ABSTRACT

Correlations of polarization components in the coordinate frame are a natural basis for searches of parity-violating modes in the cosmic microwave background. This fact can be exploited to build estimators of parity-violating modes that are local and robust with respect to partial-sky coverage or inhomogeneous weighting. As an example application of a method based on these ideas, we develop a peak stacking tool that isolates the signature of parity-violating modes. We apply the tool to Planck maps and obtain a constraint on the monopole of the polarization rotation angle $\alpha < 0.72^\circ$ at 95%. We also demonstrate how the tool can be used as a local method for reconstructing maps of direction dependent rotation $\alpha(\hat{n})$.

Key words: cosmic background radiation – cosmology: theory – polarization – techniques: polarimetric

1. INTRODUCTION

The cosmic microwave background (CMB) provides a powerful test of deviations from standard physics. The energy fluctuations and polarization of photons released at last scattering carry information that is directly linked via simple, linear evolution to the primordial state of super horizon perturbations of the metric. In addition, CMB photons have traveled over cosmological distances to reach us, probing the nature of spacetime along the way. The polarization of the CMB, in particular, is sensitive to a number of parity-violating mechanisms due to the opposite parity of $E$- and $B$-modes (Kamionkowski et al. 1997a, 1997b; Seljak & Zaldarriaga 1997).

These mechanisms can act either during the generation of primordial perturbations or during the propagation of the CMB photons through space at later times. The first possibility includes models of chiral gravity (Lue et al. 1999; Alexander & Martin 2005; Contaldi et al. 2008; Sorbo 2011) that explicitly break the parity between left- and right-handed primordial gravitational waves imprinted in super-horizon scales during inflation. The second includes the presence of parity-violating primordial magnetic fields (Kosowsky & Loeb 1996; Seshadri & Subramanian 2001) or mechanisms that induce cosmic birefringence (Carroll 1998; Lue et al. 1999; Feng et al. 2005; Li & Zhang 2008) through the presence of new fields and interactions. Another possibility is the presence of spatial anisotropies during evolution of perturbations (Bartolo et al. 2015).

The simple consequence of all these mechanisms is that they result in correlations between the $E$- and $B$-modes of the CMB polarization and between the $B$-mode and total intensity $T$. These correlations cannot exist unless parity is violated. The hope is therefore that a significant measurement of $EB$ or $TB$ correlations would be a “clean” indication of non-standard physics. The difficulty however is that these signals can also arise due to any experimental systematic that coherently rotates the polarization signal with respect to the true polarization of CMB photons. This can happen in experiments via either optical effects, or miscalibration of the polarization direction or efficiency of detectors.

With the advent of high signal-to-noise measurements of CMB polarization (Ade et al. 2014, 2015; Naess et al. 2014; POLARBEAR Collaboration 2014; Keisler et al. 2015) we have entered an era where extensive testing of parity-violating effects can be carried out along with a requirement for increasingly precise tests of polarization affecting systematics. Indeed, much work has gone into defining estimators of parity-violating statistics and their interaction with experimental polarization calibration procedures (Cabella et al. 2007; Brown et al. 2009; Pagano et al. 2009; Komatsu et al. 2011; POLARBEAR Collaboration 2015; Gruppuso et al. 2016).

Estimation of the parity-violating signal has focused on the definition of optimal estimators based on the spherical harmonic expansion of the CMB Stokes parameters $I$, $Q$, and $U$ into $T$-, $E$-, and $B$-mode spherical harmonic coefficients. The focus on working in the $T$, $E$, $B$ basis is a naturally justified one since the correlation of these modes is where the signal of parity violation is explicit. In contrast, it is not immediately obvious that correlations in the original $I$, $Q$, and $U$ coordinate frame modes can uniquely distinguish parity-violating signals as there is no one-to-one mapping of $Q$ and $U$ modes to the parity-sensitive $E$- and $B$-modes. Working in harmonic space however, involves well-known complications due to the fact that the transformations involved are non-local. When a partial-sky coverage is imposed by scanning limitations or contamination by foregrounds the orthonormality of basis functions is reduced. This leads to mixing of power at different angular scales and mixing of $E$- and $B$-modes. To deal with these unwanted effects one has to resort to complicated methods to statistically isolate the original harmonic modes (Hivon et al. 2002; Bunn et al. 2003; Smith & Zaldarriaga 2007).

