LOCAL STATISTICS FOR RANDOM DOMINO TILINGS OF THE AZTEC DIAMOND

HENRY COHN, NOAM ELKIES, AND JAMES PROPP

ABSTRACT. We prove an asymptotic formula for the probability that, if one chooses a domino tiling of a large Aztec diamond at random according to the uniform distribution on such tilings, the tiling will contain a domino covering a given pair of adjacent lattice squares. This formula quantifies the effect of the diamond's boundary conditions on the behavior of typical tilings; in addition, it yields a new proof of the arctic circle theorem of Jockusch, Propp, and Shor. Our approach is to use the saddle point method to estimate certain weighted sums of squares of Krawtchouk polynomials (whose relevance to domino tilings is demonstrated elsewhere), and to combine these estimates with some exponential sum bounds to deduce our final result. This approach generalizes straightforwardly to the case in which the probability distribution on the set of tilings incorporates bias favoring horizontal over vertical tiles or vice versa. We also prove a fairly general large deviation estimate for domino tilings of simply-connected planar regions that implies that some of our results on Aztec diamonds apply to many other similar regions as well.

1. Introduction

1.1. Statement of the main theorem. Random domino tilings of finite regions often exhibit surprising statistical heterogeneity. Such heterogeneity would be expected in the vicinity of the boundary, but in fact the presence of a boundary can make its influence felt well into the interior of the region. The research that led to this article is part of an ongoing effort to understand this phenomenon. The results proved here are the first to give a precise description of how local statistics for domino tilings can vary continuously throughout a region in response to the imposition of specific boundary conditions.

Those who study random tilings of finite regions (in the plane) by dominos have tended to focus on regions that are rectangles of even area. In particular, Burton and Pemantle [BP] have done an intensive analysis of the small-scale structure of such tilings. Their work shows that once one gets away from the boundary of the rectangle, random tilings tend to exhibit statistical isotropy. Among all random processes that take their values in the set of domino tilings of the plane, the Burton-Pemantle process has maximal entropy, and it is unique in this regard; for this reason alone, it is worth further study.
However, if one looks at random domino tilings of tileable finite regions in general, one finds that local behavior far from the boundary need not be governed by maximal entropy statistics, but can look very different. Moreover, the local behavior seen in one part of the region is in general different from local behaviors seen elsewhere.

One especially tractable proving ground for the study of this statistical heterogeneity has been the family of finite regions known as Aztec diamonds, introduced and studied in [EKLP]. Figure 1 shows an Aztec diamond of order 64 tiled randomly by dominos. In general, the Aztec diamond of order $n$ can be defined as the union of those lattice squares whose interiors lie inside the region $\{(x, y) : x + y \leq n + 1\}$.

It was shown in [JPS] (and will be proved in subsection 6.4 by different methods) that, asymptotically, the circle inscribed in the Aztec diamond of order $n$ serves as a boundary between domains of qualitatively different behavior. We call this circle the arctic circle, because, as one can see from Figure 1, the dominos outside the arctic circle are frozen into a brickwork pattern. To state the theorem more precisely, we impose a checkerboard coloring on the Aztec diamond of order $n$, so
that the leftmost square in each row in the top half of the diamond is white. We say a horizontal domino is \textit{north-going} or \textit{south-going} according to whether its leftmost square is white or black, and we say a vertical domino is \textit{west-going} or \textit{east-going} according to whether its upper square is white or black. (The motivation for this terminology comes from the “domino shuffling” algorithm introduced in \cite{EKL} and used in both \cite{IPS} and \cite{GIP}; this algorithm permits one to generate random domino tilings of Aztec diamonds in such a way that every possible tiling has the same probability of arising as every other, and indeed it was this algorithm that we used to generate the tiling shown in Figure 1.)

Say that two dominos are adjacent if they share an edge (i.e., their boundaries overlap on a segment of length 1 or more), and say that a domino is adjacent to the boundary of the Aztec diamond if it shares an edge with the boundary. We define the \textit{north polar region} as the union of those north-going dominos that are each connected to the boundary by a sequence of adjacent north-going dominos. The south, west, and east polar regions are defined similarly, and the \textit{temperate zone} is the union of those dominos that belong to none of the four polar regions.

The arctic circle theorem of \cite{IPS} states that for every \(\varepsilon > 0\), if one takes \(n\) sufficiently large, then for all but an \(\varepsilon\) fraction of the domino tilings of the diamond of order \(n\), the border of the temperate zone stays within distance \(\varepsilon n\) of the circle of radius \(n/\sqrt{2}\) with center \((0,0)\). In particular, this implies that if one increases the radius of the circle by \(\varepsilon n\), then with probability greater than \(1 - \varepsilon\), in each of the four regions in the Aztec diamond that lie outside the enlarged disk, all dominos are aligned with their neighbors in brickwork patterns. The theorem also implies that if one decreases the radius of the disk by \(\varepsilon n\), then within the shrunken disk dominos with different orientations are in some sense interspersed among one another (with probability greater than \(1 - \varepsilon\)); however, the theorem by itself gives no information on their distribution.

In Theorem 1 of this article we will give a quantitative analysis of the behavior of random tilings in the inner, disorderly zone. In particular, we will give an asymptotic formula for the proportion of domino tilings of the Aztec diamond of order \(n\) that contain a domino at a specified location, i.e., the \textit{placement probability} for that location. This formula depends only on the orientation of the domino, its parity relative to the natural checkerboard coloring of the Aztec diamond, and the relative position of the domino within the Aztec diamond (in normalized coordinates). One consequence of our formula is that random domino tilings exhibit “total statistical heterogeneity” within the central zone. That is to say, any two patches within the temperate zone that are macroscopically separated (i.e., separated by a distance on the order of \(n\)) will exhibit distinct statistics. (For a precise statement, see subsection 6.5.)

Our work builds on the generating functions derived in \cite{GIP}. One of them is a rational function in three variables whose coefficients are the placement probabilities for which an asymptotic formula is sought. The authors of the earlier article carried out a relatively straightforward complex integration to calculate coefficients corresponding to dominos in the \(2 \times 2\) block in the middle of the Aztec diamond; the resulting exact formula implies that in a diamond of order \(n\), these placement probabilities are \(\frac{1}{4} + O\left(\frac{1}{n}\right)\). In the present article we will apply the saddle point method to estimate contour integrals associated with more general coefficients of a related generating function (also derived in \cite{GIP}).
We can now prepare to state our main result. We call the union of two adjacent squares in the Aztec diamond a domino space, to avoid confusion between actual dominos occurring in a particular tiling and the locations in which dominos can occur. Domino spaces are classified as north-going, south-going, west-going, or east-going in the obvious way, so that for instance a domino is north-going if and only if it occupies a north-going domino space. Because of symmetry, we lose no generality by focusing on the placement probabilities associated with north-going domino spaces. The midpoint of the bottom edge of each north-going domino space is some point \((\ell, m)\) with \(|\ell| + |m| \leq n - 1\). We call this the location of the north-going domino space. Normalizing by dividing by \(n\), we obtain some point \((x, y)\) with \(|x| + |y| < 1\). We call this the normalized location of the north-going domino space.

**Theorem 1.** Let \(U\) be an open set containing the points \((\pm \frac{1}{2}, \frac{1}{2})\). If \((x, y)\) is the normalized location of a north-going domino space in the Aztec diamond of order \(n\), and \((x, y) \not\in U\), then, as \(n \to \infty\), the placement probability at \((x, y)\) is within \(o(1)\) of \(P(x, y)\), where

\[
P(x, y) = \begin{cases}
0 & \text{if } x^2 + y^2 \geq \frac{1}{2} \text{ and } y < \frac{1}{2}, \\
1 & \text{if } x^2 + y^2 \geq \frac{1}{2} \text{ and } y > \frac{1}{2}, \\
\frac{1}{2} + \frac{1}{\pi} \tan^{-1} \left( \frac{2y-1}{\sqrt{1-2x^2-2y^2}} \right) & \text{if } x^2 + y^2 < \frac{1}{2}.
\end{cases}
\]

The \(o(1)\) error bound is uniform in \((x, y)\) (for \((x, y) \not\in U\)).

Similarly, the south-going, east-going, and west-going placement probabilities near \((x, y)\) are approximated by \(P(-x, -y)\), \(P(-y, x)\), and \(P(y, -x)\), respectively. This follows from Theorem 1 by rotational symmetry.

The organization of the rest of this article is as follows.

In the remainder of Section 1, we discuss some qualitative features of the main theorem and give some preliminaries for the proof. In Section 2, we use the saddle point method to derive asymptotic estimates for certain numbers known as creation rates, which give placement probabilities when summed appropriately. In Section 3, we use this result to estimate, modulo an error term, the north-going placement probabilities. In Section 4, we use techniques from the theory of exponential sums to justify our bound for the error term. This completes the proof of the theorem away from the boundary of the diamond; Section 5 provides the final arguments that handle locations near the boundary.

Section 6 discusses some consequences of the theorem. In particular, by taking a detour through the theory of domino tilings in general, we show that some consequences of the arctangent formula apply not only to the particular shape we call the Aztec diamond but also to slightly deformed versions of this shape (Proposition 20). We also give a new proof of the arctic circle theorem and a large deviation estimate for certain properties of random tilings of simply-connected finite regions (Theorem 21 and Proposition 22). Section 7 briefly sketches how the method of proof of Theorem 1 can be adapted to handle the more general case of random domino tilings when there is a bias in favor of one domino orientation over the other (horizontal versus vertical). We conclude in Section 8 with speculations and open questions.

For a treatment of the probabilistic preliminaries needed for Section 6, see [D].
1.2. Features of the result. As a first comment on the qualitative features of this formula, we point out the continuity of the formula for \( P(x, y) \) (except at \((\pm \frac{1}{2}, \frac{1}{2})\)). Indeed, if we had been so naive as to ask for an asymptotic formula for the placement probabilities for all horizontal domino spaces in an asymptotically small patch of the Aztec diamond (south-going as well as north-going), we would not get a single value at all but rather a pair of values, namely \( P(x, y) \) and \( P(-x, -y) \), which are not in general equal. That is, the local statistics are not even approximately invariant under translations that exchange the two color-classes. It is therefore all the more pleasant that the local statistics are asymptotically invariant under translations that preserve the two color-classes (at least, they are invariant if, in discussing local statistics, we confine ourselves to placement probabilities, and do not inquire about correlations between placements).

Another important feature of the formula is the singular behavior that occurs near the normalized locations \((\pm \frac{1}{2}, \frac{1}{2})\), which we can explain as follows. In [EKLP] it is shown that the Aztec diamond of order \( n \) has exactly \( 2^{n(n+1)/2} \) domino tilings, and a formula derived in that article (formula (7) of Section 4) can be used to show that for \( 0 \leq k \leq n \), exactly \( \binom{n}{k} 2^{n(n-1)/2} \) of the tilings have horizontal dominos covering the leftmost squares in the first \( k \) rows from the top and have vertical dominos covering the leftmost squares in the next \( n-k \) rows. Thus, the placement probability associated with the leftmost north-going domino space in the \( k \)th row is exactly the sum

\[
2^{-n} \sum_{i=k}^{n} \binom{n}{i}.
\]

This sum is very close to 1 for \( k - \frac{n}{2} \ll -\sqrt{n} \) and very close to 0 for \( k - \frac{n}{2} \gg \sqrt{n} \); macroscopically speaking, the placement probability jumps from 1 to 0 discontinuously. It might be possible to analyze the limiting behavior of the placement probabilities in the vicinity of the singularities under suitable scaling, but we do not explore this possibility here.

An easily-understood symmetry property of \( P(\cdot, \cdot) \) is the fact that

\[
(1.1) \quad P(x, y) = P(-x, y).
\]

This is a consequence of the fact that reflecting a domino tiling through the line \( x = 0 \) carries north-going domino spaces to north-going domino spaces. A further identity satisfied by \( P(\cdot, \cdot) \) is the relation

\[
(1.2) \quad P(x, y) + P(-y, x) + P(-x, -y) + P(y, -x) = 1.
\]

To see why this is true, one need only observe that the four domino spaces that contain a particular lattice square (fewer, if the square is on the boundary) must have placement probabilities that sum to 1.

A subtler consequence of Theorem 1 is the fact that the level sets of \( P(x, y) \) (for probabilities strictly between 0 and 1) are arcs of ellipses. More specifically, for \( 0 < p < 1 \) the level set \( \{(x, y) : P(x, y) = p\} \) and the level set \( \{(x, y) : P(x, y) = 1 - p\} \), together with the singular points \((\pm \frac{1}{2}, \frac{1}{2})\), form an ellipse tangent to the boundary of the diamond at the two singular points. As \( p \to 0 \) (or \( p \to 1 \)), the ellipse becomes the inscribed circle, which is the zero-set of the function \( 2x^2 + 2y^2 - 1 \); in the case \( p = \frac{1}{2} \), the ellipse degenerates into the line segment joining the two singular points, which is the part of the zero-set of the function \((2y - 1)^2\) lying inside the Aztec diamond; and in general, the ellipse will be the zero-set of some convex combination
of $2x^2 + 2y^2 - 1$ and $(2y - 1)^2$. The point $(0, 0)$ lies on the level set $p = \frac{1}{4}$, which is an arc of an ellipse; the complementary arc of the ellipse is the level set $p = \frac{3}{4}$, and the point on this arc opposite $(0, 0)$ is the point $(0, \frac{2}{3})$. The situation is depicted schematically in Figure 2.

1.3. Preparation for the proof. Recall that, under the original (unnormalized) coordinate system, each north-going domino space in an Aztec diamond of order $n$ is assigned some location $(\ell, m)$ with $|\ell| + |m| \leq n - 1$. It is easy to check that $\ell + m$ must have the same parity as $n - 1$. Define $P(\ell, m; n)$ as the probability that a random domino tiling of the Aztec diamond of order $n$ will have a domino occupying the north-going domino space at location $(\ell, m)$; for $|\ell| + |m| > n - 1$, or $\ell + m \not\equiv n - 1 \pmod{2}$, define $P(\ell, m; n) = 0$. For instance, we have $P(0, 0; 1) = \frac{1}{2}$, $P(0, 1; 2) = \frac{3}{4}$, and $P(0, -1; 2) = P(1, 0; 2) = P(-1, 0; 2) = \frac{1}{4}$.

Define
\[
Cr(\ell, m; n) = 2(P(\ell, m; n) - P(\ell, m - 1; n - 1)).
\]

This quantity is called the net creation rate at location $(\ell, m)$, but the reason for this name and the interpretation of the quantity in terms of domino shuffling are not needed for our purposes. (For the motivation, see [GIP].)

Define $c(a, b; n)$ to be the coefficient of $z^a$ in $(1 + z)^{-b}(1 - z)^b$. (Note that $c(a, b; n)$ is the Krawtchouk polynomial $P_a$ evaluated at $b$. For information about
Krawtchouk polynomials, see [MS, p. 130]. Our proof of Theorem 1 will be based on the following result from [GIP]:

**Proposition 2.** Let \( n > 0 \). Suppose \( \ell \) and \( m \) are integers with \( \ell + m \equiv n \pmod{2} \) and \( |\ell| + |m| \leq n \). If we let \( a = (\ell + m + n)/2 \) and \( b = (\ell - m + n)/2 \), then

\[
Cr(\ell, m; n + 1) = c(a, b; n)c(b, a; n)/2^n.
\]

For other integers \( \ell \) and \( m \), we have \( Cr(\ell, m; n + 1) = 0 \).

This proposition implies that the creation rates are non-negative, if we use the identity \( c(b, a; n)b!(n - b)! = c(a, b; n)a!(n - a)! \). (This identity is a standard fact about Krawtchouk polynomials, and follows immediately from Theorem 17 on page 152 of [MS].) When combined with Proposition 2, the identity implies that \( Cr(\ell, m; n + 1) \) is a positive factor times the square of a Krawtchouk polynomial, and hence that \( Cr(\ell, m; n + 1) \geq 0 \). Note that this inequality, together with (1.3), yields

\[
(1.4) \quad P(\ell, m; n) \leq P(\ell, m + h; n + h)
\]

for \( h \geq 0 \) by induction on \( h \).

