed all ultrasonographic assessments. The length of exam was 1 hour. The time intensity curve was analyzed off-line in a blinded way, by using a time-signal intensity curve analysis program QLab (Philips Healthcare) that displayed the acoustic intensity (in decibels) during the acquisition time in a manually defined region of interest.

To reduce the artifacts caused by peak intensity variations, contrast agent arrival was defined as the time point of a stable signal intensity enhancement of at least 5 dB in the IJV.

Nine semiquantitative perfusion parameters were extracted from the time-intensity curves in the ROI designated for analysis at level of Internal Jugular Vein (IJV):

1. **Arrival time** was defined as the time from injection of contrast agent to the beginning of signal intensity increase;
2. **Absolute Intensity Peak (dB)** was the maximum intensity at the peak of the intensity curve;
3. **Time to peak intensity** was defined as the time from injection of contrast agent to reach the peak of contrast intensity;
4. **Incremental Time** was calculated as the difference between time to peak intensity and arrival time;
5. **Enhancement slope (dB/s)** was calculated as the ratio between intensity peak and incremental time;
6. **Area under the curve** was calculated from the point of the increase in image intensity greater than 5 dB above the baseline to the peak intensity;
7. **AUC during washout** was calculated from the peak intensity to the end of 1 minute acquisition;
8. **minute residue value** was calculated as the average contrast enhancement values at 58 to 60 seconds;
9. **minute wash-out rate** was calculated according to the following equation: 1-minute wash-out rate = [peak enhancement value – 1-minute residue value]/peak enhancement value ×100.

The IJV valve incompetence with retrograde flow was considered when microbubbles appeared on B-mode imaging in the internal Jugular vein before than in carotid artery.

**Time Intensity Curve Shape Analysis.** The time-dependent signal intensity changes of imaged area was classified into one of six predefined TIC shape categories, which is associated with a color (Fig 1).

A curve was generated for every participant and the distribution of the different TIC shapes throughout the IJV was described (Fig 1).

**Collateral Vein.** We also assessed the left and right prominence of the other most important veins in the neck visible on CEUS imaging of the neck: external jugular veins, anterior jugular veins, facial veins, thyroid veins, and deep cervical veins.

The number of collateral veins for the right and left side of the neck was counted.
Statistical Analysis

Continuous data were reported as median and range, and categorical data as percentages. For descriptive statistics and analysis of continuous data the U test (Mann-Whitney) or, to compare more than two groups, Kruskal-Wallis analysis of variance was used. The post hoc analysis was performed by means of the Dunn test. The Spearman’s rank correlation ($r_s$) coefficient to assess inter-variable correlation was used. Fisher’s exact test, and the $\chi^2$ test were used. Residual analysis was performed to assess differences in the distribution of venous criteria among MS subtypes. Significance was denoted when $p < 0.05$ by using two-tailed tests. Statistical analyses were performed using SPSS (version 18.0 Chicago, IL).

Results

Demographic and clinical data of MS patients, CIS, and control groups are shown in Table 1. Significant differences in age, EDSS, MSSS and disease duration were evident in the subgroups. MS patients belonged to three clinical subtypes (32 RR, 20 SP and 6 PP), and were treated in 55% of cases with various disease modify therapies (interferon beta-1, natalizumab, glatiramer acetate, fingolimod, azathioprine, and mitoxantrone).

The contrast agent was well tolerated in all individuals, without substantial side effects. Internal jugular vein wash-out rate and wash-out AUC were significantly increased in patients with MS compared with CIS and HCs (Table 2). Internal jugular vein reflux was observed in 14 veins. Even after jugular veins with retrograde flow were excluded from the statistical analysis, wash-out rate values remained significantly lower in the MS group compared to HGs and CIS [in MS patients without retrograde flow WO rate was 24.7% (range, 2.7-64.1%) CIS 29.2% (range, 13.3-42.9%) and HGs 35.4% (range, 16.2-76.8%) $p < 0.05$]. No significant differences were found between the MS, CIS and HCs in all wash-in parameters excluding intensity peak and AUC wash-in (Table 3). The right jugular vein was significantly larger than left jugular vein (CSA in right IJV 0.83 cm$^2$ vs. left IJV 0.67 cm$^2$ $p = 0.028$) and showed lower WO rate [WO rate right 19.7% (2.74-53.44) left 24.9% (5.32-65.86)] and higher intensity peak [right 91.2 dB (5.88-122.68) left 87.13 dB (6.69-121.9)]. All wash-out time parameters were similar in male and female patients with MS. No difference was found between treated and untreated patients with MS ($p = 0.857$).