In this work we point out that simple combinations of cross-correlations of Stokes parameters in the original coordinate frame are parity-violation sensitive and we show how these can be applied to data to yield an intuitive compression of the signals for parity-violating tests. Estimators based on coordinate frame correlations are simpler and, in principle, more robust with respect to inhomogeneous noise, partial-sky coverage effects, and any polarization systematics. In fact, aside from efforts to detect non-standard physics, they can provide versatile tests of experimental systematics.

This paper is organized as follows. In Section 2 we review how angular correlation functions of the Stokes parameters are related to parity-even and parity-odd angular power spectra. In Section 3 we move to the small-angle limit and show how peak stacking can be used to obtain compressions of the signal that...
isolate parity-violating correlations. We validate our peak stacking tools using simulations of the CMB sky that contain varying degrees of parity violation in the form of an overall polarization rotation. In Section 4 we use the tool to search for any parity-violating signal in the Planck maps. We discuss our results in Section 5.

2. POLARIZATION CORRELATION FUNCTIONS

The polarization of CMB photons on the full sky is described in terms of Stokes parameters $T$, $Q$, and $U$. The scalar, total intensity component $T$ is expanded in spherical harmonics as

$$T(\hat{n}) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\hat{n}),$$

where $\hat{n}$ is the unit direction vector on the sky. The Stokes parameters determining the direction of polarization on the sky are expanded on the basis of spin-2 spherical harmonics (Zaldarriaga & Seljak 1997)

$$(Q \pm iU)(\hat{n}) = \sum_{\ell m} (a_{\ell m}^E \mp i a_{\ell m}^B) Y_{\ell m}(\hat{n}).$$

The $E$- and $B$-modes transform distinctly under parity transformations $(Q \pm iU)(\hat{n}) \rightarrow (Q \mp iU)(-\hat{n})$ with the gradient-like mode $a_{\ell m}^E$ transforming with parity $(-1)^\ell$ and curl-like mode $a_{\ell m}^B$ transforming as $(-1)^{\ell+1}$. Given statistical isotropy the correlations in the expanded modes are diagonal and can be split into correlations that are insensitive to parity transformations

$$\langle a_{\ell m}^E a_{\ell m}^{E*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^T,$$

$$\langle a_{\ell m}^E a_{\ell m}^{B*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^{TE},$$

$$\langle a_{\ell m}^B a_{\ell m}^{E*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^E,$$

$$\langle a_{\ell m}^B a_{\ell m}^{B*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^B,$$

and ones that only exist if there are parity-violating modes in the pattern

$$\langle a_{\ell m}^E a_{\ell m}^{B*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^{TB},$$

$$\langle a_{\ell m}^B a_{\ell m}^{E*} \rangle = \delta_{\ell \ell} \delta_{mm} C_{\ell}^{EB}.$$  

The complex spin-2 field $\hat{P} = Q + iU$ is a convenient measure for defining correlations in coordinate space. When considering correlations of the polarization between two lines of sight $\hat{n}_1$ and $\hat{n}_2$ we have to take into account that the polarization is defined with respect to a local basis, typically based on the local meridian. Rotating the polarization, in both directions, to a common frame defined by the geodesic connecting the two points on the sky subtending angles $\gamma_1$ and $\gamma_2$ with the original x-axis at both points

$$\hat{P}(\hat{n}_j) = e^{2i\gamma_j} P(\hat{n}_j),$$

with $j = 1, 2$, one obtains a polarization definition that simplifies the relation between coordinate and harmonic space based correlations (Ng & Liu 1999; Chon et al. 2004)

$$\langle T(\hat{n}_1)T(\hat{n}_2) \rangle = \sum_{\ell} \frac{2\ell + 1}{4\pi} C_{\ell}^T P_\ell(\beta)$$

$$\langle T(\hat{n}_1)\hat{P}(\hat{n}_2) \rangle = \sum_{\ell} \frac{2\ell + 1}{4\pi} (C_{\ell}^{TE} - iC_{\ell}^{TB}) d_{\ell}^{21}(\beta)$$

where $\beta$ is the cosine of the angle between the two directions and $d_{\ell}^{21}$ are the reduced Wigner rotation matrices (Varshalovich et al. 1988). These relations can be inverted to yield angular power spectra as functions of coordinate space correlations by using the orthogonality of the basis functions in the full-sky limit. Note that the $C_{\ell}^E$ and $C_{\ell}^B$ spectra contribute to the real part of both Equations (12) and (13) but are multiplied by different basis functions. This is the reason why cut-sky effects have to be dealt with even when considering coordinate space correlation functions—the $E$- and $B$-mode contribution cannot be disentangled. The parity-violating components $\hat{P}$ and $\hat{P}^*$ however, only contribute to the imaginary parts of correlations (11) and (12). In practice this means that we can use correlations obtained in the coordinate frame to isolate the signal due to parity-violating modes. Any estimate that does not rely on a harmonic transform greatly simplifies the problem of partial-sky coverage and inhomogeneous weighting.