We will also need the following result on exponential sums.

**Theorem 3** (Kusmin-Landau). Let \( || \cdot || \) denote the distance to the nearest integer, \( I \) be an interval, and \( f \) be a real-valued function on \( I \). If \( f \) is continuously differentiable, \( f' \) is monotonic, and \( ||f'|| \geq \lambda > 0 \) on \( I \), then

\[
\sum_{n \in I \cap \mathbb{Z}} \exp(2\pi i f(n)) = O(\lambda^{-1}).
\]

The constant implicit in the \( O(\lambda^{-1}) \) term does not depend on \( I \).

A proof can be found in [GK, p. 7].

1.4. **Outline of the Proof of Theorem 1.** We begin the proof of Theorem 1 by using (1.3) to write the placement probabilities as sums of creation rates, which gives the formula

\[
(1.5) \quad P(\ell, m; n) = \frac{1}{2} \sum_{k \geq 0} Cr(\ell, m - k; n - k).
\]

(Note that the remark after Proposition 2 shows that, as claimed in the abstract, this is a weighted sum of squares of Krawtchouk polynomials.) We will estimate the creation rates, and then use our estimate to prove the asymptotic formula for the placement probabilities.

Because of Proposition 2 to estimate the creation rates it suffices to approximate the coefficients of the polynomials \((1 + z)^{n-b}(1 - z)^b\). To do this, we write the coefficients as contour integrals in the usual way, and then apply the saddle point method to these integrals. Sufficiently far outside the arctic circle, this method shows that the creation rates are exponentially small in \( n \) (Proposition 5); sufficiently far inside, it approximates them by a well-behaved function times an oscillating factor (Proposition 4). With additional work, it might be possible to obtain a uniform estimate over the entire Aztec diamond, but we can make do with just these estimates.

We would then like to substitute our creation rate estimates into (1.5) and convert the sum to an integral to determine its asymptotics. If we are willing to be
unrigorous, we can wishfully replace the oscillatory cosine-squared factor in Proposition 4 by its mean value $\frac{1}{2}$, obtaining (for locations inside the inscribed circle)

$$P(\ell, m; n) \approx \frac{1}{2} \sum_{k=0}^{t_{\text{max}}} \frac{2}{\pi \sqrt{(n-k)^2 - 2\ell^2 - 2(m-k)^2}}$$

$$\approx \frac{1}{2} \int_0^{t_{\text{max}}} \frac{2}{\pi \sqrt{(n-k)^2 - 2\ell^2 - 2(m-k)^2}} \, dk$$

$$= \frac{1}{\pi} \left( \tan^{-1} \frac{k + n - 2m}{\sqrt{(n-k)^2 - 2\ell^2 - 2(m-k)^2}} \right) \bigg|_{k=0}^{k=t_{\text{max}}}$$

$$= \frac{1}{2} - \frac{1}{\pi} \tan^{-1} \frac{n - 2m}{\sqrt{n^2 - 2\ell^2 - m^2}}$$

$$= \frac{1}{2} + \frac{1}{\pi} \tan^{-1} \frac{2y - 1}{\sqrt{1 - 2x^2 - 2y^2}},$$

where $k = t_{\text{max}}$ is the larger of the two roots of the equation $(n-k)^2 - 2\ell^2 - 2(m-k)^2 = 0$, $x = \ell/n$, and $y = m/n$; we truncate the sum and integral at $t_{\text{max}}$ on the supposition (to be discussed in the next paragraph) that essentially no creation occurs outside the arctic circle. To make this argument rigorous, we need to deal honestly with the oscillating factor in the creation rate estimate inside the arctic circle, and we need to circumvent the non-uniformity of our estimates.

The non-uniformity of the estimates can be dealt with simply by summing over a smaller interval than in (1.5). The exponentially small bounds on the creation rates outside the arctic circle show that the terms in (1.5) that come from locations outside the arctic circle contribute very little to the sum. Motivated by this, we look at the sum of all the terms that come from locations that are far enough inside the arctic circle that our creation rate estimates from Proposition 4 apply. Because the creation rates are all non-negative, this new sum underestimates the placement probability. Dealing appropriately with the oscillating factor (as described below) gives an estimate for the new sum; as we see in the computation above, this estimate turns out to be the arctangent formula from Theorem 1. A short argument shows that the placement probabilities can be no larger asymptotically (Proposition 12), and because our estimate is an underestimate we know they can be no smaller. This completes the proof. (Actually, this method works only away from the edges of the diamond, so it is not until Section 5 that the proof is completed.)

All that remains is to describe how to deal with the oscillating factor in the summand. We must show that replacing the oscillating factor by its average value has an asymptotically negligible effect on the sum. Equivalently, we must show that the difference between the original sum and the smoothed sum is small. This difference is an exponential sum, and we can estimate it using the Kusmin-Landau Theorem once some preparatory results (Lemmas 6, 7, and 14) are in place.

2. Creation Rate Estimates

Our proof of the asymptotic formula for placement probabilities begins with an estimate of creation rates, which is proved using the saddle point method. Because Proposition 3 is most conveniently stated for an Aztec diamond of order $n + 1$, we will estimate the creation rates in an Aztec diamond of order $n + 1$. From this point on, we assume that $\ell + m \equiv n \pmod{2}$, because otherwise $\text{Cr}(\ell, m; n+1)$ is
necessarily 0. As pointed out in subsection 1.4, the creation rates behave differently inside and outside the inscribed circle. If we estimate the creation rates inside it, we get the following result:

**Proposition 4.** Fix \( \varepsilon > 0 \). If \( \ell^2 + m^2 \leq (1 - \varepsilon)n^2/2 \) and \( \ell + m \equiv n \pmod{2} \), then

\[
Cr(\ell, m; n + 1) = \frac{4 \cos^2 \Phi(\ell, m; n)}{\pi \sqrt{n^2 - 2\ell^2 - 2m^2}} + O_\varepsilon(n^{-2})
\]

for some function \( \Phi(\ell, m; n) \), which we determine explicitly below.

The subscript in \( O_\varepsilon(n^{-2}) \) indicates that the implicit constant depends on \( \varepsilon \). In this paper, if any subscripts appear on a big \( O \) term, then the implicit constant depends only on the indicated variables, but the absence of subscripts should not be taken to imply that the implicit constant is absolute.

**Proof.** Let

\[
f(z) = \frac{(1 + z)^{a-b}(1 - z)^b}{z^a},
\]

where \( a \) and \( b \) are defined as in the statement of Proposition 2. To approximate the creation rate, we need to approximate \( c(a, b; n) \), which is the constant term of \( f(z) \). The constant term is given by the usual contour integral, which we will approximate using the saddle point method.

Write \( a = (1 + u)n/2 \) and \( b = (1 + v)n/2 \), so that \(-1 \leq u, v \leq 1\). Note that the \( u, v \) coordinates are related to the coordinates in the statement of the proposition by \( u = (\ell + m)/n = x + y \) and \( v = (\ell - m)/n = x - y \). We will keep \( u \) and \( v \) fixed as we send \( n \) to infinity.

The critical points of \( f(z) \) are

\[
z_1 = \frac{-v + \sqrt{u^2 + v^2 - 1}}{1 - u}
\]

and

\[
z_2 = \frac{-v - \sqrt{u^2 + v^2 - 1}}{1 - u}.
\]

Because \( \ell^2 + m^2 < n^2/2 \), we have \( u^2 + v^2 < 1 \). It follows that \( z_1 \) and \( z_2 \) are complex conjugates on the circle \(|z|^2 = (1 + u)/(1 - u)\). We now apply the saddle point method. To find the constant term of \( f(z) \), we integrate \( f(z)/(2\pi i z) \) about the circle of radius \( \sqrt{(1 + u)/(1 - u)} \) centered at the origin. One can check that, on this circle, \(|f(z)|\) is greatest at the critical points \( z_1 \) and \( z_2 \). (To check it, parametrize the circle by the angle \( \theta \) formed with the real axis. One has \( \partial \log |f(z)|^2 / \partial \theta = 0 \) if \( z \) is one of the two critical points or \( z \) lies on the real axis. At the critical points, \( \partial^2 \log |f(z)|^2 / \partial \theta^2 = n(u^2 + v^2 - 1)/(1 - v^2) < 0 \), so \(|f(z)| \) has maxima at these points. It must have minima on the real axis, since between any two local maxima there must be a local minimum.) As \( n \) goes to infinity, the integral is given asymptotically by the integrals over the parts of the path near the critical points, which can be estimated straightforwardly. This is the saddle point method. We will omit the details of the argument leading to the approximation, because they are standard, and can be found, for example, in [18, pp. 87–89].
The saddle point method tells us that the constant term of \( f(z) \) is the sum
\[
Z_1(1 + O(n^{-1})) + Z_2(1 + O(n^{-1})),
\]
where

\[
Z_1 = \frac{f(z_1)}{2\pi z_1} \sqrt{\frac{2\pi}{(\log f)'(z_1)}}
\]
and

\[
Z_2 = \frac{f(z_2)}{2\pi z_2} \sqrt{\frac{2\pi}{(\log f)'(z_2)}}.
\]

(For the proof of Proposition 3 we will not need to determine the signs of the square roots in (2.3) and (2.4), but they must be chosen so that \( Z_1 \) and \( Z_2 \) are complex conjugates.)

Simplifying \( z^2(\log f)''(z) \) yields
\[
z^2(\log f)''(z) = \frac{n(1 + u - 4z^2 - 2uz^2 - 4vz^3 + uz^4 - z^4)}{2(z^2 - 1)^2}.
\]

From this, one can check that at either critical point of \( f(z) \), \( z^2(\log f)''(z) \) has absolute value

\[
|z^2(\log f)''(z_1)| = \frac{n}{2} \sqrt{\frac{(1 - u^2 - v^2)(1 - u^2)}{(1 - v^2)}}.
\]

Let \( \Psi(u, v; n) \) be the phase of \( Z_1 \), so that \( Z_1 = |Z_1| \exp(i \Psi(u, v; n)) \). Then
\[
Z_1 + Z_2 = 2|Z_1| \cos \Psi(u, v; n),
\]
and \( c(a, b; n) \) is approximated by

\[
c(a, b; n) = 2|Z_1| \cos \Psi(u, v; n) + O\left(\frac{|Z_1|}{n}\right).
\]

Of course,

\[
|Z_1| = \frac{|f(z_1)|}{2\pi} \sqrt{\frac{2\pi}{|z^2(\log f)''(z_1)|}}.
\]

Since \( |1 + z_1|^2 = 2(1 - v)/(1 - u) \), \( |1 - z_1|^2 = 2(1 + v)/(1 - u) \), and \( |z_1|^2 = (1 + u)/(1 - u) \), we see that

\[
|f(z_1)| = 2^{n/2} \frac{(1 - v)^{(n-b)/2}(1 + v)^{b/2}}{(1 - u)^{(n-a)/2}(1 + u)^{a/2}}.
\]

We have \( \text{Cr}(\ell, m; n + 1) = c(a, b; n)c(b, a; n)/2^n \), by Proposition 3. Interchanging \( a \) and \( b \) corresponds to interchanging \( u \) and \( v \). Let \( \tilde{x} \) denote the result of interchanging \( u \) and \( v \) (and also \( a \) and \( b \)) in the expression \( x \), so that, for example, \( \tilde{u} - 2v = v - 2u \). When we substitute (2.7) and (2.4) into (2.8), we see that
\[
|Z_1||\tilde{Z}_1| = \frac{2^n}{\pi n \sqrt{1 - u^2 - v^2}}.
\]

Hence, by (2.3)
\[
\text{Cr}(\ell, m; n + 1) = \frac{4 \cos \Psi(u, v; n) \cos \Psi(v, u; n)}{\pi n \sqrt{1 - u^2 - v^2}} + O(n^{-2}).
\]
(To see that the error term is $O(n^{-2})$, one uses the fact that it is $O(|Z_1|\overline{Z}_1|/(n2^n))$ and that $|Z_1|\overline{Z}_1| = O(2^n/n)$.)

Now we check that $\cos \Psi(v, u; n) = \pm \cos \Psi(u, v; n)$. The identity
\[
c(b, a; n)!(n - b)! = c(a, b; n)a!(n - a)!
\]
suggests that this should be so, but does not seem to prove it. If we set $\alpha = z_1^2(\log f)^\prime\prime(z_1)$, we find (after some simplification) that
\[
\frac{\alpha}{\bar{\alpha}} = 1 - \frac{u^2}{1 - v^2}.
\]
Thus, $\alpha$ and $\bar{\alpha}$ have the same phase. If we combine the formulas
\[
\frac{1 + z_1}{1 + \bar{z}_1} = \frac{1 - v}{1 - u}
\]
and
\[
\frac{1 - z_1}{1 + z_1} = \frac{1 + v}{1 - v \bar{z}_1}
\]
with
\[
f(z_1) = (1 + z_1)^n \left(\frac{1 - z_1}{1 + z_1}\right)^b \left(\frac{1}{z_1}\right)^a,
\]
we find that $f(z_1)$ equals $\bar{f}(z_1)$ times a positive factor, so their phases are equal. Because
\[
Z_1 = \pm \frac{f(z_1)}{2\pi} \sqrt{\frac{2\pi}{\alpha}} \quad \text{and} \quad \overline{Z}_1 = \pm \frac{f(z_1)}{2\pi} \sqrt{\frac{2\pi}{\bar{\alpha}}},
\]
we see that $Z_1$ and $\overline{Z}_1$ have the same phase, to within a sign, so $\cos \Psi(v, u; n) = \pm \cos \Psi(u, v; n)$.

Finally, we change to the coordinates of our generating function by the substitutions $u = (\ell + m)/n$ and $v = (\ell - m)/n$. We set $\Phi(\ell, m; n) = \Psi(u, v; n)$. Then when $\ell + m \equiv n \pmod{2}$, the creation rate at the $(\ell, m)$ location in an Aztec diamond of order $n + 1$ is
\[
Cr(\ell, m; n + 1) = \frac{\pm 4 \cos^2 \Phi(\ell, m; n)}{\pi \sqrt{n^2 - 2\ell^2 - 2m^2}} + O(n^{-2}).
\]

Because creation rates must be non-negative, the $\pm$ sign in this formula can always be taken to be $+$. The constant implicit in the big $O$ depends continuously on $u$ and $v$. Thus, for fixed $\varepsilon > 0$ the constant can be chosen uniformly for all $u$ and $v$ with $u^2 + v^2 \leq 1 - \varepsilon$.

We have therefore proved the result claimed in the statement of the proposition. \Halmos

Given $\ell$, $m$, and $n$, define
\[
S_\varepsilon = \{k \in \mathbb{Z} : k \geq 0 \text{ and } \ell^2 + (m - k)^2 \leq (1 - \varepsilon)(n - k)^2/2\}.
\]
Also, define $k_{\text{max}}$ to be the greatest element of $S_\varepsilon$, and $k_{\text{min}}$ to be the least. (In Section 3, we will sum the creation rates in (1.4) as $k$ varies over $S_\varepsilon$. We will do so to make it possible to apply Proposition 1 to the terms in the sum, as described in subsection 1.4.)
Proof. We have $k_{\text{max}} = (2y - 1 + \sqrt{2((1 - y)^2 - x^2)} + O(\varepsilon))n$, where $x = \ell/n$ and $y = m/n$. For fixed $y$, this function is clearly maximized at $x = 0$. When $x = 0$, it becomes a linear function maximized at $y = 1 - \delta$ (for $|x| + |y| \leq 1 - \delta$). This yields $k_{\text{max}} \leq (1 - (2 - \sqrt{2})\delta + O(\varepsilon))n$. Therefore, $(n - k_{\text{max}})^{-1} = O(n^{-1})$ if $\varepsilon$ is small enough compared to $\delta$.

