In this article we show that a Dirac Hamiltonian in a curved background spacetime can be interpreted, when discretized, as a tight binding Fermi-Hubbard model with non unitary tunnelings. We find the form of the nonunitary tunneling matrices in terms of the metric tensor. The main motivation behind this exercise is the feasibility of such Hamiltonians by means of laser assisted tunnelings in cold atomic experiments. The mapping thus provides a physical interpretation of such Hamiltonians. We demonstrate the use of the mapping on the example of time dependent metric in 2+1 dimensions. Studying the spin dynamics, we find qualitative agreement with known theoretical predictions, namely the particle pair creation in expanding universe.

I. INTRODUCTION

Recently, much interest was devoted to a study of many body physics of quantum gases [1,2]. High degree of control of the experimental parameters has allowed for designing specific Hamiltonians [3]. A special category is then a fabrication of synthetic gauge fields [4], where a remarkable experimental progress has been achieved in last couple of years, including the realization of synthetic electric [5] and magnetic [6] fields in the bulk as well as on the lattice [7]. A non abelian synthetic gauge field of the spin orbit Rashba type has been demonstrated in the bulk [8,9]. In the case of a lattice, which will be of main interest, laser assisted hoppings [10,11] allow for a simulation of a (non abelian) lattice gauge theory [12] with cold atoms [13]. Different works addressed the question of non abelian background fields with cold atoms. Such situation occurs e.g. in the case of electrons with spin orbit coupling and can be studied with cold atomic systems, in both non interacting [14] and interacting [15,16] cases. In those scenarios, however, the tunnelings of different spin components between two adjacent lattice sites are described by unitary matrices, due to the hermiticity of the gauge field [12,17]. Moreover, an explicit form of these matrices is determined by the theory one wants to simulate, e.g. the mentioned spin orbit coupling. It is thus an interesting question, what happens, if these tunnelings become non unitary, which can be, in principle, done in the cold atomic experiments using known techniques, as explained below.

The article is structured as follows. In Sec. II we derive the mapping between continuous Dirac fields in curved background spacetime and the Fermi-Hubbard model with general tunnelings (we also derive the non-relativistic limit of the mapping in the Appendix). In Sec. III we demonstrate the use of the mapping on a specific example of the expanding universe in 2+1 dimensions. We discuss in detail the dispersion relations in continuum and on the lattice and how they are related using adiabaticity criteria. In Sec. IV we discuss how such systems can be implemented with cold atoms. We show how the toy example of expanding universe can be observed through the spin dynamics. Finally we conclude in Sec. V.

In a simple case of a static diagonal metric, the tunnelings become unitary. Alternative interpretation of the Fermi-Hubbard Hamiltonian is that of a Pauli Hamiltonian, i.e. a non relativistic limit of the Dirac Hamiltonian. In this case the tunnelings remain, in general, non unitary even for the static diagonal metric.

II. THEORETICAL MODEL

A. Continuum - lattice mapping

Driven by this motivation, let us start with a kinetic fermionic Hamiltonian in $d-1$ spatial dimensions of a form

$$H(t) = \sum_{x,k,s,s'} \Psi_k^s(x) T_{s,s'}(x,x+a_k) \Psi_{s'}(x+a_k) + \text{h.c.}, \quad (1)$$

where the sum runs over all lattice sites $x$ and directions $k = 1...d-1$ and the fermionic operators satisfy the usual anticommutation relations

$$\{\Psi_s(x), \Psi_{s'}(x')\} = \delta_{s,s'} \delta_{xx'}.$$  \hspace{1cm} (2)

Throughout the paper, we denote the spacetime coordinates as $s := (t,x)$, while the space coordinates as $x$. The matrices $T(x,x+a_k)$ represent a parallel transporter of a quantum field $\psi$ between sites $x$ and $x+a_k$. In the case of lattice gauge theories, the matrix $T$ belongs to a representation of a gauge group, which is typically compact, such as $U(n)$ with $n$ being the number of "flavor" components of the field $\psi$. In such case, the matrices $T$ become unitary. The relevant question is thus, what if the $T$ belong to a non compact gauge group? This question has actually been already addressed in the past [18-20] and more recently [21], but such interpretation seems to be problematic and was not actively pursued. Lets return to the Hamiltonian Eq. (1). In what follows, we will be interested in physics of fermions, so that $\psi$ is a spinor. As discussed later, a general matrix $T \in GL(n,\mathbb{C})$ can be engineered in cold atomic systems ($n$ is the number of spin components). We would like to emphasize, that for such a novel situation, the Hamiltonian Eq. (1) is interesting on its own right. However, it
is also interesting to look, whether some physical significance can be given to it. A starting point of our discussion will be a classical (not quantized) fermionic field in a curved spacetime, which can be described by a Lagrangian density \[ \mathcal{L}(x) = \sqrt{g} \left\{ \frac{1}{2} \bar{\psi}(x) \gamma^\mu D_\mu \psi(x) + \text{h.c.} - m \psi(x) \psi(x) \right\}. \] Let us recall that, working in a coordinate basis \( e_{\mu} \), in which the spacetime vector \( x \) is defined in terms of its components \( x^\mu, x = x^\mu e_\mu \), one may construct a local orthonormal basis \( e_\alpha \). The two bases are related through vielbeins \( e_\alpha = e_\alpha^\mu e_\mu \). The metric tensor \( g \) is defined as \( \eta_{\alpha\beta} = e_\alpha^\mu e_\beta^\nu g_{\mu\nu} \), where \( \eta \) is the Minkowski, i.e. flat metric. Then, the curved spacetime \( g \) matrices are defined as \( \gamma_\mu = \gamma^\alpha e_\alpha^\mu \) and we adopt the sign convention \( \eta = (+, -, - , ...) \). The covariant derivative acting on the spinor is \( D_\mu = \partial_\mu - \Gamma_\mu \), where \( \Gamma_\mu(x) = \frac{1}{2} \left( \gamma^\mu, \gamma^\rho \right) e_\alpha^\rho (\nabla_\mu e_\alpha) \) and \( \nabla_\mu = \partial_\mu + \Gamma_\mu \). One then obtains the evolution of the ket \( |x\rangle \)