The disadvantage is that the computation of correlation functions directly in the coordinate frame requires $O(N_p^2)$ operations, where $N_p$ is the number of pixels in the map. Typically even methods that make use of the coordinate frame correlations (10)–(13) to simplify the effect of masking and noise weighting (Chon et al. 2004) actually estimate the correlations by transforming to the harmonic space. This is done in order to make use of the fast Fourier transforms in longitude.

In the following we will show how considering a subset of all possible correlations, those constrained to the neighborhood of peaks in the Stokes parameters can make use of Equations (10)–(13) to isolate the coordinate frame signal of parity-violating modes. We will leave the development of a more general framework exploiting the unconstrained correlations in the full-sky for future work.

3. PEAK STACKS

Peak stacking, or the averaging of a map in the neighborhood of peaks in the map, has been used to determine the robustness of polarization measurements since large scale, polarization sensitive surveys appeared (Komatsu et al. 2011). Recently they have been used to analyze more detailed morphology of the CMB around acoustic peaks in an attempt to constrain deviations from statistical isotropy (Planck Collaboration 2015c). Peak stacking provides a powerful visualization of the constrained correlation pattern around an acoustic peak of the CMB. It constitutes an intuitive tool that highlights the nature of the polarization as being precisely that expected from acoustic oscillations at last scattering. In the following we consider stacks around peaks in each of the Stokes parameters of polarized maps and show how these can be used to obtain parity-sensitive stacks that have simple relations to the parity-violating spectra $C_{\ell}^{TB}$ and $C_{\ell}^{EB}$.

$$\langle P(\hat{n}_1)P(\hat{n}_2) \rangle = \sum_{\ell} \frac{2\ell + 1}{4\pi} (C_{\ell}^E - C_{\ell}^B - 2iC_{\ell}^{EB}) d_{\ell}^{11}(\beta)$$

$$\langle \hat{P}^*(\hat{n}_1)\hat{P}(\hat{n}_2) \rangle = \sum_{\ell} \frac{2\ell + 1}{4\pi} (C_{\ell}^{TE} + C_{\ell}^{TB}) d_{\ell}^{21}(\beta)$$
We will follow the notation and conventions used in Komatsu et al. (2011) and consider explicit contributions \(Q\) and \(U\) in \(P\) and expand the phase factor in Equation (9) in terms of sines and cosines. We develop the framework in the small-angle limit by considering the tangential projection, in coordinates \((x, y)\), around a point in the sky along direction \(\hat{n}\). In this case the spin-0, and \(\pm 2\) spherical harmonics are replaced by two-dimensional plane waves and their derivatives

\[ Y_l^m \rightarrow e^{i\ell \theta}, \quad (14) \]

\[ Y_{l^m} \rightarrow -e^{i2\ell(\phi-\varphi)} e^{i\theta}, \quad (15) \]

where \(\ell = (\ell_1, \ell_2)\) is the wave vector in the plane-wave expansion with \(\ell_1 = \ell \cos(\varphi)\) and \(\ell_2 = \ell \sin(\varphi)\) and \(\theta = (\theta_1, \theta_2)\) is the position vector in the tangential projection with \(\theta_1 = \theta \cos(\phi)\) and \(\theta_2 = \theta \sin(\phi)\).

The total intensity field \(T\) can now be expanded in the small-scale limit in the space of two-dimensional plane-waves

\[ T(\theta) = \int d^2\ell \int \frac{d\ell}{(2\pi)^2} T_{\ell} e^{i\ell \cdot \theta}. \quad (16) \]

Following the conventions of Komatsu et al. (2011) and Kamionkowski et al. (1997b) we also expand the \(Q\) and \(U\) Stokes fields as

\[ Q(\theta) = -\int d^2\ell \left[ E_{\ell} \cos(2\varphi) - B_{\ell} \sin(2\varphi) \right] e^{i\ell \cdot \theta}, \quad (17) \]

\[ U(\theta) = -\int d^2\ell \left[ E_{\ell} \sin(2\varphi) + B_{\ell} \cos(2\varphi) \right] e^{i\ell \cdot \theta}. \quad (18) \]

The coefficients \(E_{\ell}\) and \(B_{\ell}\) are the gradient and curl-like modes of the polarization component.