For $k \in S_\varepsilon$, we have

$$\ell^2 + (m - k)^2 \leq (n - k)^2(1 - \varepsilon)/2.$$ 

It follows that

$$(n - k)^2 - 2\ell^2 - 2(m - k)^2 \geq (n - k)^2\varepsilon.$$ 

Therefore,

$$\frac{1}{\sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}} = O(\varepsilon^{-1/2}(n - k)^{-1}) = O(\varepsilon^{-1/2}n^{-1}).$$ 

If we are not worrying about dependence on $\varepsilon$, this is $O(n^{-1})$. This completes the proof. 

In order to apply the Kusmin-Landau Theorem to deal with the exponential sums that will appear later in the proof (as discussed in subsection 1.4), we will need to specify $\Phi$, since the phase of $Z_1$ is not uniquely determined. Also, it will be convenient to extend it to a function of real, and even complex, variables (rather than just integers).

Given a point $(x, y) \neq (0, 0)$ in the plane, define $\theta(x, y)$ to be the angle in $(-\pi, \pi]$ formed by the right half of the horizontal axis and the ray from the origin through $(x, y)$.

Lemma 5. Suppose that $|\ell| + |m| \leq (1 - \delta)n$ for some fixed $\delta > 0$. Then $k_{\text{max}} \leq (1 - (2 - \sqrt{2})\delta + O(\varepsilon))n$. Hence, if $\varepsilon$ is small enough compared to $\delta$, then $(n - k_{\text{max}})^{-1} = O(n^{-1})$, and for $k \in S_\varepsilon$ we have

$$\frac{1}{\sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}} = O(\varepsilon^{-1/2}n^{-1}) = O_{\varepsilon, \delta}(n^{-1}).$$

Proof. We have $k_{\text{max}} = (2y - 1 + \sqrt{2((1 - y)^2 - x^2)} + O(\varepsilon))n$, where $x = \ell/n$ and $y = m/n$. For fixed $y$, this function is clearly maximized at $x = 0$. When $x = 0$, it becomes a linear function maximized at $y = 1 - \delta$ (for $|x| + |y| \leq 1 - \delta$). This yields $k_{\text{max}} \leq (1 - (2 - \sqrt{2})\delta + O(\varepsilon))n$. Therefore, $(n - k_{\text{max}})^{-1} = O(n^{-1})$ if $\varepsilon$ is small enough compared to $\delta$.

For $k \in S_\varepsilon$, we have

$$\ell^2 + (m - k)^2 \leq (n - k)^2(1 - \varepsilon)/2.$$ 

It follows that

$$(n - k)^2 - 2\ell^2 - 2(m - k)^2 \geq (n - k)^2\varepsilon.$$ 

Therefore,

$$\frac{1}{\sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}} = O(\varepsilon^{-1/2}(n - k)^{-1}) = O(\varepsilon^{-1/2}n^{-1}).$$ 

If we are not worrying about dependence on $\varepsilon$, this is $O(n^{-1})$. This completes the proof. 

In order to apply the Kusmin-Landau Theorem to deal with the exponential sums that will appear later in the proof (as discussed in subsection 1.4), we will need to specify $\Phi$, since the phase of $Z_1$ is not uniquely determined. Also, it will be convenient to extend it to a function of real, and even complex, variables (rather than just integers).

Given a point $(x, y) \neq (0, 0)$ in the plane, define $\theta(x, y)$ to be the angle in $(-\pi, \pi]$ formed by the right half of the horizontal axis and the ray from the origin through $(x, y)$.

Lemma 6. We can choose $\Phi(\ell, m; n)$ in Proposition 4 so that if one sets $\ell = xn$, $m = yn$, and $k = \kappa n$ in $d\Phi(\ell, m - k; n - k)/dk$, then $d\Phi(\ell, m - k; n - k)/dk$ equals

$$\theta \left( -x + y - \kappa, \sqrt{(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)} \right) -$$

$$\theta \left( 1 - \kappa - 2x, \sqrt{(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)} \right) +$$

$$\frac{x^2 - \kappa - 3y\kappa + 2\kappa^2 + y + y^2}{n\sqrt{(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)}(y + 1 - 2\kappa - x)(y + 1 - 2\kappa + x)}.$$ 

As $n$ tends to infinity, the last term is $O(1/n)$ for $k \in S_\varepsilon$ with $\varepsilon > 0$ fixed, as long as $|\ell| + |m| \leq (1 - \delta)n$ for some fixed $\delta > 0$, and $\varepsilon$ is small enough compared to $\delta$.

Proof. From (2.2), we see that we can choose $\Phi(\ell, m; n)$ to be the imaginary part

$$(2.9) \quad \text{Im} \left( \log f(z_1) - \log z_1 - \frac{1}{2\pi} \log((\log f)'(z_1)) \right).$$ 

If we substitute $m-k$ for $m$ and $n-k$ for $n$ and differentiate, then the first term of\eqref{2.9} contributes the $\theta$-terms in the formula we are proving. To see this, recall that (up to an irrelevant multiple of $2\pi i$)

$$\log f(z) = (n-b) \log(1+z) + b \log(1-z) - a \log z.$$ 

After we express this in terms of $n$, $\ell$, and $m$ and substitute $m-k$ for $m$ and $n-k$ for $n$, the right hand side becomes

$$(n/2 - k - \ell/2 + m/2) \log(1+z) + (n/2 + \ell/2 - m/2) \log(1-z)$$

\hfill (2.10)

$$(n/2 - k + \ell/2 + m/2) \log \hat{z},$$

where $\hat{z}$ is the function of $k$ that results from making the substitutions in $z_1$. Denote by $L$ the function (2.10). When we differentiate $L$ with respect to $k$ (holding $n$, $\ell$, and $m$ fixed), we get

$$\frac{\partial L}{\partial k} = \log \hat{z} - \log(1 + \hat{z}) + \frac{\partial L}{\partial \hat{z}} \frac{\partial \hat{z}}{\partial k}.$$ 

Because $z_1$ is a critical point of $f$, $\partial L/\partial z_1 = 0$, so $\partial L/\partial k = \log \hat{z} - \log(1 + \hat{z})$. Now expressing the imaginary parts of the logarithms in terms of $\theta$ gives the desired terms from the formula we are proving. (To simplify the terms to the form found in the statement of the lemma, one has to use the fact that for $\alpha > 0$, $\theta(\alpha x, \alpha y) = \theta(x, y)$.)

When we substitute and differentiate, the remaining terms in (2.9) clearly give algebraic results. We omit the details of the calculations, since they are tedious and straightforward.

The claim that the last term is $O(1/n)$ for $k \in S_\varepsilon$ is a consequence of Lemma 6. The only thing to check is that although the denominator vanishes at $\kappa = (y+1 \pm x)/2$, these two points are never in $S_\varepsilon$ (or near enough to cause problems). To see that, note that the definition (2.8) of $S_\varepsilon$ is equivalent to the set of $k \geq 0$ for which

\hfill (2.11)

$$(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2) \geq \varepsilon(1 - \kappa)^2.$$ 

Note that $\kappa = 1$ is impossible (since then we must have $x = 0$ and $y = 1$, so $|x| + |y| > 1 - \delta$). However, substituting $\kappa = (y+1 \pm x)/2$ in the left hand side of (2.11) gives $-(3x \pm (1-y)^2)/4$. Thus, the factors $y+1 - 2\kappa - x$ and $y+1 - 2\kappa + x$ in the denominator of the last term in our main formula cannot become arbitrarily small, and the last term is indeed $O(1/n)$.

In Section 5, we will need the following result (to make it possible to apply exponential sum techniques in the way described in subsection 1.4).

**Lemma 7.** The function $d^2\Phi(\ell, m-k; n-k)/dk^2$ is algebraic. For any fixed $n$, $\ell$, and $m$ satisfying $|\ell| + |m| < n$ and $\varepsilon > 0$, there exists a neighborhood $U$ in $\mathbb{C}$ of the smallest real interval containing $S_\varepsilon$ such that as a function of $k$, $d^2\Phi(\ell, m-k; n-k)/dk^2$ is holomorphic on $U$.

**Proof.** We will use the formula for $d\Phi(\ell, m-k; n-k)/dk$ from Lemma 6. Let $U$ be a small, simply-connected neighborhood in $\mathbb{C}$ of the smallest real interval containing $S_\varepsilon$, such that the points $k = n(y+1 \pm x)/2$ are not in $U$. (We checked at the end of the proof of Lemma 6 that these points are not in $S_\varepsilon$.) It follows from the definition of $S_\varepsilon$ that

$$(n-k)^2 - 2(\ell^2 + (m-k)^2) \geq \varepsilon(n-k)^2 \geq 0$$

and straightforward.
on $S_\varepsilon$. If $n = k$, then $\ell = 0$ and $m = k = n$, so $|\ell| + |m| = n$ (contradicting $|\ell| + |m| < n$). Thus, $(n - k)^2 - 2(\ell^2 + (m - k)^2) \geq \varepsilon$ on $S_\varepsilon$, and hence there is a holomorphic square root of $(n - k)^2 - 2(\ell^2 + (m - k)^2)$ on $U$, if $U$ was chosen to be sufficiently small. It follows that the third term (the algebraic term) of the formula for $d\Phi(\ell, m - k; n - k)/dk$ in Lemma 5 is holomorphic on $U$. The derivative of that term is thus algebraic and holomorphic on $U$, so to complete the proof we just need to check this for the other two terms.

The first two terms can be expressed in terms of the arcticcircle. If we do so, we find that the derivative with respect to $k$ of the sum of those two terms is

$$-3v^2 + 2y\kappa + 1 - 2\kappa - y^2$$

$$n(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)(y + 1 - 2\kappa - x)(y + 1 - 2\kappa + x).$$

This is also algebraic and holomorphic on $U$. Thus, $d^2\Phi(\ell, m - k; n - k)/dk^2$ is holomorphic on $U$ and algebraic, as desired.

We now know everything we need to know about how the creation rates behave inside the arctic circle. Outside the arctic circle, we can get an exponentially small upper bound for the creation rates. This will be used for bounding the placement probabilities outside the arctic circle (Proposition 13).

**Proposition 8.** For each $\varepsilon > 0$, there exists a positive constant $r < 1$ such that whenever $\ell^2 + m^2 > (1 + \varepsilon)n^2/2$,

$$Cr(\ell, m; n + 1) = O(r^n).$$

**Proof.** We assume that $\ell + m \equiv n \pmod{2}$, since otherwise $Cr(\ell, m; n + 1) = 0$. As in the proof of Proposition 4, we will integrate $f(z)/(2\pi i z)$ around a circle about the origin, where, as in [2.1],

$$f(z) = \frac{(1 + z)^{n-a}(1 - z)^b}{z^a b}.$$  

However, since we are looking only for an upper bound and not for an asymptotic estimate, we will not need the full saddle point method. We will only sketch the proof, because the details are straightforward but somewhat tedious to check.

We will use the same notation as in the proof of Proposition 4, for example, we write $a = (1 + u)n/2$ and $b = (1 + v)n/2$. Since $u^2 + v^2 > 1 + \varepsilon$, the critical points

$$z_1 = \frac{-v + \sqrt{u^2 + v^2 - 1}}{1 - u}$$

and

$$z_2 = \frac{-v - \sqrt{u^2 + v^2 - 1}}{1 - u}$$

of $f(z)$ are real. (Of course, the case $u = 1$ has to be handled separately, but this will not cause problems.) We will integrate $f(z)/(2\pi i z)$ around a circle of radius $R$, where $R$ will be either $|z_1|$ or $|z_2|$. We choose $R = |z_i|$ where $|f(z_i)|$ is the lesser of $|f(z_1)|$ and $|f(z_2)|$. To bound the integral, we will use the fact that the absolute value of the integral is at most as large as the greatest value of $|f(z)|$ on the circle.

It is not hard to check by straightforward manipulation of inequalities that $|f(z_1)| > |f(z_2)|$ if $uv > 0$, and $|f(z_1)| < |f(z_2)|$ if $uv < 0$. (Since $|u|, |v| \leq 1$ and $u^2 + v^2 > 1 + \varepsilon$, we cannot have $uv = 0$.) Thus, $R = |z_2|$ if $uv > 0$, and $R = |z_1|$ otherwise.
Take $i \in \{1, 2\}$ so that $R = |z_i|$. On the circle of radius $R$ about 0, $|f(z)|$ is greatest when $z = z_i$; in fact, the second derivative test shows that this is the only local maximum. Thus, the integral is bounded by $|f(z_i)|$, so $|c(a, b; n)| \leq |f(z_i)|$.

Because the sign of $uv$ doesn’t change when $u$ and $v$ are interchanged, $|\hat{f}(z_i)|$ is the lesser of $|\hat{f}(z_1)|$ and $|\hat{f}(z_2)|$. Hence, $|c(b, a; n)| \leq |\hat{f}(z_i)|$. It follows that

$$
\text{Cr}(\ell, m; n + 1) \leq \frac{|f(z_i)||\hat{f}(z_i)|}{2\pi}.
$$

A simple calculation gives $|f(z_1)||\hat{f}(z_2)| = |f(z_2)||\hat{f}(z_1)| = 2^n$. The inequalities $|f(z_i)| < |f(z_{3-i})|$ and $|\hat{f}(z_i)| < |\hat{f}(z_{3-i})|$, together with the fact that the only dependence on $n$ in any of these expressions is in the exponent, imply that the creation rate at $(u, v)$ is $O(r^n)$ for some $r < 1$. A little more care in the estimates shows that this bound can be chosen uniformly for $u^2 + v^2 > 1 + \varepsilon$, as desired.

3. Placement Probability Estimates

Now that we know the creation rates, we can determine the placement probabilities. Fix $\delta > 0$. In this section, we will look at the placement probabilities $P(\ell, m; n + 1)$ at points $(\ell, m)$ satisfying $\ell + m \equiv n \pmod{2}$ and $|\ell| + |m| \leq (1 - \delta)n$. (The congruence condition rules out the placement probabilities that we know are 0, and the inequality lets us apply results such as Lemmas 5–7.)

From (1.3), we see that

$$
P(\ell, m; n + 1) = \frac{1}{2} \sum_{k \geq 0} \text{Cr}(\ell, m - k; n + 1 - k).
$$

It will turn out that the creation rates on or beyond the arctic circle make a vanishing contribution to this sum as $n \to \infty$, so we can remove them from the sum without affecting its asymptotics. To remove these terms from the sum, fix $\varepsilon > 0$ (which we assume is small compared to $\delta$, so that we can apply results such as Lemma 7), and look at the sum

$$
\hat{P}_\varepsilon = \frac{1}{2} \sum_{k \in S_\varepsilon} \text{Cr}(\ell, m - k; n + 1 - k),
$$

where $S_\varepsilon$ is defined by (2.8). (Note that sometimes $S_\varepsilon = \emptyset$; we will see that this occurs only when the placement probability is nearly 0.) We will approximate $\hat{P}_\varepsilon$, and prove that it approximates $P(\ell, m; n + 1)$. First, we prove a few easy lemmas.

**Lemma 9.** Consider the equation $(1 - t)^2 - 2x^2 - 2(y - t)^2 = 0$. For $|x| + |y| < 1$, this equation has two real roots $t$. The greater root is 0 iff $x^2 + y^2 = 1/2$ and $y < 1/2$, and is less than 0 iff $x^2 + y^2 > 1/2$ and $y < 1/2$. The lesser root is greater than or equal to 0 iff $x^2 + y^2 \geq 1/2$ and $y > 1/2$.

**Proof.** Since the discriminant of the polynomial is $8(1-x-y)(1+x+y)$, we see that it has two real roots whenever $|x| + |y| < 1$. Clearly, 0 is a root iff $x^2 + y^2 = 1/2$, and since the sum of the roots is $4y - 2$, it is the greater root iff also $y < 1/2$. One can check the other claims similarly.

**Lemma 10.** Let $\delta > 0$, and suppose $|x| + |y| \leq 1 - \delta$. Let $\kappa(\varepsilon)$ be any branch of the multivalued function of $\varepsilon$ defined by $(1 - \varepsilon)(1 - \kappa)^2 - 2x^2 - 2(y - \kappa)^2 = 0$. Then
for \( \varepsilon > 0 \) (and sufficiently small relative to \( \delta \)), we have \( \kappa(\varepsilon) = \kappa(0) + O_\delta(\varepsilon) \). (The constant implicit in the \( O_\delta(\varepsilon) \) does not depend on \( x, y, \) or \( \varepsilon \).)