\[ \partial_0 \langle x | = -\frac{1}{2} \left[ \langle x | \left( \partial_0 + \sqrt{\gamma} \beta \gamma^\rho \right) (\sqrt{\gamma} \beta \gamma^\rho)^{-1} \right] \] which can be formally integrated to give

\[ |x\rangle = |t, x\rangle = \sqrt{2} |x\rangle (\sqrt{\gamma} \beta \gamma^\rho)^{-\frac{1}{2}}. \]

The factor \( \sqrt{2} \) is an integration constant coming from the hermitian definition of the Lagrangian Eq. (3).

The quantization of the space and time dependent field Eq. (2), \( \psi(x) \), proceeds by imposing equal time anticommutation relations for the canonically conjugate operators \( \phi(x) \), namely

\[ \{ \psi(x), \pi_\rho(x') \} = i\delta(x-x') \delta_{\rho\sigma}, \]

where \( \pi_\rho(x) \) is given by Eq. (4). We can use the relations Eq. (9) and Eq. (13) to find the relationship between the two fields \( \psi(x) \) and \( \Psi(x) \) to be

\[ \psi(x) = \sqrt{2} \left( \sqrt{\gamma} \beta \gamma^\rho \right)^{-\frac{1}{2}} \Psi(x). \]

Plugging Eq. (4) into Eq. (14) and using Eq. (15) we obtain for the anticommutator of the constant time hypersurface fields

\[ \{ \psi(x), \psi(x') \} = \delta(x-x') \delta_{\sigma\lambda}, \]

which is precisely the relation Eq. (2).

Let us now take the lattice Dirac Hamiltonian Eq. (8) and write it as

\[ H(t) = \sum_{x,k} \psi(x)^\dagger T(x, x + a_k^-) \psi(x + a_k^-) + \text{h.c.} + \psi(x)^\dagger V(x) \psi(x), \]

We now use the relation Eq. (15) to substitute for \( \psi(x) \) and write the Hamiltonian as

\[ H(t) = \sum_{x,k} \Psi(x)^\dagger T(x, x + a_k^-) \Psi(x + a_k^-) + \text{h.c.} + \Psi(x)^\dagger V(x) \Psi(x). \]
where
\[ T(x, x + a) = \frac{1}{2} (iM^0)^{-1/2} (x) M^0 P (x, x + a) (iM^0)^{-1/2} (x + a) \]
\[ V(x) = (iM^0)^{-1/2} [M^0 T_0 + (M^0 T_0)] + \sqrt{\bar{g}m\gamma^0] (iM^0)^{-1/2}, \tag{18} \]

where we have put the lattice spacing \( a = 1 \) for simplicity. Now, the Hamiltonian Eq.(17) has the same structure with the correct anticommutation relations for the operators as Eq.(1) (plus the local term). The price to pay in order to achieve this goal was to absorb the spatiotemporal dependence of the fields \( \psi(x) \) to the elements of the Hamiltonian and thus spoiling its covariance.

**Fermion doubling.** Due to the naive discretization of the Hamiltonian Eq.(4), one obtains the lattice formulation with doublers. Since in the present work we are interested only in noninteracting theory, and taking into account the fact, that one can address experimentally individual \( k \) vectors (cf. below), we don’t elaborate on this issue further. Proposals how to deal with the fermion doubling in cold atomic experiments exist in the literature, see e.g. [28] for staggered fermions formulation.

**B. Physical interpretation**

We just provided a possible interpretation of the kinetic Hamiltonian of the form Eq.(17) with general non unitary tunnelings \( T \). In Appendix, we provide an alternative mapping, corresponding to the nonrelativistic limit of the Dirac Hamiltonian leading to the Pauli Hamiltonian, yielding formally the same expression for the lattice Hamiltonian Eq.(17).

