We here propose to model active cases data from COVID-19 by a continuous effective model based on a modified diffusion equation under Lifshitz scaling with a dynamic diffusion coefficient. The proposed model is rich enough to capture different aspects of a complex virus diffusion as humanity has been recently facing. The model being continuous it is bound to be solved analytically and/or numerically. So, we investigate two possible models where the diffusion coefficient associated with possible types of contamination are captured by some specific profiles. The active cases curves here derived were able to successfully describe the pandemic behavior of Germany and Spain. Moreover, we also predict some scenarios for the evolution of COVID-19 in Brazil. The scenarios unveil how the lockdown measures can flatten the contamination curves. We can find the best profile of the diffusion coefficient that better fit the real data of pandemic.

I. INTRODUCTION

In December 2019, the world started to face a new type of severe pneumonia which appeared in Wuhan, China. Only two months later the International Committee on Taxonomy of Viruses named the virus responsible for these pneumonia cases as severe acute respiratory syndrome coronavirus 2 or SARS-CoV-2, whose disease was popularly known as coronavirus disease 2019, or simply COVID-19 [1]. Such disease was classified as a public health emergency of international concern at the end of January 2020, by the World Health Organization. Up to now, SARS-CoV-2 has spread all over the world, presenting more than 3.5 million of cases, taken approximately 247107 lives, and has a new epicenter in the United States of America which has reported almost one-third of the total amount of cases [2]. Few places in the world were able to fully control the pandemic of COVID-19. In Europe, for instance, Italy and Spain were for a long time the world’s two worst-hit countries by the COVID-19. Now, the numbers of active cases in these two countries are slowly decreasing and they are facing the final stage of the pandemic. One of the best countries in Europe to adopt measures against COVID-19 so far is Germany, who is also entering in the controllable phase of the pandemic. Behind the success of Germany are measures of social distance or lockdown procedures, and a large number of people tested for SARS-CoV-2 [3].

After spreading in Asia and Europe, now COVID-19 is a challenge for the USA, as well as for low and middle-income countries, such as Brazil. There is a serious concern on the international scientific community about the behavior of SARS-CoV-2 in such countries, since they face other severe problems such as poverty, food security, economic growth, besides other diseases like human immunodeficiency virus, tuberculosis, and malaria [4].

So far, several scientific works and reports based on numerical simulations have been published, lighting the evolution of the pandemic in different countries and reflecting the actions as well as the strategies of each country to mitigate the effects of COVID-19. Some of these studies can be found in references [4–8]. In this work we intend to collaborate with the current investigations by proposing a model which can describe the evolution of the pandemic through the solutions of a modified version of the diffusion equation.

The standard diffusion equation describes the macroscopic behavior due the effect of many micro-particle bodies, as it is observed in a Brownian motion, for instance [9]. An interesting modification of this equation was proposed in the seminal paper of Petr Horava [10], in his studies about quantum gravity, where he extended the definition of spectral dimension to theories on smooth spacetimes in anisotropic or Lifshitz scaling. In our investigation, we introduce a new version of the diffusion equation inspired by Horava’s work, and we use it to fit real active cases data of COVID-19 from Germany, Spain and Brazil. The diffusion equation with the Lifshitz scaling and the equation
of motion for the diffusion coefficient are going to be introduced in section II. In section III we are going to show
different solutions for the diffusion equation which can be used to fit the evolution of COVID-19. The availability of
our models are carefully discussed in section IV. Then, we present our final remarks and perspectives in section V.