When stacking, or averaging fields around peak locations, we are calculating constrained (or biased) correlation functions (Bardeen et al. 1986). We can write the stacking of a field \(X\) at peaks in field \(Y\) in the ensemble limit as (Komatsu et al. 2011)

\[ \langle X(\theta) \rangle = \frac{1}{N_{pk}} \int_M d\Omega \langle n_{pk}(\hat{n}) X(\hat{n} + \theta) \rangle, \quad (19) \]

where \(N_{pk}\) is the total number of peaks in an area of the sky defined by the mask \(M\) and \(n_{pk}(\hat{n})\) is the number density of peaks in the field \(Y\) in the direction \(\hat{n}\).

Introducing the dimensionless density contrast of peaks around the average peak density \(\delta_{pk}^Y = n_{pk}^Y / n_{pk}^Y - 1\), we can write the stacking as

\[ \langle X(\theta) \rangle = \frac{1}{4\pi f_{sky}} \int_M d\Omega \langle \delta_{pk}^Y(\hat{n}) X(\hat{n} + \theta) \rangle, \quad (20) \]

where \(f_{sky}\) is the fraction of the sky defined by the coverage mask and \(N_{pk}^Y = 4\pi f_{sky} n_{pk}^Y\).

The effect of peak biasing can be calculated from first principles if \(Y\) is a Gaussian random field (Kaiser 1984; Desjacques et al. 2009; Komatsu et al. 2011). The density contrast can be written as a bias of the underlying field as

\[ \delta_{pk}^Y(\hat{n}) = [b_{\nu} \delta_{pk}^Y(\hat{n}) + \partial_2^Y Y(\hat{n})], \quad (21) \]

where \(b_{\nu}\) is a scale-independent bias due to the selection of peaks of height \(\nu\), in units of the field’s standard deviation \(\sigma_0\), and \(b_{\partial^2}\) is a scale-dependent bias due to the selection involving the curvature of the field. When considering stack averages then, we are actually evaluating a quantity that is second order in the statistics of the fields involved despite the average being first order in field units. Thus, despite the field having zero mean in the unconstrained limit, the constrained mean is not expected to vanish. The averages are related to the unconstrained correlation functions of the fields via a convolution with filters determined by the biasing functions such as in Equation (21).

Introducing the short-hand \(\langle \delta_{pk}^X(\theta) X(\theta) \rangle \equiv \langle X^2 \rangle\) and making use of the definition of the angular cross-correlation relations between statistically isotropic fields \(X\) and \(Y\)

\[ \langle X\ell X\ell' \rangle = (2\pi)^2 \delta^{(2)}(\ell' - \ell) \delta_{\ell^2}^{XY}, \quad (22) \]

with \(X\) and \(Y\) belonging to the set \((T, Q, U)\), the constrained mean of the temperature field about temperature peaks is related to the total intensity angular power spectrum as

\[ \langle T^2 \rangle = \int \frac{d\ell d\ell'}{2\pi^2} \delta_{\ell^2}^{T^2} \delta_{\ell\ell'} \cos(\varphi), \quad (23) \]

as the Fourier domain counterpart of Equation (21).

Similarly, one can show that suitably rotated combinations of \(Q\) and \(U\) constrained means are related to the two cross-correlation angular power spectra

\[ \langle Q \ell Q\ell' \rangle = \langle Q^2 \rangle \cos(2\varphi) + \langle U^T \rangle \sin(2\varphi) \]

\[ = \int \frac{d\ell d\ell'}{2\pi^2} \delta_{\ell^2}^{Q^2} \delta_{\ell\ell'} \cos(\varphi), \quad (24) \]

\[ \langle U \ell U\ell' \rangle = -\langle Q^2 \rangle \sin(2\varphi) + \langle U^T \rangle \cos(2\varphi) \]

\[ - \int \frac{d\ell d\ell'}{2\pi^2} \delta_{\ell^2}^{Q^2} \delta_{\ell\ell'} \sin(\varphi), \quad (25) \]

The radial polarization projection of Equation (26) removes the azimuthal dependence of the polarization pattern around the peaks and gives a distinct signal from parity-violating modes arising from any non-vanishing \(C_{\ell^2}^{TB}\) contribution. It is therefore a useful compression of the data along with a powerful visual check for the presence of any anisotropic or polarization rotation systematics (Komatsu et al. 2011; Planck Collaboration 2015c).