The question is then what field theory is actually simulated. Let’s take an example of simulation, where the Hamiltonian Eq.(14) describes a motion in a (two dimensional) plane for a two component field \( \psi_\nu, s = 1, 2 \). If we want to interpret it as a Dirac Hamiltonian, our simulator would correspond to a Dirac Hamiltonian in 2+1 dimensions. If we are to interpret it, however, as a Pauli Hamiltonian, the simulator corresponds to a spin half fermion living in 3+1 dimensions, but whose motion is confined to a plane.

We would like to mention, that a simulation of a Dirac field in curved spacetime with cold atoms was already addressed [29], but the discretization was carried out in the limit of small lattice spacing, such that the approximation \( P \approx 1 + \alpha \Gamma \) is valid. For stationary metrics, considered in [29], it results in unitary tunnelings.

## III. CASE STUDY: EXPANDING FLRW UNIVERSE

In order to show the above derived mapping on some physically relevant scenario, we choose a textbook example of an expanding universe described by a Friedmann-Lemaître-Robertson-Walker (FLRW) metric in 2+1 dimensions with a line element
\[ ds^2 = dt^2 - b_x(t)^2 dx^2 - b_y(t)^2 dy^2. \tag{19} \]

Using the relations Eq.(18) leads to the result
\[ T_x \equiv T(x, x + a) = -i \frac{2m}{2b_x} [E^2 \sinh \partial_0 b_x + \sigma_x \cosh \partial_0 b_x] \]
\[ T_y \equiv T(x, x + a) = -i \frac{2m}{2b_y} [E^2 \sinh \partial_0 b_y - \sigma_y \cosh \partial_0 b_y] \]
\[ V(x) = m \sigma_z. \tag{20} \]

It then clear, that in the lattice formulation the FLRW metric maps to a generalized time dependent spin-orbit coupling.

**A. Continuum dispersion**

Let’s consider the continuum Hamiltonian density Eq.(44)
\[ \mathcal{H}_D = (\gamma^0)^{-1} (m - i \gamma^5 D_k) + i \Gamma_0. \]

One can derive from the line element Eq.(19) the following relations
\[ \sqrt{\bar{g}} = b_x b_y \]
\[ \gamma^0 = \gamma^0 \Gamma^0 = 0 \]
\[ \gamma^1 = \frac{1}{b_x} \gamma^1 \Gamma^1 = [\gamma^0, \gamma^1] w_{011} = 2 \sigma_x \partial_0 b_x \]
\[ \gamma^2 = \frac{1}{b_y} \gamma^2 \Gamma^2 = [\gamma^0, \gamma^2] w_{022} = -2 \sigma_y \partial_0 b_y \tag{21} \]

Using the Dirac representation of \( \gamma \) matrices \( \gamma^0 = \sigma_z, \gamma^1 = i \sigma_x, \gamma^2 = i \sigma_y \) and the above relations, one gets
\[ \mathcal{H}_D = \gamma^0 m - i \frac{1}{b_x} (\sigma_x \partial_x - 2(\partial_0 b_x) \mathbb{I}_2) - i \frac{1}{b_y} (-\sigma_y \partial_y + 2(\partial_0 b_y) \mathbb{I}_2). \tag{22} \]

Next, going to the Fourier space
\[ \Psi(t, x) = \frac{1}{2\pi} \int d^2k e^{-ikx} \psi(t, k) \tag{23} \]
the final Hamiltonian takes the form \( H(t) = \int d^2k \mathcal{H}_D \), where
\[ \mathcal{H} = \Psi(t, k)^\dagger \sqrt{g} \mathcal{H}_D + h.c. \Psi(t, k) \]
\[ = \Psi(t, k)^\dagger \sqrt{\frac{m}{-k_x \frac{b_x}{b_y} + i \frac{k_y}{b_x} - \frac{k_y b_x}{b_y}} - \frac{m}{-k_y \frac{b_x}{b_y} + i \frac{k_x}{b_y} - \frac{k_x b_y}{b_x}}} \Psi(t, k) \]
\[ = \Psi(k)^\dagger \left( \frac{m}{-k_y \frac{b_x}{b_y} + i \frac{k_x}{b_y} - \frac{k_x b_y}{b_x}} - \frac{m}{-k_y \frac{b_x}{b_y} + i \frac{k_x}{b_y} - \frac{k_x b_y}{b_x}} \right) \Psi(k), \tag{24} \]
where in the last equality we have used the relation Eq.(15) between the two fields \( \psi(t, k) = \sqrt{2/(\sqrt{g} \gamma^0)} \Psi(k) = \sqrt{2/(\sqrt{b_x b_y})} \Psi(k) \). We thus obtain the instantaneous eigenvalues of the total Hamiltonian in continuum (this result is compatible with the one of Ref. [27])
\[ \epsilon_{\pm} = \pm \sqrt{m^2 + \left( \frac{k_x}{b_x} \right)^2 + \left( \frac{k_y}{b_y} \right)^2} \tag{25} \]
B. Lattice dispersion

