We address the role of correlations between spin and charge degrees of freedom on the dynamical properties of ferromagnetic systems governed by the magnetic exchange interaction between itinerant and localized spins. For this we introduce a general theory that treats quantum fluctuations beyond the Random Phase Approximation based on a correlation expansion of the Green’s function equations of motion. We calculate the spin susceptibility, spin–wave excitation spectrum, and magnetization precession damping. We find that correlations strongly affect the magnitude and carrier concentration dependence of the spin stiffness and magnetization Gilbert damping.

Introduction—Semiconductors displaying carrier–induced ferromagnetic order, such as Mn–doped III–V semiconductors, manganites, chalcogenides, etc., have received a lot of attention due to their combined magnetic and semiconducting properties [1,2]. A strong response obtained a lot of attention due to their combined magnetic and semiconducting properties [1,2]. A strong response concerned the speed of the basic processing unit, a single chip. One of the challenges facing such magnetic devices combining information processing and storage on a single chip. One of the challenges facing such magnetic devices concerns the speed of the basic processing unit, determined by the dynamics of the collective spin.

Two key parameters characterize the spin dynamics in ferromagnets: the spin stiffness, $D$, and the Gilbert damping coefficient, $\alpha$. $D$ determines the long–wavelength spin–wave excitation energies, $\omega_Q \sim DQ^2$, where $Q$ is the momentum, and other magnetic properties. $D$ also sets an upper limit to the ferromagnetic transition temperature: $T_C \propto D^{-1}$. So far, the $T_C$ of (Ga,Mn)As has increased from $\sim 110$ K [2] to $\sim 173$ K [2,4]. It is important for potential room temperature ferromagnetism to consider the theoretical limits of $T_C$.

The Gilbert coefficient, $\alpha$, characterizes the damping of the magnetization precession described by the Landau–Lifshitz–Gilbert (LLG) equation $\frac{d\mathbf{S}}{dt} = -\gamma \mathbf{H}_{\text{eff}} \times \mathbf{S} - \alpha \mathbf{S} \times (\mathbf{S} \times \mathbf{H}_{\text{eff}})$ [3]. A microscopic expression can be obtained by relating the spin susceptibility of the LLG equation to the Green’s function $\Gamma$ [4].

$$ A = -i\theta(t) < [A(t), S_Q^{-}(0)] >$$ (1)

with $A = S_Q^{+}$, $S_Q^{+} = S_x + iS_y$. $\langle \cdots \rangle$ denotes the average over a grand canonical ensemble and $S_Q = 1/\sqrt{N} \sum_j S_j e^{-iQj}$, where $S_j$ are spins localized at $N$ randomly distributed positions $\mathbf{R}_j$. The microscopic origin of $\alpha$ is still not fully understood [5]. A mean–field calculation of the magnetization damping due to the interchange between spin–spin interactions and carrier spin dephasing was developed in Refs.[3,10]. The magnetization dynamics can be probed with, e.g., ferromagnetic resonance [11] and ultrafast magneto–optical pump–probe spectroscopy experiments [3,12,13,14]. The interpretation of such experiments requires a better theoretical understanding of dynamical magnetic properties.

In this Letter we discuss the effects of spin–charge correlations, due to the $p$–$d$ exchange coupling of local and itinerant spins, on the spin stiffness and Gilbert damping coefficient. We describe quantum fluctuations beyond the Random Phase Approximation (RPA) [15,16] with a correlation expansion [17] of higher Green’s functions and a $1/S$ expansion of the spin self–energy. To $O(1/S^2)$, we obtain a strong enhancement, as compared to the RPA, of the spin stiffness and the magnetization damping and a different dependence on carrier concentration.

Equations of motion—The magnetic properties can be described by the Hamiltonian $H = H_{MF} + H_{\text{corr}}$, where the mean field Hamiltonian $H_{MF} = \sum_{\mathbf{k},n} \epsilon_{\mathbf{k}n} a_{\mathbf{k}n}^{\dagger} a_{\mathbf{k}n}$ describes valence holes created by $a_{\mathbf{k}n}^{\dagger}$, where $\mathbf{k}$ is the momentum, $n$ is the band index, and $\epsilon_{\mathbf{k}n}$ the band dispersion in the presence of the mean field created by the magnetic exchange interaction $\Delta(\mathbf{k})$. The Mn impurities act as acceptors, creating a hole Fermi sea with concentration $c_h$, and also provide $S = 5/2$ local spins.