The constrained mean around \(Q\) and \(U\) peaks can also yield useful projections of the polarization data that distinguish between parity-conserving and parity-violating modes. Following a similar derivation used for the expressions above, one can obtain the following useful combinations of averages around \(Q\) and \(U\) peaks

\[ C_{\ell}(\theta) \equiv \langle Q^2 + U^2 \rangle = \frac{1}{2} \int \frac{d\ell d\ell'}{2\pi^2} \delta_{\ell^2}^{Q^2} \left[ C_{\ell}^{EE} + C_{\ell}^{BB} \right] J_{\ell}(\theta) \]

\[ + \int \frac{d\ell}{2\pi} \left( C_{\ell}^{EE} - C_{\ell}^{BB} \right) J_{\ell}(\theta) \cos(4\phi) \]

\[ - 2 \int \frac{d\ell}{2\pi} C_{\ell}^{TB} J_{\ell}(\theta) \sin(4\phi), \quad (27) \]

\[ \text{For a detailed summary of how } C_{\ell} \text{ is calculated we refer to Appendix B of Komatsu et al. (2011).} \]
The Astronomical Journal, 153:41 (9pp), 2017 January

\[ C_{\ell}(\theta) \equiv \langle \tilde{Q}^U + \tilde{U}^Q \rangle \sin(4\phi) + \langle \tilde{Q}^Q - \tilde{U}^U \rangle \cos(4\phi) \]
\[ = \frac{1}{2} \int \frac{\ell d \ell}{2\pi} f_{\ell}^+ (C_{\ell}^E - C_{\ell}^B) J_0(\ell \theta) \]
\[ + f_{\ell}^- (C_{\ell}^E + C_{\ell}^B) J_0(\ell \theta) \cos(4\phi), \tag{28} \]
\[ C_{\ell}(\theta) \equiv \langle \tilde{Q}^U + \tilde{U}^Q \rangle \cos(4\phi) - \langle \tilde{Q}^Q - \tilde{U}^U \rangle \sin(4\phi) \]
\[ = \frac{1}{2} \int \frac{\ell d \ell}{2\pi} 4 f_{\ell}^+ C_{\ell}^{EB} J_0(\ell \theta) \]
\[ - f_{\ell}^- (C_{\ell}^E + C_{\ell}^B) J_0(\ell \theta) \sin(4\phi), \tag{29} \]
\[ C_{\ell}(\theta) \equiv \langle \tilde{Q}^Q - \tilde{U}^U \rangle = 0, \tag{30} \]

where we have introduced the notation \( f_{\ell}^\pm \equiv f_{\ell}^P \pm f_{\ell}^R \).

Peak bias functions for the polarization fields are harder to calculate a priori since the original, unrotated \( Q \) and \( U \) are generally correlated but in the limit of large \( N_{\text{sky}} \) we expect to recover \( f_{\ell}^Q = f_{\ell}^U \to f_{\ell}^P \). In what follows we calculate \( f_{\ell}^Q \) using the same procedure described in Komatsu et al. (2011) but with \( C_{TT} \) replaced by the total polarization power \( C_{\ell}^{EE} + C_{\ell}^{BB} \) when computing the moments of the polarization field.

Under our assumption for \( f_{\ell}^Q \) the non-vanishing combinations in Equations (27)–(29) simplify to

\[ C_{\ell}(\theta) = \int \frac{\ell d \ell}{2\pi} f_{\ell}^P (C_{\ell}^E + C_{\ell}^B) J_0(\ell \theta), \tag{31} \]
\[ C_{\ell}(\theta) = \int \frac{\ell d \ell}{2\pi} f_{\ell}^P (C_{\ell}^E - C_{\ell}^B) J_0(\ell \theta), \tag{32} \]
\[ C_{\ell}(\theta) = 2 \int \frac{\ell d \ell}{2\pi} f_{\ell}^P C_{\ell}^{EB} J_0(\ell \theta). \tag{33} \]

Two important points are readily apparent when considering correlations of this form. First, in Equations (31)–(33) we can see why the coordinate frame is not a natural one for separating out \( E \)- and \( B \)-mode contributions. The correlations \( C_{\ell} \) and \( C_{\ell} \) contain distinct linear combinations of \( C_{\ell}^E \) and \( C_{\ell}^B \) but are filtered by Bessel functions of different order. This means that we can only separate \( E \)- and \( B \)-modes in the full-sky limit by using the orthonormality of the basis functions (Kamionkowski et al. 1997b; Chon et al. 2004)—the spin-2 spherical harmonics in the full-sky case. In the flat-sky approximation we cannot use the orthogonality properties of the Bessel functions since the approximation breaks down at large angles. Thus \( E \)- and \( B \)-modes are inevitably mixed when carrying out a partial-sky analysis, leading to well-known separation issues. If we are interested in parity-violating modes however, \( C_{\chi} \) provides a perfectly good estimate of the amount of \( EB \) correlation.