Combining Eq. (17), Eq. (20) and the lattice version of Eq. (23), one gets for the lattice Hamiltonian

$$H(t) = \sum_{k_x, k_y} \Psi^\dagger_k \begin{pmatrix} m - \mu_k & -\gamma_k \\ -\gamma_k & -m - \mu_k \end{pmatrix} \Psi_k,$$  \tag{26}

where the coefficients read

$$\mu_k = \frac{\sin k_x \sin \partial_x b_k}{b_x} + \frac{\sin k_y \sin \partial_y b_k}{b_y},$$

$$\gamma_k = \frac{\sin k_x \cosh \partial_x b_k}{b_x} + i \frac{\sin k_y \cosh \partial_y b_k}{b_y}.  \tag{27}$$

The instantaneous eigenenergies on the lattice are

$$\epsilon_{\pm} = -\mu_k \pm \sqrt{m^2 + |\gamma_k|^2}.  \tag{28}$$

One can also verify that the lattice dispersion relation Eq. (28) yields the dispersion relation Eq. (25) in the continuum limit. So far we have been working with \( h = c = a = 1 \). In order to find the continuum limit, we need to restore the lattice spacing \( a \) in the equations. Noting that the lattice spacing enter the lattice version of the Hamiltonian through the definition of the covariant derivative only (\( \Psi_k \partial_x \Psi_s = \Psi_k \partial_x \Psi_s - \Psi_s \partial_x \Psi_k + \gamma k = 1/a [P_j \Psi_{k+j} - \Psi_k] \) with \( P_j = \exp(-i \Gamma_{a}) \)). In our case it translates to the multiplication of tunneling matrices \( T \), Eq. (20), by a factor \( 1/a \) \( (T \rightarrow 1/T) \) and since \( \Gamma_{a} \partial_0 b_j \), by multiplication of the occurrences of \( \partial_0 b_j \) by \( a (\partial_0 b_j \rightarrow \partial_0 b_j) \). Written explicitly, the coefficients \( \mu_k, \gamma_k \) (Eq. (27)) become

$$\mu_k = \frac{\sin ak_x \sinh a \partial_x b_k}{ab_x} + \frac{\sin ak_y \sinh a \partial_y b_k}{ab_y},$$

$$\gamma_k = \frac{\sin ak_x \cosh a \partial_x b_k}{ab_x} + i \frac{\sin ak_y \cosh a \partial_y b_k}{ab_y},  \tag{29}$$

which in the continuum limit gives

$$\lim_{a \rightarrow 0^+} \mu_k = 0$$

$$\lim_{a \rightarrow 0^+} \gamma_k = k_x \frac{b_x}{b} + i k_y \frac{b_y}{b},  \tag{30}$$

which in turn yields the continuum dispersion relation as expected.

C. Note on adiabaticity

We have shown, that in the limit \( a \rightarrow 0^+ \), one recovers the correct continuum dispersion relation. In practice, however, the lattice spacing \( a \) is finite and thus care must be taken when interpreting the results of the simulation in terms of continuum theory. Intuitively, one expects to recover the continuum theory in the limit of small wavevectors \( k \), since the details of the underlying lattice should not be important. In our specific example we thus consider the limit \( (a \text{ nonzero}) \text{ at } \frac{ak}{\min k} k \ll 1 \).

In this limit, the dispersion relation Eq. (28) becomes

$$\epsilon_{\pm} \approx \frac{ak_x \partial_x b_k}{ab_x} + \frac{ak_y \partial_y b_k}{ab_y} \pm \sqrt{m^2 + \left(\frac{ak_x}{ab_x}\right)^2 + \left(\frac{ak_y}{ab_y}\right)^2},  \tag{31}$$

where we assume sufficiently slow changes in \( b \), such that only leading term in the expansions of functions \( \sinh(\partial_0 b) \) is dominant. In order to recover the continuum dispersion, the \( \sqrt{\cdot} \) term has to be dominant. Explicitly, we can consider two limiting cases (i) \( m \approx 0 \ll k_j/b_j \) and (ii) \( m \gg k_j/b_j \). In these two cases we thus have

$$m \ll \frac{k_j}{b_j} \Rightarrow \frac{k_j \partial_0 b_j}{b_j} \ll \frac{k_j}{b_j} \Rightarrow a \partial_0 b_j \ll 1$$

$$k_j \ll m \Rightarrow \frac{k_j \partial_0 b_j}{b_j} \ll m \Rightarrow a \partial_0 b_j \approx 1  \tag{32}$$

where \( j = x, y \). These conditions can be once again understood intuitively such that the characteristic rate of change of \( b \) has to be much smaller than the maximum frequency supported by the lattice \( \omega_{	ext{max}} = k_{\text{max}} = \frac{\pi}{a} \) (with \( c = 1 \)).