II. DIFFUSION EQUATION AND LIFSHITZ SCALING

The first issue to describe a pandemic evolution consists in choosing an appropriate diffusion process. The complexity
of a virus transmission such as SARS-CoV-2, demands a diffusion process characterized by a probability density
\( \rho = \rho(x, \tau; x', \tau'; \sigma) \) measuring the diffusion from a time \( \tau \) to a time \( \tau' \), and from a space coordinate \( x \) to \( x' \) at a
diffusion time \( \sigma \). Notice that \( \sigma \) and \( \tau \) are two different types of time, \( \tau \) would be understood as the standard time
variation of the pandemic, while \( \sigma \) would control the collective response to the pandemic, such as social distance
measures, for instance. Besides, as each country can adopt several strategies to mitigate the pandemic effects, it is
expected that the diffusion process would account for different degrees of anisotropy. A general continuous diffusion
equation that attends such criteria was introduced by Horava in his seminal work [10], whose form is

\[
\frac{\partial}{\partial \sigma} \rho(x, \tau; x', \tau'; \sigma) = \left( \frac{\partial^2}{\partial \tau^2} + (-1)^{z+1} \Delta^z \right) \rho(x, \tau; x', \tau'; \sigma).
\]

(1)

Here \( \tau \) is the so-called Euclidean time and \( z \) is the Lifshitz critical exponent, which measures the anisotropic scaling
of a given model [10, 11]. The Lifshitz critical exponent is essential to determine the spectral dimension, which
can be applied to several geometric objects presenting fractal behavior [10]. The relative sign \((-1)^{z+1}\) concerns the
requirement of ellipticity of the diffusion operator valid for integer \( z \), but the results can be analytically continued for
any positive real \( z \) [10, 11]. An extra relevant ingredient to proper modeling a pandemic spread is a diffusion coefficient,
which can account for the transmission rate of the virus. Therefore, this discussion suggests that a pandemic scenario
is governed by the following anisotropic diffusion equation

\[
\frac{\partial}{\partial \sigma} \rho(x, \tau; x', \tau'; \sigma) = \phi(\tau) \left( \frac{\partial^2}{\partial \tau^2} + (-1)^{z+1} \Delta^z \right) \phi(\tau)^{-1} \rho(x, \tau; x', \tau'; \sigma),
\]

(2)

where \( \phi(\tau) \) is a dynamic diffusion coefficient. We are going to show that a proper balance between \( \phi \) and \( z \) yields to
distributions that can fit real pandemic data. Let us also constrain the diffusion coefficient \( \phi(\tau) \) with the standard
Lagrangian

\[
L = -\frac{1}{2} \phi^2_{\tau} - V(\phi); \quad \phi_{\tau} = \frac{d \phi}{d \tau},
\]

(3)

where the negative kinetic part stands for the Euclidean time. Therefore, the equation of motion for the diffusion
coefficient is such that

\[
\phi_{\tau\tau} = V_{\phi}.
\]

(4)

By integrating the previous equation once, we find the first-order differential equation

\[
\phi_{\tau} = \pm W_{\phi},
\]

(5)

where we considered

\[
V(\phi) \equiv \frac{W_{\phi}^2}{2}; \quad W_{\phi} = \frac{d W}{d \phi}.
\]

(6)

The function \( W \) is known as superpotential in analogy with the bosonic sector of supersymmetric field theories.

III. SOLUTIONS

The diffusion equation (2) has the general solution

\[
\rho(x, \tau; x', \tau'; \sigma) = \rho_0 \int \frac{d\omega d^Dk}{(2\pi)^{D+1}} \phi(\tau) e^{i\omega(\tau-\tau')+ik\cdot(x-x')} e^{-\sigma(\omega^2+|k|^2)},
\]

(7)
where $\rho_0$ stands for the initial probability density subject to the pandemic (or to the diffusion process). In this work, we consider $\rho$ as the probability density of active cases of COVID-19 to make a parallel between our model and real pandemic data. The number of active cases of COVID-19 is defined as follows [3]

$$\text{Active Cases} = \text{Total Cases} - \text{Total Deaths} - \text{Recovered}, \quad (8)$$