Second, the correlators are robust with respect to potential systematics. For example, in Equations (27)–(29) we see that the contribution from mismatched peak biasing functions, proportional to \( f_{\ell}^\pm \), carries a specific dependence on the azimuthal angle \( \phi \) while the signal of interest, proportional to \( f_{\ell}^\pm \) in each case, is independent of \( \phi \). The signal can therefore be separated out by integrating over the \( \phi \) dependence. In principle, this is the same for any contaminant that is not described by statistically isotropic correlations of the form shown in Equations (3)–(8).

4. APPLICATION

We now implement two separate methods based on peak stacking as simple examples of how we could use the correlators in Equations (25)–(26) and (31)–(32) to constrain parity-violating modes in the CMB. To test our methods we use simulated CMB maps with parity-violating patterns induced by an explicit rotation of the original polarization pattern by an overall rotation angle \( \alpha \). The rotation causes the mixing of power in \( T \), \( E \), and \( B \)-modes and is described by the following angular power spectra (Lue et al. 1999; Feng et al. 2005)

\[ C_{\ell}^t = C_{\ell}, \]
\[ C_{\ell}^E = C_{\ell}^e \cos(2\alpha) + C_{\ell}^b \sin^2(2\alpha), \]
\[ C_{\ell}^B = C_{\ell}^e \sin^2(2\alpha) + C_{\ell}^b \cos^2(2\alpha), \]
\[ C_{\ell}^{EB} = \frac{1}{2} (C_{\ell}^e - C_{\ell}^b) \sin(4\alpha), \]
\[ C_{\ell}^{TE} = C_{\ell}^{T\ell} \cos(2\alpha), \]
\[ C_{\ell}^{TB} = C_{\ell}^{T\ell} \sin(2\alpha). \]

where \( C_{\ell} \) are the spectra of the original realization with vanishing \( EB \) and \( TB \) correlations.

Our second method will be a constraint on a direction-dependent rotation angle. To test the method we will use a simple toy model where the rotation angle varies as a dipole across the sky. In both cases we will also apply our estimation procedure to Planck CMB component maps.

4.1. Average Rotation

We use maps pixelized using the Healpix\(^3\) (Gorski et al. 2005) scheme at resolution \( N_{\text{side}} = 1024 \). We generate realizations of the full-sky using the synfast tool at this resolution with input theoretical power spectra \( C_{\ell} \) corresponding to the best-fit model in "base + r" fits reported in the latest Planck results (Planck Collaboration 2015a). A second set of realizations is generated using the rotated spectra \( \tilde{C}_{\ell} \) in Equations (34)–(39). We generate two realizations with rotation angles \( \alpha = 1^\circ \) and \( \alpha = 5^\circ \). All realizations are smoothed using a 30 arcmin Gaussian window function and we have used the Planck total intensity and polarization transfer functions to smooth the theory to match the experimental beam effects in all cases.

We also use the Planck R2.0 SMICA I, Q, and U maps (Adam et al. 2015) downgraded to a common resolution of \( N_{\text{side}} = 1024 \) and smoothed by the same 30 arcmin Gaussian window function as the realizations. We add the half-ring half-difference (HRHD) noise estimate to each of the realizations although the noise is significantly suppressed at our working resolution. Our polarization convention is different from that used in the Healpix package and corresponds to a change \( U \rightarrow -U \).

The analysis procedure is as follows. We run the Healpix hotpsot tool to identify all peaks (both minima and maxima) in each set of \( I \), \( Q \), and \( U \) maps. We then take tiles, 8° wide, centered at each peak location and rotate them so that the peak

\(^3\) http://healpix.sourceforge.net
Figure 1. Results from Planck-like simulations smoothed to 30 arcmin resolution with rotation angles $\alpha = 0^\circ$, 1$^\circ$, and 5$^\circ$. From top to bottom: $C_+, C_-$, $C_\times$, and $\langle T^2 \rangle$ showing the emergence of the parity-violating signal in the two estimators sensitive to $EB$ and $TB$ modes. The color scales are selected to enhance the contrast in each of the images.
is at a reference pixel. Each tile in $I$, $Q$, and $U$, is then added to separate stack averages after the monopole of each tile is subtracted (Komatsu et al. 2011; Planck Collaboration 2015c). The subtraction minimizes the effect of long-range correlations. We also exclude regions inside the mask defined by the SMICA confidence parameter. The stacks we obtain are an average of some 36,000 locations including both minima and maxima in all three Stokes parameters. We combine all maxima with thresholds above zero and the negative of all minima with thresholds below zero.