An important remark to make here, which is relevant for the implementations with cold atoms, is that a particularly important case is half filling. In the massless case, the dispersion relation Eq. (28) yields Dirac cones at \( k_{\text{max}} = 0, \pm \pi \) with Fermi energy \( E_F = 0 \). The development around the Dirac points \( k \rightarrow k_{\text{Dirac}} + k \) yields the dispersion relation for small \( k \text{ Eq. (32)} \). In other words, it is natural to work at half filling, where the relevant wavevectors lie in the vicinity of the Dirac points, which approximates well the continuum theory.

IV. IMPLEMENTATION WITH COLD ATOMS

In the experiments with cold atoms, the internal degrees of freedom are usually played by the hyperfine states of the atoms [2]. These allow for a laser assisted tunnelings between adjacent sites, say \( i, j \) of the optical lattice. Let denote the internal degrees of freedom \( s \). In order to engineer an arbitrary \( T(s) \in GL(n, \mathbb{C}) \), it is necessary to control each of the tunneling rates \( (i, s) \leftrightarrow (j, s') \) independently in all spatial directions and moreover, the rates in general vary in spacetime. Different techniques and their combination can be used in order to achieve this goal. For example, bichromatic lattices can be combined with an independent Raman laser for each transition \( s \leftrightarrow s' \) [20]. The spatial dependence is then given by a transverse profile of each Raman laser. It can be given e.g. by a (typically) gaussian laser profile which varies slowly on the lattice spacing or it can be designed using a specific phase masks [31] or array of microlenses [32], which allow for the modulation on the scale of lattice spacing and were already used in the cold atomic experiments. Another point is, that the potential \( V(x) \) in Eq. (17) is non diagonal and might be difficult to engineer. The way around is that since the underlying lattice should not be important. In our specific example we thus consider the limit \( (a \text{ nonzero}) \text{ at } \frac{ak}{\min k} k \ll 1 \).
A. Expanding FLRW universe: Time evolution of the spins

In this section we will investigate the dynamics of a typical observable accessible with cold atomic systems. We would like to emphasize, that we are interested only in qualitative features of our mapping with respect to the continuum theory. More formal and quantitative comparison between the continuum theory and its lattice counterpart is in principle possible (using the analysis in [22, 33, 34]), however it requires a significant amount of additional work, which is not crucial for the conclusions presented in the following.

We consider the spin $S$ defined either in the physical spin space (spanned by operators $\Psi_{k,x}, \Psi_{k,y}$) or the spin $S^\prime$ defined in the local diagonal basis spanned by operators $d_{k,x}, d_{k,y}$. They are defined as

\[
S^\prime_k(t) = \frac{1}{2} \langle \Psi_{k,x}^\dagger(t) \sigma^x d_{k,x}(t) \rangle
\]

\[
S^{\prime \prime}_k(t) = \frac{1}{2} \langle \Psi_{k,y}^\dagger(t) \sigma^y d_{k,y}(t) \rangle
\]

where $\sigma$ are the usual Pauli matrices. Working in the Heisenberg picture, an evolution of an arbitrary operator $O$ is governed by the Heisenberg equations of motion $\dot{O} = -i[O, H]$ with the Hamiltonian Eq.(32). Written in components the equation of motion reads

\[
\dot{O}_{k,x} = -iH_{k,x} O_{k,x}.
\]

Defining spinors as $\Psi_k = (\Psi_{k,1}, \Psi_{k,2})^T$ and $d_k = (d_{k,x}, d_{k,y})^T$ one can introduce the relation between the two bases as

\[
d_k(t) = U_k^\dagger(t) \Psi_k(t)
\]

and the time evolution operator as

\[
\Psi_k(t) = K_k(t, t_0) U_k(t_0) \Psi_k(t_0) \equiv K_k(t, t_0) d_k(t_0).
\]

Plugging these relations to the definitions of the spin observables Eq.(34), one gets

\[
S^\prime_k(t) = \frac{1}{2} \langle d_{k,x}^\dagger(t_0) K_{k,x}(t, t_0) \sigma^x d_{k,x}(t_0) \rangle
\]

\[
= \frac{1}{2} \langle K_{k,x}(t, t_0) \sigma^x d_{k,x}(t_0) K_{k,x}^\dagger(t, t_0) d_{k,x}^\dagger(t_0) \rangle
\]

\[
= \frac{1}{2} \langle K_{k,x}(t, t_0) \sigma^x K_{k,x}^\dagger(t, t_0) \rangle,
\]

where we have used the relation $\langle d_{k,x}^\dagger d_{k,x} \rangle = n_{k,x} \delta_{x'}$ and $n_{k,x} = \text{diag}(n_{k,x}, n_{k,x})$. Similarly, one gets for the spins in the local diagonal basis

\[
S^{\prime \prime}_k(t) = \frac{1}{2} \langle K_{k,y}(t, t_0) \sigma^y U_k(t_0) \rangle
\]

\[
= \frac{1}{2} \text{Tr} \left( K_{k,y}(t, t_0) \sigma^y K_{k,y}^\dagger(t, t_0) \right).
\]

In order to investigate the spin dynamics, we solve the equation Eq.(35) numerically using the Runge-Kutta integrator. For initial conditions, we assume thermal distribution $n_{k,\pm} = (\exp(B_{k,\pm}) + 1)^{-1}$ where $B$ is the inverse temperature.