**Proof.** This simply amounts to showing that \( \kappa'(\varepsilon) \) is bounded as a function of \( x, y, \) and \( \varepsilon \), for \( \varepsilon \) sufficiently small. If one computes \( \kappa(\varepsilon) \) using the quadratic formula, and then differentiates it with respect to \( \varepsilon \), one finds that it equals a continuous function of \( x, y, \) and \( \varepsilon \) (for \( \varepsilon \) near 0) divided by

\[
\sqrt{(1 - \varepsilon)(y - 1)^2 - (1 + \varepsilon)x^2}.
\]

If \( \varepsilon \) is small enough compared to \( \delta \), then \( \kappa'(\varepsilon) \) will be continuous, and hence bounded, for all \( x, y, \) and \( \varepsilon \) with \(|x| + |y| \leq 1 - \delta \). Then \( \kappa(\varepsilon) = \kappa(0) + O(\varepsilon) \), as desired.

**Proposition 11.** Let \( \delta > 0 \) and \( \varepsilon > 0 \), such that \( \varepsilon \) is sufficiently small compared to \( \delta \). If \(|\ell| + |m| \leq (1 - \delta)n \) and \( \ell + m \equiv n \) (mod 2), then

\[
\tilde{P}_\varepsilon = P(\ell/n, m/n) + O_{\varepsilon, \delta}(n^{-1}) + O_\delta(\varepsilon^{1/2}).
\]

**Proof.** From formula (1.5) and Proposition 4, we see that \( \tilde{P}_\varepsilon \) and its complex conjugate. Proposition 16 will show that the latter two sums are bounded, for all \( x, y, \) and \( \varepsilon \) with \(|x| + |y| \leq 1 - \delta \). If one computes

\[
\sum_{S} (3.1)
\]

and its complex conjugate. Proposition 16 will show that the latter two sums are bounded, for all \( x, y, \) and \( \varepsilon \) with \(|x| + |y| \leq 1 - \delta \). Then \( \kappa(\varepsilon) = \kappa(0) + O(\varepsilon) \), as desired.

Assuming Proposition 16, we can prove the desired limit by approximating the sum (3.1) with an integral. The sum is equal to

\[
(3.2) \quad \frac{1}{2} \int_{k_{\min}}^{k_{\max}} \frac{2}{\pi \sqrt{(n-k)^2 - 2\ell^2 - 2(m-k)^2}} dk + O(n^{-1});
\]

to see that the error is \( O(n^{-1}) \), note that the summand (viewed as a function of a real variable \( k \)) is \( O(n^{-1}) \) by Lemma 3, and is monotonic on \( S_\varepsilon \cap (-\infty, 2m - n) \) and \( S_\varepsilon \cap (2m - n, \infty) \).

By Lemma 3, the polynomial \((n-t)^2 - 2\ell^2 - 2(m-t)^2\) has real roots \( t \). Let \( t_{\min} \) be the lesser root, and \( t_{\max} \) the greater root. Then \( S_\varepsilon \cap [0, t_{\max}] \) if \( t_{\max} \geq 0 \), and \( S_\varepsilon = \emptyset \) if \( t_{\max} < 0 \). By Lemma 3, we have \( t_{\max} = 0 \) if \( \ell^2 + m^2 = n^2/2 \) and \( m < n/2 \), and \( t_{\max} < 0 \) if \( \ell^2 + m^2 > n^2/2 \) and \( m < n/2 \). In both of these cases, we have \( P(\ell/n, m/n) = 0 \) and \( \tilde{P}_\varepsilon = O(n^{-1}) \). Thus, we need only deal with the case \( t_{\max} > 0 \).
Suppose $t_{\text{max}} > 0$ and $t_{\text{min}} < 0$, i.e., $t^2 + m^2 < n^2/2$. It follows from Lemma 11 that $k_{\text{min}} = O(n\varepsilon)$, and $k_{\text{max}} = t_{\text{max}} + O(n\varepsilon)$. We will approximate the integral in \((3.2)\) by
\[
\frac{1}{2} \int_0^{t_{\text{max}}} \frac{2}{\pi \sqrt{(n-k)^2 - 2t^2 - 2(m-k)^2}} dk.
\]
This approximation introduces further error. To see how large the error is, first rescale by a factor of $n$, so that the function under the square root sign becomes $(1 - \kappa)^2 - 2x^2 - 2(y - \kappa)^2$. Around a root $r$, this function can be expanded as $-(\kappa - r)^2 \pm 2\sqrt{2}\sqrt{(y - 1)^2 - x^2}(\kappa - r)$ (with the sign depending on which root $r$ is). Because $|x| + |y| \leq 1 - \delta$, the coefficient of $\kappa - r$ cannot become arbitrarily small. Thus, for small $\varepsilon$, the error introduced by the approximation is bounded by a constant (depending on $\delta$) times
\[
\int_0^\varepsilon \frac{d\varepsilon'}{\sqrt{\varepsilon'}}
\]
and hence by $O(\varepsilon^{1/2})$.

One can evaluate the integral \((3.3)\) explicitly, because
\[
\int \frac{dk}{\sqrt{(n-k)^2 - 2t^2 - 2(m-k)^2}} = \tan^{-1}\left(\frac{k + n - 2m}{\sqrt{(n-k)^2 - 2t^2 - 2(m-k)^2}}\right).
\]
As $k \to t_{\text{max}}$, the right hand side of \((3.4)\) approaches $\frac{\pi}{2}$ (since the numerator of the fraction is positive as its denominator approaches 0). We see that \((3.3)\) evaluates to
\[
\frac{1}{2} + \frac{1}{\pi} \tan^{-1}\left(\frac{2m - n}{\sqrt{n^2 - 2t^2 - 2m^2}}\right).
\]

The case with $t_{\text{min}} \geq 0$ (i.e., $t^2 + m^2 \geq n^2/2$ and $m > n/2$) is completely analogous, except the integral is over the interval $[t_{\text{min}}, t_{\text{max}}]$, rather than $[0, t_{\text{max}}]$. This integral is 1, so we get that $\tilde{P}_\varepsilon = 1 + O(n^{-1}) + O(\varepsilon^{1/2})$, which agrees with $P(\ell/n, m/n) = 1$. This proves the desired result.

We still need to prove that $\tilde{P}_\varepsilon$ approximates $P(\ell, m; n+1)$. We do that as follows:

**Theorem 12.** Let $\delta > 0$ and $\varepsilon > 0$, such that $\varepsilon$ is sufficiently small compared to $\delta$. If $|\ell| + |m| \leq (1 - \delta)n$ and $\ell + m \equiv n \pmod{2}$, then
\[
P(\ell, m; n+1) = P(\ell/n, m/n) + O_\delta(\varepsilon^{1/2}) + O_{\varepsilon, \delta}(n^{-1}).
\]

**Proof.** We need to show that $\tilde{P}_\varepsilon$ approximates $P(\ell, m; n+1)$. Since Proposition 4 implies that the creation rates are all non-negative, and $\tilde{P}_\varepsilon$ is the sum of a subset of the creation rates appearing in the sum giving $P(\ell, m; n+1)$, the placement probability must be at least $\tilde{P}_\varepsilon$.

Also, given any point in the Aztec diamond, the north-going placement probabilities at the four points obtained by rotating it by multiples of 90° about the origin sum to 1. This is true because by rotational symmetry these placement probabilities are equal to the placement probabilities in each of the four directions at the original point, which must sum to 1. This is the content of \((1.2)\), except here it is expressed in terms of the placement probabilities, rather than the asymptotic formula.

One can check by direct computation that $P(x, y) + P(y, -x) + P(-x, -y) + P(-y, x) = 1$. If the difference between $\tilde{P}_\varepsilon$ and the placement probability were not
$O(\varepsilon^{1/2}) + O(n^{-1})$, then the four placement probabilities would have to sum to more than 1, which is impossible.

The statement of Theorem 12 implies that away from the edges of the diamond, the placement probabilities converge uniformly. (Given any $\varepsilon > 0$, the theorem implies that if $n$ is sufficiently large, then the placement probabilities are within a constant multiple of $\varepsilon^{1/2}$ of their limiting values. In fact, the slightly awkward theorem statement is equivalent to asserting uniform convergence; we state it that way because it seems to be the form in which it is most naturally proved, given our setup.) Thus, assuming Proposition 16, we have very nearly proved Theorem 1. In Section 5, we will complete the proof, using the following proposition:

**Proposition 13.** For each $\varepsilon > 0$, there exists a positive constant $r < 1$ such that whenever $\ell^2 + m^2 > (1 + \varepsilon)n^2/2$,

$$P(\ell, m; n + 1) = \begin{cases} O(r^n) & \text{if } m < n/2, \\ 1 + O(r^n) & \text{if } m > n/2. \end{cases}$$

**Proof.** First suppose that $m < n/2$. The desired result will follow from the equation

$$P(\ell, m; n + 1) = \frac{1}{2} \sum_{k \geq 0} C(\ell, m - k; n + 1 - k),$$

(3.5)

together with the estimate given by Proposition 8. First, we show that Proposition 8 applies to the creation rates appearing in the sum. Consider

$$\frac{\ell^2 + (m - k)^2}{(n - k)^2},$$

(3.6)

as a function of $k$. Its first derivative at 0 is

$$2 \frac{\ell^2 + m^2 - mn}{n^3},$$

which is greater than 0 since $\ell^2 + m^2 > n^2/2 > mn$. The only root of the derivative is

$$\frac{\ell^2 + m^2 - mn}{m - n} < 0.$$ 

Thus, the function (3.6) is increasing for $0 \leq k < n$. (Note that in (3.3) we need only sum up to $k = (m + n)/2$, since beyond that point $m - k < -(n - k)$ and hence $C(\ell, m - k; n + 1 - k) = 0$. Thus, $k$ never reaches the pole in (3.6) at $n$.) Therefore, $\ell^2 + (m - k)^2 > (1 + \varepsilon)(n - k)^2/2$, and Proposition 8 applies to bound the creation rates in (3.3).

Thus, for some constant $s$ between 0 and 1,

$$P(\ell, m; n + 1) \leq \sum_{k=0}^{(m+n)/2} O(s^{n-k}).$$

This geometric series is bounded by $O(s^{(n-m)/2}) = O(s^{n/4})$. This proves the desired bound, with $r = s^{1/4}$.

For $m > n/2$, we use the trick of summing the placement probabilities at the four points obtained by rotating by multiples of 90° about the origin. As in the proof of Theorem 12, the sum must be 1, and we know that three of the terms are $O(r^n)$. Therefore, the fourth must be $1 + O(r^n)$, as desired. □
4. Exponential Sums

In the proof of Proposition 11, we needed to show that \( \tilde{P}_ε \) is within \( O(n^{-1}) \) of the sum \( \tilde{P}_0 \); to do so, we made use of an estimate whose proof was deferred (Proposition 10). In this section, we will derive that estimate. We begin with the following lemma.

**Lemma 14.** Let \( F(x_1, \ldots, x_{n+1}) \) be an algebraic function of \( n+1 \) variables (defined on a subset of \( \mathbb{C}^{n+1} \) to be specified shortly), and let \( S \) be a subset of \( \mathbb{C}^n \). Suppose that for each \( (y_1, \ldots, y_n) \in S \), there exists an open set \( U \subset \mathbb{C} \) such that as a function of \( x_{n+1} \), \( F(y_1, \ldots, y_n, x_{n+1}) \) is (defined and) holomorphic on \( U \). Then there is a constant \( N \) such that for any \( (y_1, \ldots, y_n) \in S \), if we regard \( F(y_1, \ldots, y_n, x_{n+1}) \) as a function of \( x_{n+1} \) on the corresponding \( U \), then it has at most \( N \) roots in \( U \) if it is not identically zero.

**Proof.** Since \( F(x_1, \ldots, x_{n+1}) \) is algebraic, it satisfies an equation

\[
\sum_{i=0}^{d} p_i(x_1, \ldots, x_{n+1})X^i = 0,
\]

with \( p_0, \ldots, p_d \) polynomials (not all identically zero). Let \( N = \max_i \deg p_i \). We will show that \( N \) has the desired property, using induction on \( n \).

We can choose the coefficients \( p_i \) so that they have no (non-constant) common factor. Fix \( y_1 \in \mathbb{C} \), and let \( S' = \{(y_2, \ldots, y_n) \in \mathbb{C}^{n-1}: (y_1, \ldots, y_n) \in S\} \). Define \( G(x_2, \ldots, x_{n+1}) = F(y_1, x_2, \ldots, x_{n+1}) \). Since the coefficients were taken to have no common factor, they do not all vanish when we set \( x_1 = y_1 \). Their degrees do not increase when we set \( x_1 = y_1 \) (or when we remove common factors), so our lemma follows by induction on \( n \) (applied to \( G \) and \( S' \)), assuming we can prove it in the case \( n = 0 \).

Suppose \( n = 0 \). Assuming \( F \) is not identically zero, we can divide \( F \) by some power of \( X \) to get an equation satisfied by \( F \) with non-zero constant term, say \( p_h(x_1) \). (A priori, \( F \) will satisfy the new equation only where \( F \) is non-zero. However, since \( F \) is holomorphic on \( U \), its zeros are isolated. By continuity, it satisfies the equation at its zeros as well as elsewhere.) Then any root of \( F \) is a root of \( p_h \), so \( F \) has at most \( \deg p_h \) roots, and hence at most \( N \) roots. \( \square \)

**Lemma 15.** The exponential sums

\[
\sum_{k \in I} \exp(2i \Phi(\ell, m - k; n - k))
\]

remain bounded (uniformly in \( I \)) as \( n \) goes to infinity, where \( I \) can be any subinterval of \( S_ε \), as long as \( |\ell| + |m| \leq (1 - \delta)n \) for some fixed \( \delta > 0 \), and \( ε \) is small enough compared to \( \delta \).

**Proof.** To prove this, we will apply the Kusmin-Landau Theorem (Theorem 3). Lemma 3 says that \( d^2 \Phi(\ell, m - k; n - k)/dk^2 \) satisfies the conditions of Lemma 14, so there is an absolute upper bound for the number of roots that it can have as a function of \( k \) while \( n, \ell, \) and \( m \) are held fixed (unless it is identically zero for those values of \( n, \ell, \) and \( m \)). Before we apply the Kusmin-Landau Theorem, we break \( S_ε \) up into a bounded number of subintervals on which \( d\Phi(\ell, m - k; n - k)/dk \) is monotonic.
We have to look at the behavior of \( d \Phi(\ell, m - k; n - k)/dk \). As in Lemma 6, set \( k = \kappa n \), \( \ell = x n \), and \( m = y n \). Lemma 6 says that as \( n \) goes to infinity, 
\[
d \Phi(\ell, m - k; n - k)/dk = \theta \left( -x + y - \kappa, \sqrt{(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)} \right) - \theta \left( 1 - \kappa - 2x, \sqrt{(1 - \kappa)^2 - 2(x^2 + (y - \kappa)^2)} \right) + O \left( \frac{1}{n} \right).
\]

(4.2)

We would like to show that when divided by \( \pi \), (4.2) stays away from integers.

After (4.2) is divided by \( \pi \), the only possible integral values it can take on are 0, \( \pm 1 \), and \( \pm 2 \) (assuming \( n \) is large enough). If we ignore the \( O(1/n) \) term, the rest of the formula is the difference of the arguments of two points on the same horizontal line (divided by \( \pi \)). Thus, it cannot be \( \pm 2 \). It can be 0 only if the points coincide or are on the horizontal axis. It can be \( \pm 1 \) only if the points are on the horizontal axis.

The points coincide iff \( x + y = 1 \), which is impossible (since \( |\ell| + |m| \leq (1 - \delta)n \)).