There was a significant association between age at onset, increased EDSS and decreased WO rate in MS patients (table 3) calculated for each patient as the lowest value between the two IJV that is the value that takes into account for each patient the more diseased vein (age at onset $r = -0.346$ EDSS $r = -0.402$, $p < 0.05$, Table 3).

The TIC pattern of the HCs consisted predominantly type 2 fast WO (fast wash-in enhancement followed by fast WO phase) and was observed in 73% of HCs and 16% of MS patients. The TIC pattern predominantly in MS patient was type 3 [fast wash-in enhancement followed by delayed WO (46.4% of MS patients and 8.3% of HCs; $p < 0.001$)] (Figure 2).

Subjects with higher number of collateral veins (>2 collaterals) showed higher IJV intensity peak [82.3 dB (43.8-122.6) vs. 91.0 dB (5.9-122.7) $p = 0.044$]. A non-significant trend to higher residual value and AUC WO [residual value 59.2 dB (1.5-109.2) vs. 72.3 dB (3.7-114.2) $p = 0.07$; AUC WO (2 429 (78-4 464) vs. 2 757 (109-4 537) $p = 0.083$] was observed in MS patients with higher number of collaterals.
**Table 1.** Demographic and clinical characteristics of HCs, CIS patients, all MS patients and MS subtypes patients.

**Discussion**

We utilized CEUS to describe and quantify the IJV outflow in MS, CIS and HC. The main result was that MS patients showed, on average, approximately 30% reduction of the venous outflow through the IJV in supine position measured as WO rate percentage. The WO rate was reduced more in patients with primary progressive MS than in patients with RR MS or CIS. These findings suggest than the altered IJV dynamics could be a consequence rather than a cause of MS.

These alterations in IJV dynamics have been demonstrated in other studies using MR imaging [30], Pletismography [31] and Flebography [32] in patients with Multiple Sclerosis associated with CCSVI, a condition characterized by impaired venous outflow from the central nervous system to the heart [33–34]. One common feature of CCSVI is stenosis of one or both IJV with a greater cerebral venous drainage system [29].

Altered venous outflow was also demonstrated in other studies using MR imaging [30], Pletismography [31] and Flebography [32] in patients with Multiple Sclerosis associated with CCSVI, a condition characterized by impaired venous outflow from the central nervous system to the heart [33–34]. One common feature of CCSVI is stenosis of one or both IJV with a greater cerebral venous drainage system [29].

The IJVs are the main drainage route for the cerebral venous system in supine position; in standing position these veins collapse and allow little blood flow. At steady-state the arterial inflow into the cranium must equal the venous outflow from the cranium. In MS patients the arterial inflow is preserved [35] since a reduction of venous outflow should result in an increase in the conduit’s compliance, reduced flow pulsatility and increase outflow through collateral veins. Instead the upstream distention of the periventricular veins [36–37] is much more likely to be caused by constriction of the intracranial veins, perhaps by compression by inflammatory perivascular cuff.

The association of IJV WO rate with EDSS score suggest that outflow changes could be related to MS disability and pathophysiology. Although many studies showed higher frequency of IJVs anomalies in MS patients, there are no evidence for significant associations with disability [38]. Our results are comparable to the studies that utilize quantitative methodology to evaluate alteration of cerebral venous drainage [39–40]. The IJV wash-out rate could represent a more comprehensive quantitative measure of the severity of drainage impairment and, therefore, may be more useful in predicting clinical outcome than other imaging modalities that outcome categorical diagnosis.