For $b_{x,y}(t)$ one could choose any smooth functions with some asymptotic values for $t \to \pm \infty$. For numerics related reasons, we choose a function such that $\partial_t b_{x,y} = 0$ at the beginning and the end of the expansion, namely

\[
b_j(t) = \begin{cases} 
1 & t < 0 \\
1 + B_j \sin^2 \left( \frac{\pi t}{\tau_j} \right) & 0 \leq t \leq \tau_j \\
1 + B_j \cos^2 \left( \frac{\pi t}{\tau_j} \right) & t > \tau_j
\end{cases}
\]

where $j = x, y$, $B_j$ is the amplitude and $\tau_j$ the duration of the expansion. This gives

\[
\partial_t b_j \leq B_j \frac{\pi}{2\tau_j} \sin \left( \frac{\pi t}{\tau_j} \right) \leq B_j \frac{\pi}{2\tau_j}
\]

which can be directly used to evaluate the adiabaticity criteria Eq.(32).

We consider three characteristic cases

(i) massless isotropic ($m = 0, b_x = b_y$)

(ii) massless anisotropic ($m = 0, b_x \neq b_y$)

(iii) massive isotropic ($m \neq 0, b_x = b_y$)

The massless isotropic case is trivial, because the field is conformally invariant and there is no associated dynamics of the spins, which we have verified in our simulation. This is in qualitative agreement with the fact, that there are no particle creations in the massless isotropic case [25]. The same argument holds for case (ii) for field evaluated at the Dirac points. In order to observe the spin dynamics, one thus has to look in the vicinity, but not directly at the Dirac point.

Motivated by the realization in cold atomic experiments, we choose in the following relatively large value of the inverse temperature $\beta = 5$.

Massless anisotropic case. In Fig.(1) we show the spin dynamics for the massless anisotropic case for different wavevectors $k_i$, i.e. the direction which does not undergo the expansion. The spins in the diagonal basis do not evolve after the expansion is finished ($t/\tau = 1$), which is the case for all $k$ (the effect is not clearly visible in Fig.(1) due to the strong thermal background, see also Fig.(2)). This is in contrast to the spin evolution in the fermionic basis where the spins continue to evolve under the action of the free propagator. This is an important fact with respect to the experimental signatures of the expansion (cf. below).

An example of spin dynamics for different amplitudes of the expansion is shown in Fig.(2), where we evaluate $S^\prime_k$ and $S^{\prime \prime}_k$ in the vicinity of the Dirac point $(0,0)$, namely $(k_x, k_y, \pi) = (0.02, 0.02)$. One can see, as discussed above, that in the diagonal basis, the spin evolution stops when the expansion is finished, as opposed to the fermionic basis. For $B_x = (0.2, 1, 10)$ using Eq.(41) gives $\partial_t b_x \leq 0.063, 0.31, 3.1$. According to Eq.(32), the cases $B_x = (0.2, 1)$ are thus well adiabatic, while $B_x = 10$ is not.

To complete the discussion of the massless anisotropic case, we show in Fig.(3) the effect of the thermal background for
different temperatures ($\beta = \infty, 40, 5$). The qualitative features of
the expansion are not affected by the thermal background, however they may be strongly suppressed (e.g. for $\beta = 5$).

Massive isotropic case. Another situation yielding non trivial spin dynamics is an isotropic expansion, but where the field is massive, since the mass term explicitly breaks the conformal invariance. In this case, for small masses the mass term further enforces the restriction to the small $k$ values (cf. the discussion in Sec. III C, $m \gg \frac{k}{\tau}$). An example of the spin dynamics for $B_x = B_y = 1$ and $m = (0.1, 0.25, 0.5)$ is shown in Fig. 2. One can see, that for increasing mass, the expansion has smaller effect on the spin dynamics (decrease in amplitude), i.e. the particle pair creation is suppressed. Another comment is that in the lattice formulation the mass term plays the role of effective magnetic field along $z$ direction, which induces spin precession. This is clearly visible in the fermionic basis, where the precession rate is proportional to the mass (i.e. effective magnetic field), however the amplitude of the precession decreases with increasing mass.