They are on the horizontal axis iff
\[
x^2 + (y - \kappa)^2 = (1 - \kappa)^2/2.
\]

(4.3)

The definition (2.8) of \( S_{e} \) implies that
\[
x^2 + (y - \kappa)^2 \leq (1 - \varepsilon)(1 - \kappa)^2/2,
\]

so no \( k \in S_{e} \) gives a \( \kappa \) satisfying (4.3). (Note that \( \kappa = 1 \) is impossible since then \( |x| + |y| = |0| + |1| > 1 - \delta \)).

In fact, the above argument, combined with continuity considerations, shows that the two points cannot get arbitrarily close to each other or the horizontal axis, and they clearly cannot get arbitrarily far from the origin. Thus, even taking into account the \( O(1/n) \) term, \( (d \Phi(\ell, m - k; n - k)/dk)/\pi \) really does stay slightly away from integers as \( n \to \infty \). Hence, the Kusmin-Landau Theorem tells us that the exponential sums are bounded (uniformly in \( I \)).

**Proposition 16.** The sum
\[
\sum_{k \in S_{e}} \frac{1}{\pi \sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}} \exp(2i \Phi(\ell, m - k; n - k))
\]
is \( O(n^{-1}) \) as \( n \) goes to infinity, as long as \( |\ell| + |m| \leq (1 - \delta)n \) for some fixed \( \delta > 0 \), and \( \varepsilon \) is small enough compared to \( \delta \).

**Proof.** Let
\[
a(k) = \frac{1}{\pi \sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}}
\]
and
\[
b(k) = \sum_{k' = k_{\text{min}}}^{k - 1} \exp(2i \Phi(\ell, m - k'; n - k')).
\]

For \( k \in S_{e} \), \( a(k) = O(n^{-1}) \) (by Lemma 6) and \( b(k) \) is bounded (by Lemma 15). Suppose \( |b(k)| \leq B \) for all \( k \in S_{e} \).
To bound the sum in the statement of the proposition, we will apply summation by parts. We have
\[
\sum_{k \in S_x} \frac{\exp(2i \Phi(\ell, m - k; n - k))}{\pi \sqrt{(n - k)^2 - 2\ell^2 - 2(m - k)^2}} = \sum_{k \in S_x} a(k)(b(k + 1) - b(k))
\]
\[
= \sum_{k \in S_x} a(k)(b(k + 1) - b(k))
\]
\[
= \sum_{k=\min+k_{\max}+1} a(k-1)b(k) - \sum_{k=\min+k_{\max}+1} a(k)b(k)
\]
\[
= \sum_{k=\min+k_{\max}+1} b(k)(a(k-1) - a(k)) + O(n^{-1}).
\]

This sum is bounded in absolute value by \( B \sum_k |a(k-1) - a(k)| + O(n^{-1}) \). The function \( a(k) \) is monotonic on \((-\infty, 2m - n)\) and \((2m - n, \infty)\) (on the subintervals where it is real, of course), so within each of these intervals, the sum \( \sum_k |a(k-1) - a(k)| \) telescopes. The boundary terms are \( O(n^{-1}) \), and hence the entire sum is \( O(n^{-1}) \).

5. Conclusion of the Proof

The results proved in the preceding three sections give us Theorem 12, a weakened version of Theorem 1 in which we are restricted to estimating the placement probabilities at normalized locations \((x, y)\) with \(|x| + |y| < 1 - \delta\), for some fixed \( \delta > 0 \). That is, we are required to keep \((x, y)\) from getting too close to the boundary of the diamond. Here we will show how the restriction on \((x, y)\) can be relaxed, provided that we are careful to stay away from the points \((\pm \frac{1}{2}, \frac{1}{2})\).

Fix \( \delta > 0 \), and consider the region in the Aztec diamond of order \( n \) defined (relative to normalized coordinates) by the constraint \( x^2 + y^2 > \frac{1}{2} + \delta \). This region splits up into four pieces. Proposition 13 tells us that the north-going placement probabilities tend uniformly to 1 in the northern piece and to 0 in the other three pieces. The only regions that are not covered by this method are four small curvilinear trapezoids near the points \((\pm \frac{1}{2}, \pm \frac{1}{2})\), defined by the inequalities \( x^2 + y^2 < \frac{1}{2} + \delta \) and \( 1 - \delta < |x| + |y| < 1 \). If \((x, y)\) stays away from these four points as \( n \) goes to infinity, then we can indeed conclude that the placement probabilities for north-going dominoes at location \((x, y)\) are as claimed in Theorem 1. This completes the proof of the main theorem, except near the points \((\pm \frac{1}{2}, \frac{1}{2})\), which we will now deal with.

Let \( R \) be the subregion of the Aztec diamond of order \( n \) consisting of the two lower of the four curvilinear trapezoids defined by \( x^2 + y^2 < \frac{1}{2} + \delta \) and \( 1 - \delta < |x| + |y| < 1 \). In \( R \), we use the inequality (14). It says that for \( h \geq 0 \),
\[
P(\ell, m; n) \leq P(\ell, m + h; n + h).
\]
If \( n \) is sufficiently large, then for each point \((\ell, m)\) in \( R \), there exists an \( h \) such that the point \((\ell, m + h)\) of the diamond of order \( n + h \) has normalized coordinates satisfying \( x^2 + y^2 < \frac{1}{2} + \delta \), \( 1 - 2\delta < |x| + |y| < 1 - \delta \), and \( y < 0 \). Let \( S \) be the set of all \((x, y)\) satisfying these three constraints. Inequality (14) tells us that the placement probabilities within \( R \) are at most as large as those within \( S \). However, the part of Theorem 1 that we have already proved gives estimates for the placement
probabilities in $S$, and shows that they tend uniformly to 0 as $\delta \to 0$. (To see the convergence to 0 most easily, look at the level curves of the placement probabilities.) We thus conclude that as $\delta \to 0$, the placement probabilities in $R$ tend uniformly to 0. This completes the proof of Theorem 1.

Unfortunately, our techniques do not give us an explicit bound for the difference between the placement probabilities and the arctangent formula in an Aztec diamond of a given order. This is not because the methods are inherently ineffective; rather, it is because we have not determined the dependence on $\varepsilon$ in the $O(n^{-1})$ term of the error bound in Theorem 12. To determine it, we would have to do so for the error term in Proposition 4, which seems more trouble than it would be worth (but could perhaps be done).

Using these techniques, we can also prove the arctic circle theorem of [JPS]. One direction, that the regions outside the inscribed circle are indeed frozen, follows from Proposition 4. To see this, consider the region $R$ defined (relative to normalized coordinates) by $x^2 + y^2 > \frac{1}{\varepsilon} + \varepsilon$, with $\varepsilon > 0$. The number of domino spaces in this region of an Aztec diamond of order $n$ is less than $n^2$, so the probability that a non-north-going domino will appear in the subregion with $y > \frac{1}{\varepsilon}$, or that a north-going domino will appear in the rest of $R$, is exponentially small, by Proposition 13. From this, we see that with probability approaching 1 (as $n$ goes to infinity), all the dominos in $R$ will be aligned in brickwork patterns, and thus contained in the polar regions. This is half of the arctic circle theorem.

The other direction, that the polar regions almost never extend substantially into the interior of the inscribed circle, requires an additional result for its proof. Intuitively, it follows from our main theorem, which tells us that inside the inscribed circle all four types of placement probabilities are positive. This trivially implies that the polar regions cannot almost always cover a given part of the interior of the circle, but showing that they almost never do is harder. We will prove it in subsection 6.4.

6. Consequences of the Theorem

6.1. Height functions. Height functions for domino tilings, which were introduced in the mathematics literature in [T] (and independently in a slightly different form in the physics literature in [L]), are a very useful device in the study of tilings of simply-connected subsets of the plane. (A more general approach to height functions can be found in [STCR].) In any such region that can be tiled by dominos, the number of enclosed white squares and the number of enclosed black squares under an alternating coloring of the squares must clearly be equal. It follows that if one travels around the boundary of the region counterclockwise, then one will see a black square on one’s left half the time and a white square on one’s left half the time; to see why, notice that the edges of the square grid that lie within the region pair sides of black squares with sides of white squares, so the excess of unpaired (i.e., boundary) sides of black squares over unpaired sides of white squares is four times the excess of black squares over white squares. As one travels around the boundary, any temporary excess of one kind of square over the other that is observed along the way represents a “debt” that will eventually have to be paid. Moreover, the same is true simultaneously for all the boundaries of all the simply-connected regions that are formed by suitable subsets of the tiles in question. Height functions provide a uniform framework for keeping track of all these debts simultaneously.
If $R$ denotes a finite, simply-connected region composed of lattice squares that have been alternately colored black and white, a **height function** on $R$ is an integer-valued function $h$ on the vertices of the lattice squares which satisfies the following two properties for adjacent vertices $u$ and $v$: first, if the edge from $u$ to $v$ is part of the boundary of $R$, then $|h(u) - h(v)| = 1$, and second, if the edge from $u$ to $v$ has a black square on its left, then $h(v)$ is either $h(u) + 1$ or $h(u) - 3$. It is not hard to show that such a function necessarily satisfies a discrete Lipschitz condition: if vertices $u$ and $v$ are at distance $d$ from each other in the sup-norm, then $|h(u) - h(v)| \leq 2d + 1$. Note also that if $h(\cdot)$ is a height function, then so is $h(\cdot) + C$ for any integer $C$.

Every height function on $R$ determines a domino tiling of $R$, consisting of dominoes that occupy all the domino spaces that are bisected by edges $uv$ with the property that $|h(u) - h(v)| = 3$. Conversely, every domino tiling of $R$ arises in this way from a height function on $R$ that is unique modulo addition of a global constant. We can remove this ambiguity by constraining a particular vertex on the boundary of $R$ to have some particular integer value as its height; then every domino tiling of $R$ has a unique height function subject to this constraint, and what is more, all these height functions agree with one another on the boundary of $R$. For instance, in the case of the Aztec diamond of order $n$, we set things up so that the middle vertex on the west edge of the diamond has height $0$ and the middle vertex on the northern edge has height $2n$. (Note that this differs by $1$ from the height function convention used in [EKLP].) Then the heights for a typical domino tiling of an Aztec diamond are as shown in Figure 3. (The shading convention for the lattice squares is the same as that in Section 1, i.e., so that the leftmost square of each row in the top half of the diamond is white.)

One can also develop an analogous theory of height functions for other sorts of tilings, for example, tilings of regions in the triangular lattice by lozenges (two unit equilateral triangles joined along an edge). This theory is simpler geometrically than that for domino tilings; for the details, see [1]. (See also [BH] for an independent, earlier development of height functions for this lattice in physics.) Height functions can furthermore be applied to the square ice model studied by Lieb, as is shown in [vB]. The results of subsections 6.2 and 6.3 generalize straightforwardly to other
sorts of height functions. However, because the focus of this article is on domino tilings, we will not go into the details of the generalization.

Suppose \( u, v, \) and \( w \) are three consecutive vertices along a path in a simply-connected region \( R \) that is tiled by dominos, such that neither the edge \( uv \) nor the edge \( vw \) bisects a domino. Then \( |h(u) - h(v)| = |h(v) - h(w)| = 1 \), with \( h(w) = h(u) \) if the three points are collinear and \( h(w) = h(u) \pm 2 \) if they are not. This principle makes it fairly easy to go through the tiling, assigning heights to the vertices. Alternatively, one can use this method just to find the heights along the boundary, and then find the heights in the interior by the following procedure. To determine the height of a particular vertex in the interior of a tiled region, start at the point on the boundary of the region due north of the vertex (whose height is independent of the tiling) and proceed downward, subject to the following rule: when one travels southward along an edge that bisects a north-going (resp. south-going) domino space, the height decreases (resp. increases) by 3, whereas, when one travels southward along an edge that bisects a north-going (resp. south-going) domino space that is not occupied by a domino in the tiling, the height increases (resp. decreases) by 1. A similar rule can be formulated for describing how the height changes as one travels horizontally through the interior of the diamond. The fact that these rules are consistent with each other is a consequence of the fact that any region that can be tiled by dominos must contain exactly equal numbers of black and white squares.

If we take the average of all the (finitely many) height functions associated with the different tilings of a region, we get a real-valued function on the vertices called the average height function. As a consequence of the rule described in the preceding paragraph, one can give a simple description of how the average height changes from vertex to vertex, in terms of the placement probability \( p \) associated with the domino space that is bisected by the edge that connects the two vertices. For instance, if \( u \) and \( v \) are neighbors, with \( u \) to the north or west of \( v \), then the average height at \( v \) is equal to the average height at \( u \) plus \( 4p - 1 \) if edge \( uv \) bisects a south-going or west-going domino space, while the average height at \( v \) is equal to the average height at \( u \) minus \( 4p - 1 \) if edge \( uv \) bisects a north-going or east-going domino space.

Here we are interested in the asymptotic behavior of the average height function for domino tilings of the Aztec diamond. The arctangent formula tells us that these probabilities \( p \) are slowly varying, so the average height function is locally approximated by functions of the form \( ax + by + c \) (with \( a, b, \) and \( c \) slowly varying). We call the pair \( (a, b) \) the tilt of the plane \( z = ax + by + c \). Let us normalize our height functions by dividing through by \( n \), both in the domain and in the range. Thus, in the limit we expect to see some sort of function \( H(\cdot, \cdot) \) on \( \{(x, y) : |x| + |y| \leq 1\} \) satisfying the piecewise-linear boundary condition \( H(x, y) = 1 - x^2 + y^2 \) for \( |x| + |y| = 1 \), as well as a Lipschitz condition with constant 2 relative to the sup-norm distance. In addition, the formulation in the previous paragraph of how the average height changes when moving between vertices tells us that we should have \( \frac{\partial H}{\partial y} = 2(p_n - p_s) \) and \( \frac{\partial^2 H}{\partial x^2} = 2(p_s - p_e) \), where \( p_n, p_s, p_e, \) and \( p_w \) are the north-going, south-going, east-going, and west-going placement probabilities at \( (x, y) \), respectively.

It can be shown (although we do not prove this here) that the domino shuffling algorithm of \( \text{EKLP} \) can be interpreted directly in terms of height functions, and that half of the values of the average height function for the diamond of order \( n + 1 \)
are equal to certain corresponding values of the average height function for the
diamond of order \(n\). Hence the average height functions for the Aztec diamonds of
orders \(n\) and \(n + 1\) cannot be too far apart. However, such considerations are not
sufficient to yield a proof that the normalized average height functions converge to
a continuum limit.

The arctangent formula gives us the strength we need in order to conclude that
a limit exists. Recall that the average height function can be derived by taking
cumulative sums and differences of local placement probabilities, with various co-
efficients. Taking this assertion to the limit as \(n \to \infty\), and using the fact that the
placement probabilities approach a continuum limit, we see that the normalized
average height function also approaches a limit. (It is true that the errors in the
placement probabilities are going to add, and that there are more and more of them
as \(n\) gets large, but each individual error is going to be small, so that when we divide
by \(n\) the normalized error is small as well.) The limit must be some function \(H(x, y)\)
(defined for \(|x| + |y| \leq 1\)) with the property that \(\frac{\partial H}{\partial x} = 2P(y, -x) - 2P(-y, x)\)
and \(\frac{\partial H}{\partial y} = 2P(x, y) - 2P(-x, -y)\) for all \((x, y)\) in the interior of its domain. (Here,
we have expressed the placement probabilities near \((x, y)\) for all four domino ori-
etations in terms of \(P\) via rotational symmetry.) That is, the tilt of the tangent
plane at a point (associated with the average height function) can be expressed in
terms of the local placement probabilities for random domino tilings. This means
that we ought to be able to reconstruct the function \(H(\cdot, \cdot)\) from Theorem 1 via
integration, making use of the known boundary conditions satisfied by \(H\). If we do
this, it turns out that \(H\) can be written in closed form, and indeed, a formula for
\(H\) can be written especially compactly if one makes use of the formula for \(P(\cdot, \cdot)\)
itself. Specifically, one can verify that the following formula for \(H(\cdot, \cdot)\) holds:

**Proposition 17.** The normalized average height functions for large Aztec dia-
monds converge uniformly to

\[
H(x, y) = 2 \left( yP(x, y) - yP(-x, -y) + (1 - x)P(-y, x) + (1 + x)P(y, -x) \right).
\]

**Proof.** We simply check that this formula satisfies the differential equations and
boundary conditions. \(\square\)

Within the temperate zone, the average height function is real analytic; in each
of the polar regions, it is an affine function of \(x\) and \(y\). On the arctic circle itself,
avay from the points \((\pm \frac{1}{2}, \pm \frac{1}{2})\), the function \(H(x, y)\) is differentiable but not twice-
differentiable. It takes the value 2 at the points \((0, \pm 1)\) and the value 0 at the
points \((\pm 1, 0)\), with piecewise-linear behavior on the boundary of the normalized
diamond. The level set \(H = 1\) consists of the two line segments joining midpoints
of opposite sides of the normalized diamond.