$$ H_{\text{corr}} = \beta_c \sum_{\mathbf{q}} \Delta S^z_{\mathbf{q}} S^z_{-\mathbf{q}} + \Delta \sum_{\mathbf{q}} \left( \Delta S^z_{\mathbf{q}} \Delta s^z_{-\mathbf{q}} + c.c. \right), $$ (2)

where $\beta_c \sim 50–150$ meV nm$^{-3}$ in (III,Mn)V semiconductors [1] is the magnetic exchange interaction. $c$ is the Mn spin concentration and $s_{\mathbf{q}} = 1/\sqrt{V} \sum_{\mathbf{nn}'} \mathbf{a}_{\mathbf{kk}'} \mathbf{a}_{\mathbf{kk}'}^\dagger$, the hole spin operator. $\Delta = A - \left< A \right>$ describes the quantum fluctuations of $A$. The ground state and thermodynamic properties of (III,Mn)V semiconductors in the metallic regime ($c_h \sim 10^{20}$ cm$^{-3}$) are described to first approximation by the mean field virtual crystal approximation, $H_{MF}$, justified for $S \to \infty$ [1]. Most sensitive to the quantum fluctuations induced by $H_{\text{corr}}$ are the dynamical properties. Refs.[3,15] treated quantum effects to $O(1/S)$ (RPA). Here we study correlations that first arise at $O(1/S^3)$. By choosing the $z$–axis parallel to the ground state local spin $S$, we have $S^x = 0$ and $S^z = S$. The mean hole spin, $s$, is antiparallel to $S$, $s^x = 0$ [1].
The spin Green’s function is given by the equation
\[
\partial_t \langle S^+_{Q} \rangle = -2i [S(t) + \beta c \langle s \times S^-_{Q} \rangle^+ + i \Delta \langle s^-_{Q} \rangle + \frac{\beta c}{N} \times \\
\sum_{kpnn'} \langle (\sigma_{nn'} \times \Delta S_{p-k-Q}^+ \Delta [a_{kn}^+ a_{pn}^+] \rangle \rangle,
\] (3)
where \( \Delta = \beta c S \) is the mean field spin–flip energy gap and \( s = 1/N \sum_{kn} \sigma_{nn}/f_{kn} \) is the ground state hole spin. \( f_{kn} = \langle a_{kn}^+ a_{kn} \rangle \) is the hole population. The first line on the right hand side (rhs) describes the mean field precession of the Mn spin around the mean hole spin. The second line on the rhs describes the RPA coupling to the itinerant hole spin \( 10 \), while the last line is due to the correlations. The hole spin dynamics is described by
\[
(i \partial_t - \varepsilon_{kn'} + \varepsilon_{k-Q}) \langle a_{k-Q}^+ a_{kn} \rangle = \frac{\beta c}{2\sqrt{N}} \left[ (f_{kn} - f_{kn'}) \langle S^+_{Q} \rangle + \sum_{qmn} \langle (\sigma_{nm} \cdot \Delta S_q) \Delta [a_{k-Q}^+ a_{k+q+m}^+] \rangle \right] - \sum_{qmn} \langle (\sigma_{nm} \cdot \Delta S_q) \Delta [a_{k-Q}^+ a_{k+q+m}^+] \rangle.
\] (4)

The spin–flip excitation energy \( \Delta \) by \( \Delta + \Sigma_{RPA} \). The RPA contribution \( 13 \) also predicts maximum \( D \) at very small hole concentrations, while in the six–band model \( 24 \) increases and then saturates with hole doping. Here we illustrate the main qualitative features due to ubiquitous correlations important in different ferromagnets \( 19, 22 \) by adopting the single–band Hamiltonian \( 15 \). We then discuss the role of the multi–band structure of \( 11, 13 \) semi-conductors by using a heavy and light hole band model.