The spin provides an ideal experimental signature of the expansion since it is routinely measured in nowadays cold atomic experiments by probing the populations of atomic levels [2]. Moreover, the time of flight measurements allow to address a specific wavevector $k$ of the Brillouin zone, namely the neighbourhood of the Dirac points.
B. Interactions

So far, we were considering only non interacting theory. Although non abelian lattice gauge theories are non trivial already at this level, the most interesting physics can be obtained in the presence of interactions. A natural interaction term for spin half fermions in optical lattice is $H_{int} \propto U \sum_{\ell} n_\ell n_{\ell+1}$, where $n_\ell = \psi_\ell^\dagger \psi_\ell$ is the density operator. Once again, one entirely legitimate approach is to consider a Hamiltonian $H = H_{kin} + H_{int}$, with $H_{kin}$ Eq. (1) and $T \in GL(2, \mathbb{C})$ as such and study its properties ($H$ could also describe interacting bosons instead of fermions or both bosons and fermions. The interspecies interaction might lead to interesting physical phenomena, such as particle number fractionalization [35-37]. The other approach is to design directly a given field theory. For example, a proposal of simulation of a Thirring model (i.e. 1+1 dimensional field theory) with cold atoms was made [38], where the interaction term reads $J^\mu J_\mu$ with $J^\mu = \psi^\dagger \gamma^\mu \psi$. In curved spacetime, the replacement $\gamma^\mu \rightarrow \gamma^\mu$ makes the interaction term spacetime dependent. One can thus try to modify the proposal [38] in a way that creates the correct interaction term, which might be an interesting test bed situation, since as one dimensional theory, the massless Thirring model is soluble also in curved spacetime [39].

V. CONCLUSION

In this article we have shown how to map the continuous Dirac fields in curved background spacetime to the Fermi-Hubbard model with general nonunitary tunnelings both in the relativistic and non-relativistic cases. Next, we have demonstrated the mapping on the example of an expanding FLRW universe in 2+1 dimensions. Motivated by the experimental feasibility of such Hamiltonian in cold atomic experiments with laser assisted tunnelings, we could explicitly demonstrate the effect of time dependent non unitary tunnelings on the spin dynamics. We found, that the dynamics of the spin (representing the particle mode occupation) shares the same qualitative features as those predicted by the quantum field theory in FLRW spacetime, namely the dependence on mass and no particle creation in the massless isotropic (conformally invariant) case.

Hamiltonian is

\( E \) obtained from the Dirac Hamiltonian of the form

\[
H = \gamma^\mu P_\mu + m, \quad (48)
\]

and \( h = \text{diag}(h_{ii}(x^k)) \), where \( i = 1..d-1 \) and the diagonal terms depend only on spatial coordinates \( x^k \). First thing we note, is that in this case, the vielbein fields are also diagonal, \( e_\mu^i = 0 \) for \( \mu \neq \alpha \). In particular \( e_0^0 = 1 \) implying \( (\gamma^\mu)^{-1} = \frac{1}{\gamma^\mu} = \gamma^\mu \). Also, \( \Gamma_0 = 0 \). We then obtain for the Dirac Hamiltonian

\[
\mathcal{H}_D = \gamma^\mu m - i \frac{1}{2m} (\gamma^\mu D_k) (\gamma^\nu D_j), \quad (49)
\]

The total Hamiltonian, expressed in terms of field variables, then reads

\[
H_p = \frac{1}{2} [ (\psi, \mathcal{H}_p \psi) + (\mathcal{H}_p \psi, \psi) ] . \quad (50)
\]

The scalar product can be evaluated by integrating per parts in curved spacetime. The reason why one wants to do that is to obtain terms of type \( (D\psi^a)(D\psi) \) rather than \( \psi^a D^a \psi \), since the former can be mapped to a Hubbard model with only nearest neighbor hopping. Evaluating Eq. \( (50) \), we get

\[
H_p = \frac{1}{2} \int d^{d-1}x \sqrt{g} \gamma^\nu \gamma^\mu \gamma^\lambda \psi \psi \psi \psi + \text{h.c.}
\]

\[
\int d^{d-1}x \sqrt{g} m \psi \psi . \quad (51)
\]

At this point \( \psi \) is still \( 2^{d/2} \) component spinor, where \( n \) is the integer part of \( n \). By construction, the Hamiltonian \( H_p \) contains only even operators and we can thus split the spinor into two parts, say \( \psi = (\chi, \varphi) \). Each of the spinors \( \chi, \varphi \) has \( 2^{(d-1)/2} \) components, which will have independent dynamics.

In case of the diagonal static metric and \( d = 4 \), we find

\[
\left( \begin{array}{cc}
\gamma^\mu m + \epsilon^\mu & 0 \\
0 & \gamma^\nu m + \epsilon^\nu
\end{array} \right) , \quad (52)
\]

where the subscript \( P \) stands for the Pauli Hamiltonian. One can identify \( \gamma^\mu, \epsilon^\mu \) and \( O \) by comparing Eq. \( (45) \) with Eq. \( (44) \).