One may ask, for diamonds of finite order \(n\), how closely the distribution on
height functions is clustered around its mean value. We will see in the next sub-
section that the standard deviation of the height at any fixed location in the Aztec
diamond of order \(n\) is at most \(8\sqrt{n}\). However, numerical evidence suggests that, at
the center of the diamond, the standard deviation of the height is much smaller—
more like \(\log n\), or perhaps even less than that.
Our formulas for \( \frac{\partial^2 H}{\partial x^2} \) and \( \frac{\partial^2 H}{\partial y^2} \), in combination with the arctangent formula, yield (within the temperate zone) the equation
\[
\frac{\partial^2 H}{\partial y^2} - \frac{\partial^2 H}{\partial x^2} = \frac{8}{\pi \sqrt{1 - 2x^2 - 2y^2}}.
\]
We can rewrite this equation in a slightly more illuminating way. For \( t > 0 \) and \( |x| + |y| \leq t \), define
\[
H(x, y, t) = tH(x/t, y/t).
\]
That is, we undo the scaling introduced in Section 1. Then off the arctic circle we have
\[
\frac{\partial^2 H}{\partial y^2} - \frac{\partial^2 H}{\partial x^2} = 8u(x, y, t),
\]
where
\[
u(x, y, t) = \begin{cases} 
\frac{1}{\pi \sqrt{t^2 - 2x^2 - 2y^2}} & \text{if } x^2 + y^2 < t^2/2, \text{ and} \\
0 & \text{if } x^2 + y^2 \geq t^2/2.
\end{cases}
\]
This function is a fundamental solution to the wave equation in two dimensions, with speed of propagation \( 1/\sqrt{2} \). That is, \( u \) is a distribution satisfying
\[
\frac{\partial^2 u}{\partial t^2} = \frac{1}{2} \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right),
\]
\[u(x, y, 0) = 0\]
and
\[\frac{\partial u}{\partial t}(x, y, 0) = \delta(x, y),\]
where \( \delta \) is the (two-dimensional) Dirac delta function. (For more details on fundamental solutions to the wave equation, see [R, p. 164].)

Note that Proposition 4 shows that, except for an oscillating factor, the creation rates also behave like \( 2u \). William Jockusch has shown in personal communication how to use a generating function developed in [GIP] to explain this behavior, by viewing the creation rates as numerical approximations to a solution of the wave equation.

He has also pointed out that from his methods, one ought to be able to deduce a weak version of Theorem 1. More specifically, one should be able to show that in any macroscopic subregion of a randomly tiled Aztec diamond of order \( n \) (i.e., any subregion of size comparable to that of the diamond), the expected density of north-going dominos is within \( o(1) \) of that predicted by integrating the arctangent formula; in particular, this would suffice to prove Proposition 17. Unfortunately, his methods would not rule out the possibility of small-scale fluctuations in the placement probabilities, such as one gets if one looks at placement probabilities for all horizontal domino spaces rather than just the north-going ones.

### 6.2. Robustness.

The formula for the average height function that was derived in the preceding section from the arctangent formula applies not only to Aztec diamonds, but also to all regions that approximate them in a suitable sense. (Here, as hereafter, the term “region,” without qualifiers, should be understood to refer to finite regions in the plane that are unions of lattice squares and can be tiled with dominos.) It is not enough that the region being tiled should have a boundary that is roughly “Aztec” in shape. For instance, Figure 4 shows a random domino tiling of a region obtained from the Aztec diamond of order 32 by adding some squares.
along its boundary, while the region that is shown in Figure 5, also studied in [SZ], was obtained by adding an extra row of length 64 in the middle of the diamond. (These random tilings were obtained via the method described in [PW] and are indeed truly random, to the extent that pseudo-random number generators can be trusted.) In neither case do we get behavior consistent with the arctangent formula. On the other hand, Figure 6 shows a random tiling of an Aztec diamond to which two rows of length 64 have been added, and the resemblance to Figure 1 is evident.

The sense of mystery dissolves if one considers the behavior of the height function along the boundary in each of the three cases. In the first case, the height function is nearly constant along the boundary; in the second, the direction of change of the height function is the same along the southwest and northwest edges (and also the same along the southeast and northeast edges); and in the third, the direction of change of the height function switches as one rounds any of the four corners of the region. Since it is the third situation that resembles the boundary behavior of height functions of Aztec diamonds, it is not surprising that the third situation should also give behavior in the interior that is similar to what one sees for Aztec diamonds. (In fact, if we view the third region as an Aztec diamond of order 33 with two vertical dominos removed, then since almost all tilings of the Aztec diamond contain those two dominos, the local statistics in the third region differ little from those in the Aztec diamond of order 33.)

Note, incidentally, that if instead of adding a row of length 64, as we did in Figure 5, we removed a row of length 64, then the resulting region is easily seen to have a unique tiling, consisting entirely of horizontal brickwork. Although this situation may seem trivial, it can shed some light on what is happening in Figure 6.
The horizontal brickwork pattern seen almost everywhere in Figure 5 is the unique arrangement of dominos such that the height increases (or decreases, depending on whether the dominos in the pattern are north-going or south-going) as quickly as possible as one moves vertically. In an Aztec diamond with a row of length 64 removed, the heights on the boundary are such that the only way to span the gap between the heights on the lower half of the boundary and those on the upper half is to change at this rate. Thus, the only way to tile the region is with a brickwork pattern. In the case of Figure 5, the occurrence of an extra row of length 64 gives the height function a tiny bit of slack, and we can see where this slack gets used by following the fault-line that runs from left to right.

Of course, we could have predicted ahead of time that small modifications of the shape of the boundary can have a drastic impact on the tiling situation, since for instance adding a single square to a region (or removing a single square) can create a region with odd area, which cannot be tiled at all. Hence, we will want to assume that all the regions we discuss actually admit tilings by dominos, as stipulated in the first paragraph of this subsection.

We will show in this subsection that regions similar to Aztec diamonds, such as Figure 6, have approximately the same average height functions as the Aztec diamonds they resemble. This will follow as a consequence of a more general result, asserting that the value of the average height function depends in a continuous manner on the values of the fixed heights along the boundary. That is, if one modifies the shape of the boundary in such a way that the height function along the new boundary, when plotted in three dimensions (the two original dimensions
plus a third dimension for height), is close to the graph of the old, the average heights of vertices in the interior will not change very much.

Before we can do this, we first prove a general monotonicity result about height functions. The idea for this approach was suggested by Robin Pemantle in personal communication. Let $R$ denote a simply-connected region in the plane with some fixed checkerboard coloring, and let $V$ be the set of vertices in $R$. Let $V'$ be a subset of $V$ that contains all the vertices on the boundary of $R$; we will assume that $V'$ is connected, in the sense that the subgraph of the square grid induced by the vertex set $V'$ is connected. A partial height function is a function $f : V' \to \mathbb{Z}$ subject to the local constraint that if $u$ and $v$ are adjacent vertices such that the directed edge from $u$ to $v$ has a black square on its left, then $f(v) - f(u)$ is either 1 or $-3$. It is called complete height function if it is defined on all of $V$; a complete height function $\hat{f}$ extends a partial height function $f$ if it agrees with $f$ where $f$ is defined.

Throughout this subsection (and the next), $H$ will denote a complete height function chosen at random (according to some distribution); thus, for any vertex $v$, $\text{Exp}[H(v)]$ (the expected value of $H(v)$) is the value at $v$ of the average height function.

Given a connected subset $V'$ of $V$ that contains all the boundary vertices, and given a partial height function $f$ on $V'$, we let $\mu_f$ denote the uniform distribution on the set of complete height functions that extend $f$ to $V$.

**Lemma 18.** If $f$ and $g$ are two partial height functions defined on $V'$ and agreeing modulo 4, with $f \leq g$, then $\mu_f$ is stochastically dominated by $\mu_g$. That is, there
exists a probability measure $\pi$ on the set of pairs $(\hat{f}, \hat{g})$ of complete height functions extending $f$ and $g$ respectively, such that

$$\sum_{\hat{g}} \pi(\hat{f}, \hat{g}) = \mu_f(\hat{f}),$$

$$\sum_{\hat{f}} \pi(\hat{f}, \hat{g}) = \mu_g(\hat{g}),$$

and

$$\pi(\{ (\hat{f}, \hat{g}) : \hat{f} \leq \hat{g} \}) = 1.$$  

Proof. We use induction on the size of $V \setminus V'$ (holding $V$ fixed and varying $V'$). The case where this set is empty is trivial. Assume that the lemma is true whenever $|V \setminus V'| = k - 1$, and suppose we have a situation in which $|V \setminus V'| = k$. It clearly suffices to consider the case in which $f(v) < g(v)$ for some vertex $v$ in $V'$ that is adjacent to at least one vertex in $V \setminus V'$. Let $w$ be a vertex in $W = V \setminus V'$ adjacent to $v$.

Given that $f(v)$ has some specific value, any extension of $f$ to $V'' = V' \cup \{w\}$ would have to give $w$ height $h$ or $h - 4$ (for some particular $h$ whose value we don’t care about—it’s $f(v)$ plus or minus 1 or 3), while any extension of $g$ to $V''$ would have to give $w$ height $h'$ or $h' - 4$ (with $h'$ determined from $g(v)$ the same way $h$ is determined from $f(v)$). Because $f$ and $g$ agree modulo 4 on $V'$ and $h' > h$, we have $h' - 4 \geq h$.

Let $f'_1$ and $f'_2$ be the two extensions of $f$ to $V''$ that assign $w$ height $h$ and $h - 4$, respectively, and let $g'_1$ and $g'_2$ be the two extensions of $g$ to $V''$ that assign $w$ height $h'$ and $h' - 4$, respectively. (If such extensions do not exist, it is not a problem, as we will see below.) The distribution $\mu_f$ is a weighted superposition of $\mu_{f'_1}$ and $\mu_{f'_2}$, where the $i$th term $(i = 1$ or $2)$ is given weight proportional to the number of extensions of $f'_i$ to $V$ (which should be taken to be zero in the case where the extension to $V''$ does not exist). Similarly, $\mu_g$ is a superposition of $\mu_{g'_1}$ and $\mu_{g'_2}$. Since $f'_i \leq g'_j$ for all $i, j$ in $\{1, 2\}$, and $h \equiv h' \pmod{4}$, we can use our induction hypothesis to conclude that $\mu_{f'_i}$ is stochastically dominated by $\mu_{g'_j}$ for all $i, j$, which implies that $\mu_f$ is stochastically dominated by $\mu_g$, as was to be shown.

Corollary 19. If $f$ and $g$ are two partial height functions on $R$ defined on $V'$ and agreeing modulo 4, with $f \leq g + 4$, then for all $v$, Exp$[H(v)]$ under the measure $\mu_f$ is at most 4 more than Exp$[H(v)]$ under the measure $\mu_g$.

Proof. Apply Lemma 18 to the partial height functions $f$ and $g + 4$.

For applications of Lemma 18 and Corollary 19, it is important to note that the values of height functions on connected regions are determined modulo 4, given the value at any one point, because the defining conditions for a height function imply that if two height functions agree modulo 4 at any point, then they do so at each neighboring point. Also, given two partial height functions defined on different sets, we say that they agree modulo 4 if all height functions extending them agree modulo 4.

Proposition 20. Suppose that $R_1, R_2$ are two simply-connected regions in the plane, with mandated partial height functions $f_1, f_2$ along their boundaries that agree modulo 4, such that every vertex $v_1$ on the boundary of $R_1$ is within sup-norm distance $\Delta_1$ of some vertex $v_2$ on the boundary of $R_2$, and vice versa, and
such that whenever vertices \( v_1 \) and \( v_2 \) on the respective boundaries are within sup-norm distance \( \Delta_1 \) of each other, the heights \( f_1(v_1) \) and \( f_2(v_2) \) are within \( \Delta_2 \) of each other. Then, for any \( v \) in \( R_1 \cap R_2 \), the expected value of \( H(v) \) under \( \mu_f \) and the expected value of \( H(v) \) under \( \mu_f \) differ by at most \( 2\Delta_1 + \Delta_2 + 1 \).

Proof. Let \( f_{1,\text{max}} \) be the highest extension of \( f_1 \) to \( R_1 \), let \( f_{1,\text{min}} \) be the lowest extension of \( f_1 \) to \( R_1 \), and define \( f_{2,\text{max}} \) and \( f_{2,\text{min}} \) similarly. (It is not hard to show that the complete height functions extending a given partial height function form a lattice under the usual partial ordering, so it makes sense to talk about the highest and lowest extensions.) Let \( v \) be on the boundary of \( R_1 \cap R_2 \) (and hence on the boundary of \( R_1 \) or \( R_2 \)). If \( v \) is on the boundary of \( R_1 \), then we can find a nearby \( w \) on the boundary of \( R_2 \) so that

\[
\begin{align*}
\text{if } v & \text{ is on the boundary of } R_2 \text{, then we can find a nearby } w \text{ on the boundary of } R_2 \text{ so that} \\
f_{1,\text{max}}(v) & \leq f_{1,\text{max}}(w) + 2\Delta_1 + 1 \\
& = f_1(w) + 2\Delta_1 + 1 \\
& \leq f_2(v) + \Delta_2 + 2\Delta_1 + 1 \\
& = f_{2,\text{min}}(v) + \Delta_2 + 2\Delta_1 + 1.
\end{align*}
\]

Since the two height functions agree modulo 4 at \( v \), \( f_{1,\text{max}}(v) \leq f_{2,\text{min}}(v) + 4K \), where \( 4K \) is the greatest multiple of 4 that is less than or equal to \( 2\Delta_1 + \Delta_2 + 1 \). It follows from this (and the corresponding inequality in the other direction) that if \( f_1 \) is any extension of \( f_1 \) to \( R_1 \) and \( f_2 \) any extension of \( f_2 \) to \( R_2 \), then for each \( v \) on the boundary of \( R_1 \cap R_2 \), \( f_1(v) \) differs from \( f_2(v) \) by at most \( 4K \).

Now let \( v \) be any vertex in \( R_1 \cap R_2 \). If we compute \( \text{Exp}[H(v)] \) by conditioning on the heights on the boundary of \( R_1 \cap R_2 \), then it follows from Corollary \( \mathbb{F} \) that the expected value of \( H(v) \) under \( \mu_f \) differs by at most \( 4K \) (and hence at most \( 2\Delta_1 + \Delta_2 + 1 \)) from its expected value under \( \mu_f \).

As an application of this result, we may consider a modification of the Aztec diamond of order \( n \), whose symmetric difference with the true Aztec diamond of order \( n \) is a narrow fringe around the border of the true diamond, of width \( o(n) \). Suppose that the black and white squares of the symmetric difference are equinumerous, and moreover that they are not segregated but intermix in such a manner that the height function along the border of the modified diamond is within \( o(n) \) of the height function along the border of the true diamond. Lastly, let us suppose that the modified diamond has at least one domino tiling. Then we can conclude that the average height function for the modified diamond is within \( o(n) \) of the average height function for the true diamond.