Figure 1 shows the peak stacks in $C_\alpha$, $C_\alpha$, $C_\alpha$, and $\langle U^2 \rangle$ for simulations with $\alpha = 0^\circ$, $1^\circ$, and $5^\circ$. For all cases the $C_\alpha$ and $C_\alpha$ stacks, that are not sensitive to parity-violating modes, display the expected radial envelope that decreases to the mean field limit as we move away from the peak. $C_\alpha$ and $\langle U^2 \rangle$ only show a radial signal for the $\alpha = 0^\circ$ cases. For the $\alpha = 1^\circ$ case the $C_\alpha$ stack, sensitive to $EB$ modes shows a clear signal whereas for the respective $\langle U^2 \rangle$ stack the signal is close to the background level but clearly visible in the $\alpha = 5^\circ$ case.

For both $C_\alpha$ and $\langle U^2 \rangle$ stacks, a signal with azimuthal dependence and amplitude roughly comparable to the background noise is visible close to the center of the stacks. This signal does not bias the estimate of parity violation since it averages to zero when integrating in azimuthal angle $\phi$.

The azimuthally averaged profiles for the stacks are shown in Figure 3. The stacks from simulated maps are consistent with the expected Bessel functions of zeroth and fourth order while the amplitude grows as a function of overall rotation $\alpha$. The

Figure 2. Stacks for $C_\alpha$ (top) and $\langle U^2 \rangle$ (bottom) for Planck SMICA maps compared to those from the $\alpha = 1^\circ$ simulation. The SMICA stack for $C_\alpha$ appears to show a weak radial signal consistent with a $J_4(\theta)$ radial profile but with an additional azimuthal modulation. The background noise level in the $\langle U^2 \rangle$ stack is too large to identify a consistent TB signal.

4.2. Direction-dependent Rotation

An analysis using peak stacks is not restricted to constraining the monopole of a possible rotation. In fact, if birefringence exists, there is no reason why it should induce a coherent rotation of the polarization angle over the entire sky. Recent constraints on birefringent effects have employed multipole based estimators for the direction dependent angle (Gluscevic et al. 2012; POLARBEAR Collaboration 2015) based on the estimator developed by Gluscevic et al. (2009). The methods result in an estimate of the monopole expansion of the angle $\alpha_\ell$. These estimates based on measures of rotation in multipole space face the same problems with respect to inhomogeneous weighting and partial-sky coverage as conventional power spectrum estimation methods. In contrast, an estimate based on peak stacks can provide a map of any potential signal without complications due to sky coverage and is only limited by the fact that peak stacking is not an optimal compression of all the information in the maps. It also has the advantage, shared with any coordinate space based measure, that it is more suitable to
Figure 3. Azimuthally averaged profiles of the stacks shown in Figures 1 and 2. For each panel we show the profiles for the three simulations and for the Planck SMICA map. The model curves are calculated using Equations (25)--(26) and (31)--(33). We use a minimal $\Lambda$CDM Planck best-fit, including tensors, as input power spectra and apply a rotation of $\alpha = 5^\circ$. The model curves include only signal power. The shaded area shows the standard deviation of the profile calculated from an azimuthal averaging of the stack variances for the SMICA maps centered on the SMICA case except for the $C_\ell$ and $U_\ell$ cases where no signal is expected. The model curves are a very accurate prediction of the observed signal. The $C_\ell$ signal-only curve differs from the observed values at small angular scales where the noise bias of the polarization becomes significant.
detecting any signal that is compact on the sky. This makes it complementary to multipole based methods that are ideally suited to detecting signals that are centered around certain angular scales or that have well defined, statistically isotropic, signatures.