due to the current number of patients detected and confirmed as infected with SARS-CoV-2. The number of active cases is also a relevant metric for public health and primary care functions, as it allows measuring capacity versus hospitalization needs. Such a number is used to plot the distributions of active cases of COVID-19 for different countries as we see in [3]. Before starting to make numerical integrals of Eq. (7) to depict the active cases curves, let us comment on the dimensionality of the model. A (spatial) bi-dimensional model seems most natural to discuss the diffusion process in the population. This usually is captured by the bi-dimensional networks with persons being nodes and relation being links [12]. Moreover, one particular feature of the transmission of this virus is that it occurs by contact between persons [1]. This feature is captured by a nearest-neighbor interaction between the nodes. It can be argued that one can project down this nearest-neighbor interaction bi-dimensional network into a long-range interaction chain (one-dimensional chain) with appropriate boundary conditions. Thus in the passing to the continuum model we can in a reasonable approximation consider a $D = 1$ model with $x$ ranging from $-\infty$ to $+\infty$. For the numerical integration in the reciprocal space, we can take therefore $-\infty \leq \omega \leq +\infty$, and $-\infty \leq k \leq +\infty$.

A. Model I - Standard Gaussian solutions

The simplest model that we can analyze consist in

$$W_\phi = 0; \quad \phi(\tau) = 1, \quad (9)$$

where the diffusion coefficient is normalized. This first model will enable us to observe the influence of the critical exponent and of the diffusion time in our curves.

The Fig. 1 shows four different behaviors for the solution of the diffusion equation. The diffusion time and the critical exponent $\alpha$ are competing parameters. Particularly in the top left curve, with a same diffusion time large values of $\alpha \geq 1$ makes the Gaussian flattened, whereas bottom right for $\alpha < 1$ the Gaussian tends to blow up even for sufficiently large diffusion time. The best scenario in the sense of flattening the Gaussian curve seems to be the increasing of both diffusion time and critical exponent $\alpha$ (top right). The features of $\sigma$ presented in the previous scenarios yield us to indeed understand the diffusion time as equivalent to a lockdown period.

In this work we adopted the lockdown definition introduced by Flaxman et al. [5], which means a scenario where regulations and laws regard strict social interaction. These regulations/laws include the banning of any non-essential public gatherings, closure of educational, public and cultural institutions, and ordering people to stay at home apart from exercise or essential tasks.

B. Model II - Solutions for a (anti)kink-like diffusion coefficient

In this example we are going to consider the following superpotential

$$W = \frac{\lambda}{8} \phi^2 \left( 1 - \frac{\phi^2}{\alpha^2} \right), \quad (10)$$

where $\lambda$ and $\alpha$ are real constants. Such superpotential leads us to

$$V = \frac{\lambda^2}{4} \phi^2 \left( 2 - \frac{\phi^2}{\alpha^2} \right)^2. \quad (11)$$

which is known as $\lambda \phi^6$ potential, and it is depicted in the left panel of Fig. 2. The minima or vacua values of $V$ correspond to $\phi_v = 0$, and $\phi_v = \pm \sqrt{2\alpha}$. The region between these different minima is called a topological sector, and it mediates the transmission rate in our pandemic model. This potential was applied in subjects like higher-order phase transitions in GinzburgLandau theory [13, 14], modeling domain walls in ferroelastic transitions [15], and in
new physics beyond the standard model of particles at high energies scales [16, 17]. The previous definition of $W$ yields to the first-order differential equation

$$\phi_\tau = \pm \frac{\lambda}{2} \phi \left( 2 - \frac{\phi^2}{\alpha^2} \right),$$

whose analytic solutions are

$$\phi(\tau) = \alpha \sqrt{1 + s \tanh(\lambda(\tau - \tau_1))}; \quad s = \pm 1,$$

exhibiting anti-kink and kink-like profiles as one can see in Figure 2. Once $\phi(\tau)$ can be interpreted as the transmission rate of the virus, in Fig. 2, we observe that for $\tau \ll \tau_1$ the virus is not transmitted, however its transmission increases until an approximately constant rate ($\phi_v = \sqrt{2/\alpha}$) as $\tau$ gets bigger than $\tau_1$. The applicability of such a model is going to be carefully discussed later, in section IV.