Notice that these results give us no direct information about how individual placement probabilities change in response to small changes in the shape of the boundary, though some weak information can be obtained by way of the height function. It would be quite interesting to obtain robustness results for the placement probabilities themselves.
6.3. Variance. In Proposition 17 of subsection 6.1 we gave a formula for the normalized average height function, or rather its limit as the size $n$ of the Aztec diamond goes to infinity, and in subsection 6.2 we showed that the same formula applies to many regions that are roughly similar to the Aztec diamond. However, we obtained no information about how closely a typical height function for a region (an Aztec diamond or something else) should approximate the average height function. Here we use Azuma’s Inequality [AS, p. 85] to bound the amount of variation that values of random height functions are likely to exhibit.

Let $H$ denote the (unnormalized) height function corresponding to a random domino tiling of some simply-connected region in the plane, and let $v$ denote a vertex in the region, such that there is a path of $m$ vertices from the boundary of the region to $v$. We will show in this subsection that the variance of the random variable $H(v)$ is at most $64m$. In fact, we actually get a stronger result:

**Theorem 21.** Let $f$ be a partial height function defined on the boundary of a simply-connected region $R$, and let $v$ be a vertex in the interior of $R$, such that there is a path of $m$ vertices from the boundary of $R$ to $v$. Then, for all $c > 0$, the probability that $H(v)$ (the value of a random height function at $v$ under the uniform distribution $\mu_f$) differs from its expected value by more than $c\sqrt{m}$ is less than $2e^{-c^2/32}$.

**Proof.** Let $x_0, x_1, \ldots, x_{m-1} = v$ be a lattice-path connecting a point $x_0$ on the boundary of $R$ to the point $v$. Let $F_k$ be the partition of the space of possible height functions in which two height functions are regarded as equivalent if they agree at $x_0, x_1, \ldots, x_k-1$. Let $M_k$ be the conditional expectation $\text{Exp}[H(v)|F_k]$, the function from the set of height functions to the reals that assigns to each height function $h$ the average value of $h'(v)$ as $h'$ ranges over all height functions in the equivalence class of $h$.

Note that $M_m$ is just the function $H(v)$ itself, while $M_0$ is the average value of the height at $v$, averaged over all height functions. The functions $M_0, M_1, \ldots, M_m$ form a martingale; that is, \[ \text{Exp}[M_{k+1}|F_k] = M_k. \]

On each component of $F_k$, $M_{k+1} = \text{Exp}[H(v)|F_{k+1}]$ takes on at most two distinct values, according to the two different values of $H(x_k)$ that are consistent with the already-known values of $H(x_0), H(x_1), \ldots, H(x_{k-1})$. From Corollary 19, we see that these two values of $M_{k+1}$ differ by at most 4. Since $M_k$ is their weighted average, it follows that $M_k$ and $M_{k+1}$ never differ by more than 4. Then, applying Azuma’s Inequality (Corollary 2.2 on page 85 of [AS]) to the quantities $M_k/4$, we get

\[ \text{Prob}[|M_m - M_0|/4 > t\sqrt{m}] < 2e^{-t^2/2}. \]

Replacing $t$ by $c/4$, we get

\[ \text{Prob}[|H(v) - \text{Exp}[H(v)]| > c\sqrt{m}] < 2e^{-c^2/32}. \]

This completes the proof.

If we are interested in estimating the variance, we can derive a consequence of the preceding inequality: Assuming for simplicity of derivation (and without loss
of generality) that $\exp[H(v)] = 0$, we have
\[
\var[H(v)] = \exp[(H(v))^2] = \int_0^\infty \text{Prob}[(H(v))^2 > x] \, dx
\]
\[
= \int_0^\infty \text{Prob}[|H(v)| > \sqrt{x}] \, dx
\]
\[
< \int_0^\infty 2e^{-x/(32m)} \, dx
\]
\[
= 64m.
\]

As a final aside, we mention that our proof of Theorem 21 also yields the following more general result:

**Proposition 22.** Let $R$ be a simply-connected region in the plane and let $v, w$ be vertices in the interior of $R$, such that there is a path of $m$ vertices from $v$ to $w$, staying entirely within $R$. Then, for all $c > 0$, the probability that $H(v) - H(w)$ (under the uniform distribution on domino tilings of $R$) differs from its expected value by more than $c\sqrt{m}$ is less than $2e^{-c^2/32}$.

6.4. The arctic circle theorem. We will now use Theorem 21 to complete the proof of the arctic circle theorem, which we began in Section 5. We still need to show that the polar regions almost never extend very far into the interior of the inscribed circle $x^2 + y^2 = \frac{1}{2}$ (defined relative to normalized coordinates). Let $\varepsilon > 0$, and consider the region $R$ in an Aztec diamond of order $n$ defined by $x^2 + y^2 < \frac{1}{2} - \varepsilon$.

A domino is in the north or south polar region if and only if the heights on the vertices of the domino are equal to those at the same locations in the all-horizontal tiling, which is the minimal tiling of the Aztec diamond (under the partial ordering of tilings induced by comparison of height functions). An analogous statement connects the other two polar regions to the all-vertical tiling, which is the maximal tiling. Proposition 17 shows that, asymptotically, the average height function disagrees with the minimal and maximal height functions within the inscribed circle (although outside of that circle it agrees with one or the other). In particular, if a domino in $R$ is part of the polar regions, then the heights on it differ from the average heights at those locations by an amount at least proportional to $n$. (Of course, the constant of proportionality depends on $\varepsilon$.) We see that, by taking $c = \sqrt{n}$ in Theorem 21, the probability that a domino in $R$ will be part of the polar regions is exponentially small in $(\sqrt{n})^2 = n$. Since the number of dominos in $R$ is on the order of $n^2$, the probability that any will be contained in the polar regions is exponentially small.

We have now proved a slightly stronger version of the arctic circle theorem than that proved in [IPS]. There, it is shown that for any $\varepsilon > 0$, for sufficiently large $n$, the boundary of the temperate zone stays within distance $\varepsilon n$ of the arctic circle with probability greater than $1 - \varepsilon$. We have shown that this probability differs from 1 by an amount exponentially small in $n$.

6.5. Heterogeneity. The arctangent formula gives us an indication of a certain sort of local homogeneity: places in the tiling that are close together tend to be governed by the same statistics. Here we would like to prove a converse result, and show that within the temperate zone, places in the tiling that are far apart tend
to be governed by different statistics. More precisely, we would like to show that within the temperate zone, the quadruple 

\[ (p_n, p_e, p_s, p_w) = (\mathcal{P}(x, y), \mathcal{P}(-y, x), \mathcal{P}(-x, -y), \mathcal{P}(y, -x)) \]

(whose components are the four placement probabilities near the location \((x, y)\)) uniquely determines \(x\) and \(y\). This means, to put it somewhat fancifully, that if you found yourself stranded somewhere in the temperate zone of a random domino tiling of a huge checkerboard colored Aztec diamond, then, provided that you had a compass to tell you which way was north, you could determine your relative position within the diamond merely by examining the local statistics of the tiling.

The heterogeneity claim is not hard to prove, since we know that the level sets for all four placement probabilities are arcs of ellipses having a very specific geometry. In particular, level sets for \(p_n\) and \(p_s\) are arcs of ellipses that intersect in at most two points, and these two points have the same \(y\)-coordinate; similarly, level sets for \(p_e\) and \(p_w\) are arcs of ellipses that intersect in at most two points, and these two points have the same \(x\)-coordinate. It follows that if two points have the same probability quadruples, they must have the same \(x\)- and \(y\)-coordinates; that is, the two points must coincide.

However, we wish to prove more. Consider that the elements of the quadruple sum to 1, so that the quadruple has three degrees of freedom. However, \(x\) and \(y\) together embody only two degrees of freedom, so as \(x\) and \(y\) sweep through their range of joint allowed values, the quadruple determined by \(x\) and \(y\) will not sweep through the full set of probability vectors of length 4. On the other hand, the asymptotic normalized average height function \(H\) introduced in subsection 6.1 manifests exactly two of the degrees of freedom of \((p_n, p_e, p_s, p_w)\) in its first-order derivatives. What we would like to show is that inside the temperate zone, the map \((x, y) \mapsto (\frac{\partial H}{\partial x}, \frac{\partial H}{\partial y})\) is one-to-one, and has as its range the region \(\{(s, t) : |s| + |t| < 2\}\). (The possible significance of this fact will be explained more fully in Section 8.) Putting it differently, we may say that if one views the graph of the restriction of the function \(H\) to the interior of the temperate zone as a surface, then the Gauss map from the surface to the sphere is injective.

To prove the claim, we first note that, as discussed in subsection 6.1, \(\frac{\partial H}{\partial x} = 2p_w - 2p_e\) and \(\frac{\partial H}{\partial y} = 2p_n - 2p_s\). With \(y\) fixed and \(x\) increasing, \(p_e\) increases while \(p_w\) decreases, achieving equality (by symmetry) at \(x = 0\). Thus, the sign of \(\frac{\partial H}{\partial x}\) tells us the sign of \(x\), and similarly, the sign of \(\frac{\partial H}{\partial y}\) tells us the sign of \(y\). Hence, to prove the injectivity of the map, it suffices to focus on the part of the temperate zone that lies in the interior of one particular quadrant, say the second. Within that quarter-disk, \(\frac{\partial H}{\partial x}\) and \(\frac{\partial H}{\partial y}\) are both non-negative functions, taking the values 0 on the respective axes \(x = 0\) and \(y = 0\) and increasing as one moves away from these axes. These monotonicity properties do not of themselves rule out the possibility that \(\frac{\partial H}{\partial x}\) and \(\frac{\partial H}{\partial y}\) have the same value for two different points in that quarter-disk, so we must resort to a slightly more arduous approach.

Using the arctangent formula, one can check that

\[
\frac{\cos \left( \frac{\pi}{2} \frac{\partial H}{\partial y} \right)}{\cos \left( \frac{\pi}{2} \frac{\partial H}{\partial x} \right)} = \frac{1 - x^2 - 3y^2}{1 - 3x^2 - y^2}
\]
and
\[
\sin \left( \frac{\pi}{2} \frac{\partial H}{\partial y} \right) = -\frac{y}{x}
\]
\[
\sin \left( \frac{\pi}{2} \frac{\partial H}{\partial x} \right) = -\frac{x}{y}
\]
(If \(3x^2 + y^2 = 1\), then the first ratio is not defined. However, since \(x^2 + y^2 < \frac{1}{2}\), either the first ratio or its reciprocal is defined.) Given the values of these two ratios, there are in general at most two possibilities for \((x, y)\), only one of which will be in the desired quadrant. The only case in which knowledge of the two ratios does not restrict us to at most two possibilities for \((x, y)\) is when the first ratio is 1. This happens iff \(\frac{\partial H}{\partial x} = \frac{\partial H}{\partial y}\), i.e., along the line through the origin that bisects the quadrant. Since one can check using the explicit formulas for \(\frac{\partial H}{\partial x}\) and \(\frac{\partial H}{\partial y}\) that the partial derivatives increase as one moves away from the axes along that line, they still determine \((x, y)\). It follows that the map \((x, y) \mapsto (\frac{\partial H}{\partial x}, \frac{\partial H}{\partial y})\) is injective on the quadrant, as was to be shown.

Now we will see that the map is in fact a surjection to the set \(\{(s, t) : |s| + |t| < 2\}\). If one sets \(x = (1 - t - ct^2)/2\) and \(y = (1 + t - ct^2)/2\) with \(c > \frac{1}{2}\) (so that \((x, y)\) lies on a parabola that is symmetric about the axis \(x = y\) and that lies inside the closed temperate zone in the vicinity of \((\frac{1}{2}, \frac{1}{2})\)), then, sending \(t\) to zero from above, we find that the north-going and east-going probabilities tend towards
\[
\frac{1}{2} + \frac{1}{\pi} \tan^{-1} \frac{1}{\sqrt{2c - 1}}
\]
and
\[
\frac{1}{2} + \frac{1}{\pi} \tan^{-1} \frac{-1}{\sqrt{2c - 1}}
\]
which sum to 1 for all \(c\) between \(\frac{1}{2}\) and infinity and which vary (as an ordered pair) over the open segment connecting \((1, 0)\) to \((\frac{1}{2}, \frac{1}{2})\), as \(c\) goes from \(\frac{1}{2}\) to infinity.

Plugging the limits \(p_n \to p, p_s \to 0, p_e \to 1 - p, p_w \to 0\) into the formulas \(\frac{\partial H}{\partial x} = 2p_w - 2pc\) and \(\frac{\partial H}{\partial y} = 2p_n - 2ps\), we find that the boundary of the open square \(\{(s, t) : |s| + |t| < 2\}\) consists of limit points of the set of tilts \((\frac{\partial H}{\partial x}, \frac{\partial H}{\partial y})\) that are achieved by the average height function in the temperate zone, and hence (by continuity) that that we do indeed obtain the open square as the set of tilts achieved by the average height function in the temperate zone.

6.6. Entropy. The entropy of a random variable that takes on any of \(N\) values with respective probabilities \(q_1, \ldots, q_N\) is defined as \(\sum_{i=1}^{N} -q_i \log q_i\) (with \(0 \log 0 = 0\) by convention); for example, the entropy of a uniform random domino tiling of the Aztec diamond of order \(n\) is \(\frac{n(n+1)}{2} \log 2\), because there are exactly \(2^{n(n+1)/2}\) tilings (see [EKLP] for a proof). We have seen that for large \(n\), nearly all of this entropy is due to the variety exhibited inside, as opposed to outside, the arctic circle. It would be good to have more quantitative information on this. Specifically, given a patch of an Aztec diamond, one can define a random variable whose values are the near-tilings of the patch that result from restricting a uniform random tiling of the Aztec diamond to just the patch (such near-tilings are allowed to have untiled squares along the boundary of the patch), and one can consider the entropy of this new random variable. If the patch is very large (while not long and skinny, for example like a \(2 \times n\) rectangle), but the order of the Aztec diamond is much larger still, then we believe that this entropy, when divided by the area of the patch, is...
close to a value which we would call the local entropy, and which would depend only on the normalized location of the patch.

In this subsection, we make a small start towards calculating local entropy by showing that it vanishes outside the arctic circle and that it is positive inside the arctic circle (assuming it is well-defined there). Assuming that local entropy is well-defined everywhere, this gives us another way of interpreting the arctic circle, namely as the boundary between the zero-entropy region and the positive-entropy region.

The vanishing (and perforce the well-definedness) of local entropy outside the temperate zone is a simple consequence of the arctic circle theorem. To prove the other half of our claim, consider an $m \times m$ patch $P$ sitting inside the temperate zone of an extremely large Aztec diamond, with $m$ even.

If $a$, $b$, $c$, and $d$ are the northwest, northeast, southwest, and southeast squares in a $2 \times 2$ block in a plane region $R$ that can be tiled by dominos, then the proportion of tilings of $R$ that have a horizontal domino covering squares $a$ and $b$ and another horizontal domino covering squares $c$ and $d$ (write this proportion as $p_{ab,cd}$ for short) is clearly equal to the proportion $p_{ac,bd}$ of tilings that contain vertical dominos covering squares $a$ and $c$ and squares $b$ and $d$; moreover, by one of the lemmas proved in [GIP], both proportions are equal to $p_{ab}p_{cd} + p_{ac}p_{bd}$, where $p_{ab}$ denotes the proportion of tilings that have a domino covering $a$ and $b$, etc. (that is, $p_{ab}$, $p_{cd}$, $p_{ac}$, and $p_{bd}$ are just placement probabilities under uniform random tiling). In our particular situation, if one looks inside the patch $P$ taken from the temperate zone of a large Aztec diamond, all four placement probabilities are bounded away from zero, say by $\varepsilon > 0$, so the probability that a random tiling contains a $2 \times 2$ block centered at any particular vertex in $P$ is at least $4\varepsilon^2$. In particular, we can look at the $(m/2)^2$ vertices that are at the centers of the $(m/2)^2$ non-overlapping $2 \times 2$ blocks into which $P$ can be naturally decomposed. Using linearity of expectation, we can see that the expected number of such $2 \times 2$ blocks in a random tiling of the Aztec diamond is at least $m^2\varepsilon^2$. However, this allows us to set a lower bound on the entropy, as measured by the variety of configurations one sees locally. For, by freely rotating these blocks (i.e., changing horizontal blocks to vertical blocks or vice versa), we can create $2m^2\varepsilon^2$ other local patterns, all equally likely. Standard techniques in information theory permit one to conclude that the entropy of the near-tiling of $P$ is at least $\varepsilon^2 \log 2$ times the area of $P$.