In the case of two bands of spin–up and spin–down states \( 15 \), we obtain by Fourier transformation
\[
\langle S^+_{Q} \rangle = \frac{2S}{\omega + \delta + \Sigma_{RPA}(Q, \omega) + \Sigma_{corr}(Q, \omega)}.
\] (5)
where \( \delta = \beta c s \) gives the energy splitting of the local spin levels. \( \Sigma_{RPA} \) is the RPA self energy \( 13, 10 \).

\[
\Sigma_{corr} = \frac{\beta c}{2N} \sum_{kp} \left[ (G_{pk} + F_{pk}) \frac{\omega + \varepsilon_{k} - \varepsilon_{k+Q} + \Delta + i\Gamma}{\omega + \varepsilon_{k} - \varepsilon_{k+Q} + \Delta + i\Gamma} - (G_{pk} - F_{pk}) \frac{\omega + \varepsilon_{p-Q} - \varepsilon_{p}}{\omega + \varepsilon_{p-Q} - \varepsilon_{p} + \Delta + i\Gamma} \right].
\] (6)
is the correlated contribution, where
\[
G_\sigma = \langle S^+ \Delta [a_{kn}^+ a_{pn}^+] \rangle, \quad F = \langle \Delta S^+ a_{kn}^+ a_{kn} \rangle. \tag{7}
\]

\( \Gamma \sim 100-1000 \) meV is the hole spin dephasing rate \( 25 \). Similar to Ref.\( 10 \) and the Lindblad method calculation of Ref.\( 14 \), we describe such elastic effects by substituting the spin–flip excitation energy \( \Delta + i\Gamma \). We obtained \( G \) and \( F \) by solving the corresponding equations to lowest order in \( 1/S, \) with \( \beta S \) kept constant, which gives \( \Sigma_{corr} \) to \( O(1/S^2) \). More details will be presented elsewhere \( 18 \).

**Results** — First we study the spin stiffness \( D = D_{RPA} + D_{corr} + D_{corr} \). The RPA contribution \( D_{RPA} \) reproduces Ref.\( 15 \). The correlated contributions \( D_{corr} > 0 \) and
correct number of magnetic ion degrees of freedom [15].

We evaluated Eqs. (8) and (9) for zero temperature $D_{c}^{corr} < 0$ were obtained to $O(1/S^2)$ from Eq. (18):

$$D_{c}^{corr} = -\frac{\hbar^2}{2m_h S^2 N^2} \sum_{kp} \left[ f_k(1 - f_{p}) \frac{\varepsilon_p (\hat{\mathbf{p}} \cdot \hat{\mathbf{Q}})^2}{\varepsilon_p - \varepsilon_k} ight]$$

$$+ f_k(1 - f_{p}) \frac{\varepsilon_k (\hat{\mathbf{k}} \cdot \hat{\mathbf{Q}})^2}{\varepsilon_p - \varepsilon_k}, \quad (8)$$

$$D_{p}^{corr} = \frac{\hbar^2}{2m_h S^2 N^2} \sum_{kp} f_k(1 - f_{p}) \times$$

$$\left[ \varepsilon_k (\hat{\mathbf{k}} \cdot \hat{\mathbf{Q}})^2 + \varepsilon_p (\hat{\mathbf{p}} \cdot \hat{\mathbf{Q}})^2 \right] \times$$

$$\left[ \frac{2}{\varepsilon_p - \varepsilon_k} + \frac{1}{\varepsilon_p - \varepsilon_k + \Delta} - \frac{\Delta}{(\varepsilon_p - \varepsilon_k)^2} \right], \quad (9)$$

where $\hat{\mathbf{Q}}$, $\hat{\mathbf{k}}$, and $\hat{\mathbf{p}}$ denote the unit vectors.

For ferromagnetic interaction, as in the manganites [19, 24], the Mn and carrier spins align in parallel. The Hartree–Fock is then the state of maximum spin and an exact eigenstate of the many–body Hamiltonian (Nagaoka state). For anti–ferromagnetic $\beta$, as in (III,Mn)V semiconductors, the ground state carrier spin is anti–parallel to the Mn spin and can increase via the scattering of a spin–$\uparrow$ hole to an empty spin–$\downarrow$ state (which decreases $S_z$ by 1). Such quantum fluctuations give rise to $D_{c}^{corr}$, Eq. (9), which vanishes for $f_k \neq 0$. $D_{c}^{corr}$ comes from magnon scattering accompanied by the creation of a Fermi sea pair. In the case of a spin–$\uparrow$ Fermi sea, Eq. (8) recovers the results of Refs. [15, 24].

We evaluated Eqs. (8) and (9) for zero temperature after introducing an upper energy cutoff corresponding to the Debye momentum, $k_D^3 = 6\pi^2 c$, that ensures the correct number of magnetic ion degrees of freedom [15].