FIG. 1: The solution (7) with $\phi = 1$ for $\rho_0 = 1$, $D = 1$, $x = x'$, $\tau' = 2.5$ at four scenarios. (top left) $\sigma = 1/10$, $z = 1$ (black solid curve), $z = 2$ (red dashed curve), and $z = 3$ (blue dotted curve); (top right) $\sigma = 1/30$ and $z = 1$ (black solid curve), $\sigma = 1/20$ and $z = 2$ (red dashed curve), and $\sigma = 1/10$ and $z = 3$ (blue dotted curve); (bottom left) $z = 1$, $\sigma = 1/30$ (black solid curve), $\sigma = 1/20$ (red dashed curve), $\sigma = 1/30$ (blue dotted curve); and (bottom right) $z = 1/2$, $\sigma = 1/30$ (black solid curve), $\sigma = 1/20$ (red dashed curve), and $\sigma = 1/30$ (blue dotted curve).

FIG. 2: In the left panel we depicted potential $V(\phi)$ Eq. (11), and in the right panel we present solution $\phi$ Eq. (13), for $s = 1$ yielding to a kink (blue solid curve), and for $s = -1$ leading to an anti-kink (blue dotted curve).
C. Model III - Solutions for a double (anti)kink-like diffusion coefficient

As a next example, let us deal with a more complex model for the diffusion coefficient. Such a model is derived from

\[ V = \frac{\cos^4(\kappa \phi) \left( \beta^2 \tan^2(\kappa \phi) + 1 \right)}{2 \beta \kappa}, \]  

(14)

this potential is known as double sine-Gordon model and it is applied to study ultra short optical pulses in He^3 [18, 19], in decaying of false vacuum and phase transitions in field theory [19, 20]. The left panel of Fig. 3 shows part of the periodic form of potential \( V \) (14). There we can see one topological sector between vacua \( \phi_v = \pm n \pi / (2 \kappa) \).

An interesting feature about this model is that the parameter \( \beta \) can deform this potential at \( \phi = 2 \pi n / \kappa \). Such deformation is responsible for the double (anti)kink profiles observed in the right panel of Fig. 3, and it is also related to the variation of the transmission rate of our pandemic model.

The previous potential yields to the first-order differential equation

\[ \phi_{\tau} = \pm \frac{\cos^2(\kappa \phi) \sqrt{\beta^2 \tan^2(\kappa \phi) + 1}}{\beta \kappa}, \]  

(15)

which is satisfied by the analytic solutions

\[ \phi(\tau) = \frac{1}{\kappa} \left( s \tan^{-1} \left( \frac{\sinh(\tau - \tau_1)}{\beta} \right) + n \pi \right), \]  

(16)

for \( s = \pm 1 \), and \( n = 0, \pm 1, \pm 2, ... \). The behavior of these analytic solutions \( V \) can be appreciated in Fig. There it is shown that \( \phi(\tau) \) has three different regimes of transmission rate, the first one for \( \tau \ll \tau_1 \) where \( \phi_v = n \pi / (2 \kappa) \), the second regime occurs when \( \tau \approx \tau_1 \) and \( \phi \approx 2 \pi n / \kappa \), and the third one appears for \( \tau \gg \tau_1 \) and \( \phi_v = n \pi / (2 \kappa) \). These regimes can lead us to distributions with different waves of contagious, as we are going to show below. In the next section we are going to analyze the viability of model III and compare the numerical curves of \( \rho \) derived from it with those obtained through model II.

![FIG. 3: In the left panel we depicted potential \( V(\phi) \) Eq. (14), and in the right panel we present solution \( \phi \) Eq. (16), for \( s = 1 \) yielding to a double kink (blue solid curve), and for \( s = -1 \) leading to a double anti-kink (blue dotted curve).](image)

IV. MODELING ACTIVE CASES OF COVID-19

As it is known, the active cases data can present a high level of uncertainty once it depends on the number of the tests performed by each country and also the countries’ transparency in reporting the tests. To depict active cases curves that could reproduce the existent data and able to predict the behavior of the pandemic, we decided first to test our model against a now well-established data set, and for that, we choose data from Germany. Nowadays Germany is the 6th leading country in the world in numbers of COVID-19 cases, accumulating a total of 164967 cases up to May 02 [21]. Moreover, Germany is the third leading country in the total number of tests, reporting a total amount of 2547052 tests for SARS-CoV-2, which corresponds to 30400 tests per million of population (considering the data up to May 02) [21]. Therefore, to constraint some free parameters in our model, we use the data from Germany as guidance. Despite this procedure, we still have other free parameters to represent the particular features of each country’s strategy to deal with the pandemic. We present the features of our models against real active cases data from Germany, Brazil, and Spain below.
Germany