As an example of how one could employ coordinate space based correlation function methods to constrain \( \alpha(\mathbf{n}) \) we modify our peak stacking pipeline to consider averages inside lower resolution pixels. The toy model we use to test this method is obtained by generating a map \( \alpha(\mathbf{n}) \) using the Healpix alm2map tool with a pure \((\ell = 1, m = 1)\) dipole mode with \( \alpha_{11} = 20^\circ \) as input. We use the map to apply a pixel dependent rotation of the polarization in the simulated Planck map with no initial parity-violating modes. The peak stacking procedure described in Section 4.1 is repeated but the results are binned by low resolution pixels of \( N_{\text{side}} = 8 \). We then use the peak value of the \( \hat{C}_\kappa \) estimate in each pixel, \( \hat{C}_\kappa = \max(|\hat{C}_\kappa(\theta)|) \), as a tracer of the amount of average rotation in each low resolution pixel since \( \hat{C}_\kappa \) gives the highest signal-to-noise determination of the rotation.

The results of this exercise are summarized in Figure 4 which shows how \( \hat{C}_\kappa \) traces the input \( \alpha(\mathbf{n}) \) in the simulation. We also show the result of running this estimate on the SMICA map itself. The \( \alpha(\mathbf{n}) \) map for SMICA does not show any obvious signal although it is interesting to note that the two pixels at the extremes of the range in \( \hat{C}_\kappa \) lie close to the excluded region that fails the SMICA confidence criterion. We leave a full analysis of the significance of these estimates for future work, but in Figure 5 we show the binned distribution of pixel values outside and inside the excluded region. All pixels that lie outside a \( \pm 3\sigma \) bound defined by a best-fit Gaussian to the excluded pixels lie either inside the masked area or are immediately adjacent to it. The variance in the map also appears to be anisotropic with minima around the equatorial poles, which correlates with the variance due to Planck’s scan strategy.

5. DISCUSSION

We have shown how correlations of Stokes parameters of CMB maps can yield robust, local estimates of parity-violating signals. This can be useful when analyzing maps to search for localized signals for which complementary harmonic based estimators are not ideal. Techniques based on coordinate frame correlation function estimators are therefore similar in spirit to many techniques used to investigate possible localized anomalies in the CMB (see Planck Collaboration 2015a for a recent overview) which rely on coordinate frame statistics.

We used the correlators defined here to build simple tools to image parity-violating effects. We focused on peak stacking techniques as these provide a powerful compression of the acoustic signature in the polarization and are relatively easy to compute as opposed to the full, unconstrained correlations at the same resolution level. We have found the signal of parity
violation appears as expected in simulations where a non-zero effect was included and that our analytic estimates of the signal are in good agreement with simulations. Our estimators run on Planck maps yield a limit on a sky-averaged rotation angle that is compatible with estimates in the literature obtained using different methods.

Our methods are not limited to the small angle limit we have adopted in this work. Peak stacking techniques are optimal for signals that modify the correlations on acoustic scales around a degree on the sky. They are well suited for along the line-of-sight birefringence effects. Other classes of parity-violating models however, may induce signals on larger angular scales if the effects were active during the inflationary phase in the early universe. In future work we will extend our methods to the full sky. An additional advantage of this will be the exploitation of the full information in the maps. This will increase the signal-to-noise of any estimate and will allow for much higher resolution reconstructions of maps such as those shown in Figure 4.

We used a simple exercise to show how the localized nature of these methods can be harnessed to reconstruct maps of spatially varying rotation angle. The example used a very large input rotation dipole as the signal to be reconstructed and the resulting map was much lower resolution than the input Planck maps. The choice of resolution was dictated by the limited number of peaks in the maps and we expect similar applications using the full-sky information will yield much higher resolution reconstructions.

Another advantage of methods based on coordinate frame correlations is the relatively straightforward implementation of noise weighting. We have not explored this here but we expect the results would be improved by correctly noise weighting the correlation estimators since the polarization information in current maps is still in the relatively low signal-to-noise regime. This would also help in targeting smaller angular resolutions in current and near-term polarization data.

On small scales an interesting prospect is to explore how localized, peak stack estimators based on correlation functions of the polarization could help to extract lensing information from CMB maps. Gravitational lensing of CMB photons, now routinely measured (see Planck Collaboration 2015b and references therein for a summary), leaves an imprint in the polarization signal that mixes E- and B-modes. Current estimates are based on higher-order correlations in harmonic space (Okamoto & Hu 2003) and real space (Carvalho & Moodley 2010; Bucher et al. 2012). Complementary techniques similar to those developed in this work may be feasible. In particular, peak stacking may be ideally suited to isolate the lensing signal in a manner that is reminiscent of exploratory methods used to isolate the CMB lensing signal due to halos (Baxter et al. 2015; Madhavacheril et al. 2015).