In the most general case it yields rather lengthy expressions. In order to proceed with the calculation, we will thus consider a simple, yet non-trivial scenario with a static diagonal metric of the form

\[
\gamma = \left( \begin{array}{cc}
1 & 0 \\
0 & h
\end{array} \right) , \quad (47)
\]

where \( h = \text{diag}(h_{ii}(x^k)) \), where \( i = 1..d-1 \) and the diagonal terms depend only on spatial coordinates \( x^k \). First thing we note, is that in this case, the vielbein fields are also diagonal, \( e_\mu^i = 0 \) for \( \mu \neq \alpha \). In particular \( e_0^0 = 1 \) implying \( (\gamma^\mu)^{-1} = \frac{1}{\gamma^\mu} = \gamma^\mu \). Also, \( \Gamma_0 = 0 \). We then obtain for the Dirac Hamiltonian

\[
\mathcal{H}_D = \gamma^\mu m - i \frac{1}{2m} (\gamma^\mu D_k) (\gamma^\nu D_j), \quad (49)
\]

The total Hamiltonian, expressed in terms of field variables, then reads

\[
H_p = \frac{1}{2} [ (\psi, \mathcal{H}_p \psi) + (\mathcal{H}_p \psi, \psi) ] . \quad (50)
\]

The scalar product can be evaluated by integrating per parts in curved spacetime. \]

At this point \( \psi \) is still \( 2^{d/2} \) component spinor, where \( n \) is the integer part of \( n \). By construction, the Hamiltonian \( H_p \) contains only even operators and we can thus split the spinor into two parts, say \( \psi = (\chi, \varphi) \). Each of the spinors \( \chi, \varphi \) has \( 2^{(d-1)/2} \) components, which will have independent dynamics.

In case of the diagonal static metric and \( d = 4 \), we find

\[
\left( \begin{array}{cc}
\gamma^\mu m + \epsilon^\mu & 0 \\
0 & \gamma^\nu m + \epsilon^\nu
\end{array} \right) , \quad (52)
\]

where \( \epsilon \) and \( O \) are even and odd operator, defined by the property \( [\gamma^\mu, \epsilon] = 0 \) and \( \{\gamma^\mu, O\} = 0 \) and \( \gamma^\mu \) is in the Dirac representation. The lowest order expression for the nonrelativistic Hamiltonian is

\[
\mathcal{H}_p = \gamma^\mu m + \epsilon^\mu + \frac{1}{2m} \gamma^\nu \gamma^\lambda \psi \psi \psi \psi . \quad (56)
\]
where \( f_{k j} = \sqrt{g} e^k_{\ell} e^j_{\ell} \). The commutator in the second term is familiar from non-abelian gauge theories and we have \([\nabla_k, \nabla_j] = \partial [\nabla_k, \nabla_j] - [\nabla_k, \nabla_j]\), which acts locally on the spinor \( \chi \). The first term can be integrated per parts to yield (using \( \tilde{\Gamma}^\dagger_i = -\Gamma^\dagger_i \))

\[
\int d^3x \chi^\dagger f_{ii} \nabla^i \chi = \int d^3x \{ f_{ii} (\nabla^i \chi)^\dagger (\nabla_i \chi) - (\partial^i f_{ii}) \chi^\dagger (\nabla_i \chi) \}. \tag{54}
\]

We thus write the Pauli Hamiltonian as

\[
H_p = \int d^3x \frac{1}{2m} \left[ f_{ii} (\nabla^i \chi)^\dagger (\nabla_i \chi) - (\partial^i f_{ii}) \chi^\dagger (\nabla_i \chi) - \chi^\dagger f_{kj} \sigma^k \sigma^j [\nabla_k, \nabla_j]_{k<j} \right] + \text{h.c.} + \sqrt{g} m \chi. \tag{55}
\]

We are now in the position to discretize the Pauli Hamiltonian, which is to follow exactly the same steps as in the case of Dirac Hamiltonian. Using again the prescription Eq.(15), which now takes a simple form \( \chi(x) = \sqrt{2} \sqrt{g}^{-1/2} X(x) \), we arrive at a Hamiltonian, which can be formally written as Eq.(17), where we have to replace \( \Psi \rightarrow X \) and the matrices \( T, V \) now depends only on spatial coordinates \( x \) and read

\[
T(x, x + a_i) = -\sqrt{g}^{-1} \left( f_{ii} + \frac{1}{2} \partial_i f_{ii} \right) P(x, x + a_i)
\]

\[
V(x) = 2m + \sqrt{g} \left[ f_{ii} + f_{ii} - (\partial_i f_{ii}) \right]
+ \left( \frac{1}{2} \sqrt{g} \sigma^k \sigma^j [\nabla_k, \nabla_j]_{k<j} \right) + \text{h.c.} \right], \tag{56}
\]

where \( f_{ii} = f_{ii}(x - a_i) \) and we have to replace \( \Gamma \rightarrow \tilde{\Gamma} \) in the definition of the parallel propagator Eq.(7).

It is interesting to notice, that in the case of relativistic Dirac Hamiltonian taking static diagonal metric Eq.(47), \( \gamma \) are unitary, \( \Gamma^\dagger \) are antihermitean, \( \Gamma^\dagger_j = -\Gamma^\dagger_k \) and the parallel propagators Eq.(11) become unitary. We thus have \( T \) which is also unitary, contrary to the Pauli Hamiltonian case.