In this first scenario we shown in Figs. 4, and 5, the active cases curves for Germany integrated from model II and III, respectively. There, the black solid curves are the numerical solutions generated from Eq.(7), which best fitted the real data depicted in blue dots. The parameters constrained in the fitting process were $\rho_0 = 10^7$ (for Fig 4), $\rho_0 = 10^5$ (for Fig. 5), and time scaling $t = 2\tau$ representing the number of days of pandemic. Moreover, we also used $\sigma = 28$ (for Figs. 4, and 5), referring to the number of lockdown days in Germany [22].

The left panels of Figs. 4, and 5 predict that the pandemic of COVID-19 is going to be fully controlled in Germany after day 102 of infection (or after May 26, 2020), when the number of active cases is going to be less than 1000 people. Besides, the active cases curves unveil that the kink and the double anti-kink solutions, Eqs. (13), and (16) deform the standard Gaussian curve. By comparing the right panels of Figs. 4, and 5, we realize that the double anti-kink solution yields us to a better fitting of real data, reproducing a change in the decreasing of the number of active cases at $t \approx 60$ day.

Spain

The graphics of Figs. 6, and 7 shown the currently infected people by SARS-CoV-2 in Spain. At the present moment, Spain reported an amount of 245567 cases of COVID-19, which makes it the second leading country in the world pandemic rank [23]. The active cases data for Spain are depicted as blue dots in Figs. 6, and 7, and to plot our numerical curves we considered $\sigma = 43$ lockdown days [22]. We can observe that the black solid curves are in good agreement with the pandemic data, and they predict that the active cases of COVID-19 are going to be fully controlled in Spain after day 120 (June 11, 2020), where the number of infected people will be less than 1000. Moreover, in this scenario the kink and the double anti-kink like solutions Eqs. (13), and (16), strongly deform the standard Gaussian curve. As in the case of Germany, the double anti-kink curve leads us to a better fitting of real data, reproducing a second wave of contagious after day 50.
The pandemic of COVID-19 starts in Brazil eleven days after spreads in Europe. Despite this few difference in time, the evolution of the contamination in Brazil was deeply different from Germany and Spain, as we can see in the graphics of Figs. 8, and 9. The numerical solutions presented in Figs. 8, and 9 were depicted using the same values for $\rho_0$ and $t$ from Germany curves and the same value for $z$ from Spain curves. Moreover, we derived two possible scenarios of lockdown measures, the black solid curves show a model with $\sigma = 30$ lockdown days while the red solid curves were depicted with $\sigma = 90$ lockdown days.

Furthermore, we also included the active cases data from Brazil as blue dots [24]. The real data from Brazil reveal an abrupt change of contamination which started on day 48 (April 13, 2020) and developed to a new increasing rate after day 56 (April 26, 2020). Along this period, besides the pandemic, Brazil has been facing a political crisis, which would explain the behavior of the COVID-19 infection here observed. Another problem with Brazil’s data is its high degree of uncertainty. Up to May 02, 2020, Brazil reported a total of 97100 cases of COVID-19, figuring at the 9th leading country in the world pandemic rank [3]. However, Brazil has performed only 339552 tests of COVID-19, representing a total of 1597 per million of people [3].