7. Further Results

Although we have phrased our results in terms of domino tilings, there is an easy equivalence between domino tilings of finite regions and dimer configurations on certain finite graphs. Specifically, if we replace each square cell by a vertex, and draw an edge connecting any two vertices whose associated cells are adjacent, then a domino tiling of a region corresponds to a dimer-cover of the derived graph, that is, to a set of edges of the derived graph with the property that every vertex belongs to exactly one of the chosen edges. In this way, the study of domino tilings is seen to be equivalent to the study of dimer-covers, which is one of the better-understood statistical mechanics models in two dimensions. Studying domino tilings of special regions, such as Aztec diamonds, is tantamount to studying the dimer model in the presence of special boundary conditions. The uniformity of the distribution
corresponds to a degenerate situation in which all dimer configurations have the same energy.

There has been surprisingly little work on the behavior of the dimer model in the presence of general boundary conditions; researchers in statistical mechanics have tended to study either toroidal (i.e., periodic) boundary conditions or boundary conditions that correspond to domino tilings of a rectangle. Our work can in a sense be regarded as a somewhat strange chapter in the study of the dimer model, in which highly unphysical boundary conditions are imposed. (Precursors of this research include [E], [GG], and [SZ].)

In his original article on the dimer model [Ka], Kasteleyn considered imposing an energy function that favors one orientation of dimer over another (horizontal versus vertical). The authors of [GIP] followed this lead, and showed how their methods also led to exact results for random domino tilings of the Aztec diamond when the distribution was skewed towards dominos of a particular orientation. Here, we will state the results that follow from applying the methods of this paper to the case of biased tilings.

Let $p$ be strictly between 0 and 1. For each $n$, there is a unique probability distribution on the tilings of the Aztec diamond of order $n$ (in fact, on any simply-connected region) such that given any tiling of all of the diamond except for a $2 \times 2$ block, the conditional probability that the $2 \times 2$ block will contain two horizontal dominos is $p$. For more details on this distribution, see [IPS] or [GIP]. We call this the Gibbs distribution with bias $p$. (For more information on Gibbs distributions in general, see [G].)

The main difference between the biased distribution and the uniform distribution is the shape of the temperate zone. We will see shortly that, in the biased case, its boundary is given by the “arctic ellipse” $x^2 p + y^2 (1-p) = 1$ (in normalized coordinates).

It was conjectured in [JPS] that the analogue of the arctic circle theorem holds in the biased case. Our methods prove that conjecture, as well as an arctangent formula that describes the behavior within the temperate zone.

We begin by defining the biased placement probabilities $P_p(\ell, m; n)$ the same way we defined the ordinary placement probabilities (except, of course, that we use the biased distribution). The biased creation rates are also defined analogously to the ordinary creation rates, by

$$Cr_p(\ell, m; n) = \frac{1}{p}(P_p(\ell, m; n) - P_p(\ell, m - 1; n - 1)).$$

The proofs depend on a biased version of Proposition 2, which is proved in [GIP]. To state it, we will need a more general form of Krawtchouk polynomial. Define $c_p(a, b; n)$ to be the coefficient of $z^a$ in $(1+(1-p)z/p)^{n-b}(1-z)^b$. (See [MS] p. 151.) We need the following result from [GIP].

Proposition 23. Let $0 < p < 1$, and set $a = (\ell + m + n)/2$ and $b = (\ell - m + n)/2$. If $a, b \in \mathbb{Z}$, then

$$Cr_p(\ell, m; n + 1) = c_p(a, b; n)c_p(b, a; n)p^n.$$  

Otherwise, $Cr_p(\ell, m; n + 1) = 0$.

Using this proposition, straightforward modifications to the proof of Proposition 4 prove the following generalization:
Proposition 24. Fix $\varepsilon > 0$. If $\frac{\ell^2}{p} + \frac{m^2}{1-p} \leq (1 - \varepsilon)n^2$ and $\ell + m \equiv n \pmod{2}$, then

$$Cr_p(\ell, m; n + 1) = 2\cos^2 \Phi_p(\ell, m; n) + O_c(n^{-2})$$

for some function $\Phi_p(\ell, m; n)$, which can be determined explicitly.

Every result needed for the proof of Theorem [3](such as the creation rate estimates outside the arctic ellipse) has a straightforward generalization to the biased case; in the interest of saving space, we will omit their statements. The proofs are completely analogous to the proofs for the uniform distribution. One arrives at the following biased counterpart to Theorem [2]:

Theorem 25. Let $0 < p < 1$, and let $U$ be an open set containing the points $(\pm p, 1-p)$. If $(x, y)$ is the normalized location of a north-going domino space in the Aztec diamond of order $n$, and $(x, y) \notin U$, then, as $n \to \infty$, the placement probability at $(x, y)$ for the Gibbs distribution with bias $p$ is within $o(1)$ of $P_p(x, y)$, where

$$P_p(x, y) = \begin{cases} 
0 & \text{if } \frac{x^2}{p} + \frac{y^2}{1-p} \geq 1 \text{ and } y < 1 - p, \\
1 & \text{if } \frac{x^2}{p} + \frac{y^2}{1-p} \geq 1 \text{ and } y > 1 - p, \\
\frac{1}{2} + \frac{1}{2} \tan^{-1}\left(\frac{y-(1-p)}{\sqrt{p-p^2-(1-p)x^2-py^2}}\right) & \text{if } \frac{x^2}{p} + \frac{y^2}{1-p} < 1.
\end{cases}$$

The $o(1)$ error bound is uniform in $(x, y)$ (for $(x, y) \notin U$).

Similarly, the south-going, east-going, and west-going placement probabilities near $(x, y)$ are approximated by $P_p(-x, -y)$, $P_{1-p}(-y, x)$, and $P_{1-p}(y, -x)$, respectively. This follows from Theorem 25 by rotational symmetry.

One can also prove biased versions of the robustness and variance results from subsections 6.2 and 6.3. (In fact, the proofs are practically identical to the proofs given in those subsections.) Using them in combination with the same methods used in subsection 6.3, we can prove a slightly strengthened version of the “arctic ellipse conjecture” from [IPS]:

Theorem 26. Let $0 < p < 1$, and $\varepsilon > 0$. The probability that, in a random domino tiling with bias $p$ of an Aztec diamond of order $n$, the boundary of the polar regions is more than a distance $\varepsilon$ in normalized coordinates from the ellipse $\frac{x^2}{p} + \frac{y^2}{1-p} = 1$ is exponentially small in $n$.

8. Speculations

In this article we have focused primarily on one particular family of finite regions, namely, Aztec diamonds. Here we will indicate what it might mean to have a theory that would apply to all simply-connected finite regions, and how Aztec diamonds might play a role in the project of classifying the different possible local behaviors that random tilings of such regions can exhibit away from their boundaries.

The results of subsections 6.2 and 6.3 tell us that for any large simply-connected region $R$ that can be tiled by dominoes, height functions associated with random tilings of $R$ will cluster around their average. We furthermore know that this average height function depends in a monotone way on the values of the height function on the boundary of $R$, and is stable under certain kinds of slight perturbations of the boundary of $R$. However, what these theorems do not tell us is whether
this dependence is robust under scaling as well. Proposition 17 tells us that such
robustness does in fact hold for Aztec diamonds: that is, when one normalizes two
large Aztec diamonds, one finds that the normalized average height functions are
very close to one another. That this is true along the boundary is a triviality;
that it is true in the interior is a much subtler property, known to us only as a
consequence of Theorem 1.

We conjecture that scaling-robustness of height functions is true in general. That
is, suppose \( R_1, R_2, \ldots \) are finite, simply-connected, domino-tileable regions
that grow without bound, such that suitably rescaled copies of the \( R_n \)'s converge to
some compact subset \( R^* \) of the plane. Moreover, suppose that the height functions
associated with the boundaries of the \( R_n \)'s, when rescaled by the same respective
amounts, converge to some function on the boundary of \( R^* \). Then we believe that
the average height functions associated with the \( R_n \)'s, when rescaled, converge on
the interior of \( R^* \) as well as on the boundary to some function \( H \). If the boundary
values behave reasonably (perhaps piecewise smoothness suffices), then \( H \)
should be piecewise smooth (with reasonably shaped pieces).

Under this picture, we view \( H \) as the solution to a somewhat strange sort of
Dirichlet problem. We will have more to say about this analogy shortly, but first
we must leave the issues of large-scale structure (embodied in the average height
function) and discuss the small-scale structure of random tilings.

Consider simply-connected regions \( R_1, R_2, \ldots \) as above. In each region \( R_n \),
choose a north-going domino space \( \sigma_n \) with normalized location \((x_n, y_n) \) in \( R^* \),
so that \((x_n, y_n) \to (x^*, y^*) \) as \( n \to \infty \), and suppose that the asymptotic renormal-
ized height function \( H \) is differentiable at \((x^*, y^*) \). Assume that \((x^*, y^*) \) is in the
interior of \( R^* \) and that \( H \) is “non-extremal” at \((x^*, y^*) \), in the sense that its tilt
\((s, t) = (\frac{\partial H}{\partial x}, \frac{\partial H}{\partial y}) \) satisfies \(|s| + |t| < 2\). Then we conjecture that the placement
probabilities at the chosen north-going domino spaces \( \sigma_n \) converge. The arctangent
formula tells us that the conjecture is in fact true for Aztec diamonds.

Note that if we were to replace each \( \sigma_n \) by another north-going domino space
\( \sigma'_n \) obtained by shifting it by some fixed vector \((i, j) \) with \( i + j \) even, we would get
the same point \((x^*, y^*) \) in the normalized limit. Hence, the preceding conjecture
implies approximate local translation-invariance for the first-order statistics gov-
erning random tilings of large regions, provided one stays away from the boundary
(and the tilt is non-extremal).

This corollary gives us a way to understand the importance of our hypothesis of
non-extremality. For instance, consider the region shown in Figure 7; it has only
one tiling, whose local statistics are in no sense governed by any of the statistics
seen in Aztec diamonds. Taking a suitable limit of such regions one gets a height
function whose tilt \((s, t) \) satisfies \(|s| + |t| = 2\) and hence violates non-extremality.
Indeed, the statistics do not even exhibit local translation-invariance. (Note also
that for the Aztec diamond itself, \( H(\cdot, \cdot) \) is extremal at \((x^*, y^*) \) if and only if the
asymptotic entropy at normalized location \((x^*, y^*) \) is zero, which is the case if and
only if the asymptotic density of \(2 \times 2\) blocks at normalized location \((x^*, y^*) \) is
zero.)

Having made a conjecture about convergence of first-order statistics, we naturally
wonder about higher-order statistics as well. We conjecture that in fact all finite-
order statistics in the vicinity of the points \((x_n, y_n) \) stabilize as \( n \to \infty \), yielding
statistics that in some sense “belong” to the limit point \((x^*, y^*) \) (as long as the tilt at
(x*, y*) is non-extremal). Then, applying the translation-invariance remark made in the preceding paragraph, it follows that each (x*, y*) determines a process whose values are domino tilings of the entire plane. For instance, taking the Rn’s to be Aztec diamonds and the point (x*, y*) to be the center of the normalized diamond, it is natural to conjecture that at the center of the Aztec diamond of order n, the local finite-order statistics converge to those of the maximal entropy process mentioned in the Introduction. (This special case was conjectured in [IPS].) Letting (x*, y*) vary inside the rescaled temperate zone, we would get a two-parameter family of tiling-valued processes; they would all be distinct from one another because they would have distinct first-order statistics. The maximal entropy process would be unique among these processes not only in having the highest entropy but also in being invariant under the full group of lattice translations, rather than merely the color-preserving subgroup of index 2.

It can be shown rigorously that such processes, if they exist, have a combinatorial analogue of the “Gibbs property” studied in equilibrium statistical mechanics; that is, given a tiling of a cofinite subset of the plane whose finite complement is tileable, if one conditions the random process on that particular tiling, then the conditional distribution on tilings of the entire plane is uniform.

Here we leave aside caution and put forward some conjectures about what sort of shape the ultimate theory we are striving towards will take. These surmises might be false, but we believe they are the natural avenues to pursue in further investigations of the theory.

In the first place, we conjecture that the tiling-valued processes associated with the points (x*, y*) will turn out to be ergodic, or indecomposable, in the usual sense of the theory of dynamical systems. It is not hard to use the ergodic theorem for Z2-actions (see [K]) to show that every ergodic, translation-invariant (under color-preserving translations), tiling-valued random process determines placement probabilities pn, ps, pw, and pe and thence determines a tilt (s, t) = (2(pw − pe), 2(pn − ps)). We predict that in those cases where the tilt is non-extremal (i.e., |s| + |t| is strictly less than 2), there is in fact a unique ergodic Gibbs measure with tilt (s, t). If this were true, it would have many nice consequences; for instance, the four numbers pn, ps, pe, pw would all be determined by the pair (s, t), and thus would exhibit only two degrees of freedom, despite the fact that the only obvious constraint governing them is pn + pe + pw = 1. A further nice property is that the temperate zones of Aztec diamonds would be universal in the sense that they would manifest, in the limit, all possible forms of non-extremal local behavior that random
tilings of large simply-connected regions can manifest away from boundaries. This universality is not peculiar to Aztec diamonds, but instead arises from the fact, proved in subsection 6.5, that Aztec diamonds exhibit all possible non-extremal tilts.

An especially nice benefit of the preceding conjecture is that it would open the door to a variational approach to the problem of finding the average height function \( H \) on \( R^* \) given only its values on the boundary of \( R^* \). Given any candidate for \( H \), define \( N_n \) as the number of domino tilings of \( R_n \) whose normalized height functions stay close to \( H \). It does not seem too far-fetched to hope that the logarithm of \( N_n \), when divided by the area of \( R_n \), converges to an integral over \( R^* \), in which the integrand is the entropy associated with the unique ergodic Gibbs process with tilt \( \left( \frac{\partial H}{\partial x}, \frac{\partial H}{\partial y} \right) \). Since finding the average height function on \( R_n \) corresponds in some sense to maximizing \( N_n \), we would hope that finding the asymptotic normalized height function on \( R^* \) corresponds to maximizing this integral. It might not always be possible to solve the associated calculus of variations problem explicitly, but such a theorem would be a major advance towards a complete understanding of how the presence of boundary conditions can affect the behavior of a domino tiling in the interior of a region.

The preceding idea has in fact been used by physicists, in the context of crystals; see for example [NHB, pp. 3562–3563]. There, it is claimed that the shape of a crystal surface is determined by minimizing the total surface free energy, which is obtained by integrating a local contribution (the surface free energy density) depending only on the gradient of the surface. This is believable physically, but in any particular lattice model it seems difficult to establish rigorously; it is not even clear on purely mathematical grounds why there should exist a surface free energy density depending only on the gradient. The analogous statement in random tiling theory is the existence of a local entropy depending only on the tilt of the height function, but it is conceivable (although we consider it unlikely) that the local entropy might not be determined by the local asymptotic behavior of the normalized height function. The only approach that we know of that might lead to a rigorous proof (or even a heuristic argument) is to prove the conjectures above about local statistics and Gibbs measures.

Acknowledgements

We thank Robin Pemantle for suggesting the idea behind Lemma 18. Thanks also to David Feldman for providing helpful comments on the manuscript, to Sameera Iyengar for writing the program that produced the random tiling shown in Figure 1, to M. Josie Ammer and Dan Ionescu for writing the first programs to compute placement probabilities for Aztec diamonds, to Pramod Achar, Federico Ardila, Dan Ionescu, and Ben Raphael for helping to write the programs that produced the random tilings shown in Figures 4, 5, and 6, and to David Wilson for helping to create the figures.