Figs. (1a) and (b) show the dependence of $D$ on hole doping, characterized by $p = e_h/c$, for two couplings $\beta$, while Figs. (1c) and (d) show its dependence on $\beta$ for two doping $p$. Figure (1) also compares our full result, $D$, with $D^{RPA}$ and $D^{RPA} + D^{corr}$. It is clear that the correlations beyond RPA have a pronounced effect on the spin stiffness, and therefore on $T_c \propto D$ [1, 5] and other magnetic properties. Similar to the manganites [19, 24], $D_{c}^{corr} < 0$ destabilizes the ferromagnetic phase. However, $D_{p}^{corr}$ strongly enhances $D$ as compared to $D^{RPA}$ [15] and also changes its $p$–dependence.

The ferromagnetic order and $T_c$ values observed in (III,Mn)V semiconductors cannot be explained with the single–band RPA approximation [15], which predicts a small $D$ that decreases with increasing $p$. Even within the single–band model, the correlations strongly enhance $D$ and change its $p$–dependence: $D$ now increases with $p$. Within the RPA, such behavior can be obtained only by including multiple valence bands [16]. As discussed e.g. in Refs. [1, 7], the main bandstructure effects can be understood by considering two bands of heavy ($m_{hh} = 0.5m_e$) and light ($m_{lh} = 0.086m_e$) holes. $D$ is dominated and enhanced by the more dispersive light hole band. On the other hand, the heavily populated heavy hole states dominate the static properties and $E_F$. By adopting such a two–band model, we obtain the results of Figs. (2a) and (b). The main difference from Fig. (1) is the order of magnitude enhancement of all contributions, due to $m_{lh}/m_{hh} = 0.17$. Importantly, the differences between $D$ and $D^{RPA}$ remain strong. Regarding the upper limit of $T_c$, due to collective effects, we note from Ref. [2] that $T_c$ is proportional to $D$ and the mean field Mn spin. We thus expect an enhancement, as compared to the RPA result, comparable to the
difference between $D$ and $D^{\text{RPA}}$.

The doping dependence of $D$ mainly comes from its dependence on $E_F$, shown in Figs. 2(c) and (d), which differs strongly from the RPA result. Even though the two band model captures these differences, it fails to describe accurately the dependence of $E_F$ on $p$, determined by the successive population of multiple anisotropic bands. Furthermore, the spin–orbit interaction reduces the hole spin matrix elements [22]. For example, $|\sigma_{nn'}|/|\sigma_{nn'}|^2$ is maximum when the band states are also spin eigenstates. The spin–orbit interaction mixes the spin–↑ and spin–↓ states and reduces $|\sigma_{nn'}|^2$. From Eq. (3) we see that the deviations from the mean field result are determined by the coupling to the Green’s functions $\langle \sigma_{nn'} \Delta |n',a_n| \rangle$ (RPA), $\langle \Delta S^z \sigma_{nn'}^+ \Delta |n',a_n| \rangle$ (correction to RPA due to $S^z$ fluctuations leading to $D_{\sigma}^{\text{corr}} > 0$), and $\langle \Delta S^z \sigma_{nn'}^+ \Delta |n',a_n| \rangle$ (magnon–Fermi sea pair scattering leading to $D_{\sigma}^{\text{corr}} < 0$). Both the RPA and the correlation contribution arising from $\Delta S^z$ are proportional to $\sigma_{nn'}$. Our main result, i.e. the relative importance of the correlation as compared to the RPA contribution, should thus also hold in the realistic system. The full solution will be pursued elsewhere.

We now turn to the Gilbert damping coefficient, $\alpha = 2S/\omega \times \text{Im} \ll S \gg ^{-1}$ at $\omega \rightarrow 0$. We obtain to $O(1/S^2)$ that $\alpha = \alpha^{\text{RPA}} + \alpha^{\text{corr}}$, where $\alpha^{\text{RPA}}$ recovers the mean–field result of Refs. 10, 11 and predicts a linear dependence on the hole doping $p$, while

$$\alpha^{\text{corr}} = \frac{\Delta^2}{2N^2S^2} \sum_{kp} \text{Im} \left[ \frac{f_k (1-f_p)}{\Delta+i\Gamma} \times \left( \frac{1}{\varepsilon_p - \varepsilon_k - \delta} + \frac{1}{\varepsilon_p - \varepsilon_k + \Delta+i\Gamma} \right) \right]$$

arises from the carrier spin–flip quantum fluctuations.