For these reasons, it is challenging to make any prediction about the evolution of the pandemic in Brazil. Although, our curves seem to be in good agreement with the active cases data so far, and we also can realize that a long time social distance flatten the curves of the active cases. The peaks of the two active cases curves from Figs. 8, and 9 have considerable differences about 115000, and 141000 cases, respectively. Moreover, the peaks are predicted to happen on days 92 (May 27, 2020), and 86 (May 21, 2020) for black and red solid curves from Fig. 8, and on days 95 (May 30, 2020), and 110 (June 04, 2020) for black and red curves from Fig. 9. It is relevant to mention, that up to May 02, 2020, Brazil can attend in maximum 32703 patients with needs for ICU [25]. Besides, the solutions from Fig. 8 predict that the pandemic in Brazil will not be fully controlled earlier than day 131 (June 22, 2020). In the longer predicted scenario, observed in the red solid curve of Fig. 9, the pandemic will going to be fully controlled after day 198 (August 28, 2020), when the number of active cases is less than 1000. We also realize that the double
anti-kink like solutions are able to fit better the real data than the single kink-like ones, reproducing the increasing in the number of active cases after day 48.

FIG. 8: In these graphics we present the active cases solutions for $t = 2\tau$ (time in days), $D = 1$, $x = x'$, $\rho_0 = 10^7$, $\tau' = 86$, $\tau_1 = 48.5$, $\alpha = 0.6$, $s = 1$, $\lambda = 4$, $z = 50$, $\sigma = 30$ (black solid curve), and $\sigma = 90$ (red solid curve). The peaks of black and red curves are approximately 268000 and 153000 cases, respectively. We also depicted the active cases data from Brazil (blue dots), since February 26, 2020 until May 02, 2020 [24].

FIG. 9: In these graphics we present the active cases solutions for $t = 2\tau$ (time in days), $D = 1$, $x = x'$, $\rho_0 = 10^5$, $\tau' = 47.5$, $\tau_1 = 40.5$, $\kappa = 0.06$, $s = 1$, $\beta = 10^7$, $z = 50$, $\sigma = 30$ (black solid curve), and $\sigma = 90$ (red solid curve). The peaks of black and red curves are approximately 329000 and 188000 cases, respectively. We also depicted the active cases data from Brazil (blue dots), since February 26, 2020 until May 02, 2020 [24].

V. CONCLUSIONS

In this work we introduced a modified version of the diffusion equation, mediated by a Lifshitz scaling together with the diffusion coefficient $\phi(\tau)$. The diffusion time $\sigma$ is analogous to the so-called fictitious time in stochastic quantization theories [26]. We were able to find an analytic solution for this diffusion equation, and to use the standard Gaussian curves to interpret $\sigma$ as the lockdown time, if such an equation is applied to model pandemic cases.

Therefore, we investigate two possible models with $\phi(\tau)$ having (anti)kink, and double (anti)kink-like profiles. These models were used to fit real active cases data of COVID-19 from three different countries (Germany, Spain, and Brazil). We successfully depicted the active cases curves for Germany and Spain, and use them to constraint some of our free parameters to generate curves for Brazil. Then, we predicted four scenarios for the advance of the pandemic in Brazil, based on 30 and 90 lockdown days. Up to May 02, 2020, 16.57% of active cases in Brazil are classified as critical [3]. Therefore, knowing that Brazil has 32703 ICU facilities available [25], the maximum number of active cases allowed for this country is 197363, if the rate of critical cases still constant in the next weeks, as well as if the ICUs were allocated only for patients diagnosed with COVID-19. These scenarios alert for a potential crash in the health care system of Brazil if no lockdown measure is taken in the next weeks. Moreover, the solution which best fitted the active cases data up to May 02, 2020 is the red curve from Fig. 9. Such a solution predicts that the pandemic is going to be fully controlled after day 198 (August 28, 2020), when the number of active cases is less than 1000.
It is relevant to point that the Lifshitz scaling exponent was essential to depict the numerical active curves here studied. Moreover, we also verified that the double (anti)kink-like profiles were able to fit better the real data than the single (anti)kink-like solutions. Consequently, we can conjecture that multiple anti(kink)-like models, like those introduced in [27], would improve the level of precision of our active cases curves. Another interesting perspective consists in investigating solutions for the diffusion equation derived from models with multiple (anti)lump like solutions, such as those presented in [28]. Moreover, the methodology here adopted can be applied to other pandemics, as well as to other COVID-19 data set like new daily cases, for instance.