The slope enhancement, peak intensity, and time to peak values are similar in MS and HCs and indicates that total amount of contrast agent passing through the ROI is similar in MS and HC and that venous filling with blood coming from the brain occurs with normal velocity. Therefore, the differences in the time courses (expressed as higher plateau of the wash-out phase) indicate an obstructive pattern with slower drainage of the vein, reduction of outflow and accumulation of contrast in the vessel.

Time Intensity Curve reflects the inflow and outflow venous dynamics represents venous physiology and could be associated with venous patency or obstruction. Using TIC shape analysis in our study, it was possible to demonstrate a significant difference between patients with MS and HCs. The TIC shapes differed significantly in the two groups. The type 2 TIC shape consists of a rapid enhancement phase followed by an early washout is the most frequently observed in healthy controls and is the normal IJV dynamics. TIC shapes with initial rapid enhancement followed by a plateau phase or gradual increase of the enhancement, or by a second peak of enhancement were associated with MS. The association of IJV TIC shapes and disease status is quite new in MS research and we believe that this
A simplified method might be useful to distinguish MS patients with or without associated vein outflow reduction/obstruction. Whereas arterial flow is tightly regulated and primarily controlled by metabolic demand, the lower blood pressure of the venous system makes venous flow more dependent on physiological conditions such as respiration and posture. The motor mechanisms of cerebral venous return are represented by the cardiac output, the so called *vis a tergo*, and by aspiration of the

doi:10.1371/journal.pone.0092730.t003
atrium and pleural cavity, or vis a fronte [14–15]. The aspiration effect of the blood is a consequence of the negative pressure of the pleural cavity in inspiration [14]. Such mechanism of aspiration determined by the respiratory pump is particularly relevant in IJV. Therefore one hypothesis is that alteration of IJV outflow might be secondary to reduction of driving force of thoracic pump due to a weak respiratory muscular contraction of the chest [41] occurring early in the disease course and gradually worsening over time or secondary to some medications, such as muscle relaxants, that can depress breathing.

A raised pressure in the jugular veins could also be an earliest evidence of general systemic congestion, heart failure, hyperkinetic circulatory states, increased blood volume, bradycardia, increased intrapericardial, intrathoracic or intra-abdominal pressure, partial obstruction of the superior vena cava and tricuspid stenosis. However all these conditions have been ruled out in patients in this study who were almost all young and without other cardiac or systemic diseases associated with Multiple Sclerosis.

Moreover, compression of the veins draining the central nervous system by a muscle can be another cause of compromised cerebral venous outflow. The omohyoid muscle is usually located next to the IJV and it is known that an atypical omohyoid muscle can compress the IJV and in this way may affect cerebral venous drainage [42]. Recently Dolic et al., using MR venography, found that 22% of MS patients present with extraluminal abnormalities of the IJVs [43]. Jayaraman et al., who evaluated these veins using CT angiography [44], found a similar prevalence of severe extrinsic stenosis of the IJVs. Many investigators found reduced CBF in the GM and WM of patients with MS [2,45], in the deep grey matter the magnitude of CBF reduction increase with the severity of the disease [46] suggesting a continuum of decreased tissue perfusion, beginning in the white matter and spreading to the grey matter as the disease progresses.

Increased blood concentrations of the vasocostrictive compound endothelin-1 (ET-1) in patients with MS might also contribute to the slowdown of cerebral outflow [47].

A limit of the study is the low number of the control group due to ethical limitations to the use of contrast agent in normal subjects without any clinical indications.

A general limitation of quantifying replenishment kinetics is the dependence on the microbubble destruction and detection that could cause more complex replenishment kinetics.

Although the ultrasound contrast agent used in this study is known to be not soluble in blood and the low mechanical index harmonic imaging technique was used to limit bubble destruction, some microbubbles may have been inherently destroyed during the 1-minute scanning that we have used. Therefore, the wash-out of microbubbles in the region of interest on contrast-enhanced sonography might have been exaggerated compared with the actual blood wash-out and with the contrast wash-out in CT or magnetic resonance perfusion studies.

In conclusion, these results suggest that MS is associated with changes in the dynamics of the internal jugular vein.
