Coherent quantum control over many-particle quantum systems requires high-fidelity dynamics. One way of achieving this is to use adiabatic schemes where the system follows an instantaneous eigenstate of the Hamiltonian over time scales that do not allow transitions to other states. This, however, makes control dynamics very slow. Here we introduce another concept that takes advantage of preventing unwanted transitions in fermionic systems by using Pauli blocking: excitations from a protected ground state to higher-lying states are avoided by adding a layer of buffer fermions, such that the protected fermions cannot make a transition to higher-lying excited states because these are already occupied. This allows us to speed up adiabatic evolutions of the system. We do a thorough investigation of the technique, and demonstrate its power by applying it to high-fidelity transport, trap expansion, and splitting in ultracold-atom systems in anharmonic traps. Close analysis of these processes also leads to insights into the structure of the orthogonality catastrophe phenomenon.

DOI: 10.1103/PhysRevA.96.043601

1. INTRODUCTION

Preparation of and coherent control over many-particle quantum states require quantum-engineering techniques that lead to high fidelities. Adiabatic processes, where the system follows an eigenstate of the time-dependent Hamiltonian, are known to allow for this; however they require that the Hamiltonian be varied sufficiently slowly in order to avoid transitions to other eigenstates [1]. This leads to long process times and leaves the system vulnerable to decoherence, reducing also the possible repetition rates of the process.

How quickly or slowly an eigenstate can be followed depends roughly on the distance to the next-closest-lying eigenstate [1]. Therefore, one strategy for expediting adiabatic processes is to adjust the instantaneous speed of the process with respect to the size of the instantaneous level gap such that the transition probability to unwanted eigenstates remains small during the whole process [2–4]. This, however, requires the knowledge of the energy eigenspectrum during the whole process.

In recent years, a number of techniques to speed up adiabatic processes have been developed under the name “shortcuts to adiabaticity” [5,6]. One example of these techniques relies on the implementation of an additional counter-diabatic Hamiltonian, which is designed to compensate for any excitations that appear during the finite-time evolution process, such that the system does not leave the eigenstates of the original Hamiltonian [7–9]. However, this additional Hamiltonian can be very complicated and thus be demanding to implement experimentally. Other shortcut techniques are based on Lewis-Riesenfeld invariant inverse engineering [10], which allows for a fast transfer of all initial eigenstates simultaneously to all final eigenstates (up to a phase).

Generalizing these techniques to many-particle systems is not a straightforward task, as the number of degrees of freedom increases exponentially with larger particle numbers. The effects of this are well known and can be seen immediately when considering one of the simplest systems possible, namely an ideal, spin-polarized, one-dimensional Fermi gas at low temperatures: even in the presence of almost perfect single-particle process fidelities, the overlap between two many-particle wave functions scales with $N^{-\alpha}$, where $\alpha$ depends on the specific nature of the change between the initial and final Hamiltonian [11]. This is the so-called orthogonality catastrophe (OC) [12,13], which has recently been examined for systems of ultracold fermions [14,15].

Here, however, we show that this behavior does not necessarily limit the engineering of many-particle states, as the OC does not affect all states inside a Fermi sea in the same way. In fact, one can always find a kernel of particles that is essentially unperturbed, and whose size scales with the overall number of particles. This is due to the fact that transitions inside the Fermi sea are forbidden by the Pauli exclusion principle and lead to the so-called Pauli blocking, which has recently been examined to engineer cold-atomic systems [16–20].

In this work we will consider a system of trapped, ultracold, spin-polarized fermionic atoms, and explore the idea of using Pauli blocking for speeding up adiabatic evolutions. In addition to the ground-state layer of particles that should be protected from making transitions we are also adding a buffer layer of particles; see Fig. 1(a). The basic idea now is that only the fermions close to the Fermi edge can make transitions, whereas all atoms inside the Fermi sea need significantly more energy to get excited. Since we are only interested in the protected particles, this will allow us to carry out adiabatic processes much faster, as long as the energies introduced by the dynamics do not allow for particles in the protected layer to make transitions. Once the evolution is finished, the buffer fermions can be discarded by, for example, lowering the trap walls [21], weakening and squeezing the trap [22,23], or inducing spin flips as in similar techniques for the evaporative cooling of bosons [24].

As this technique can most easily protect ground states, it is particularly well suited to prepare initial states in potentials where direct ground-state cooling is either challenging or
FIG. 1. (a) Schematic of the key idea: In order for the particles in the protected zone to remain in the lower-energy eigenstates during a time-dependent change of the external control parameters, a buffer zone is added. The Pauli principle then prevents the protected atoms from accessing any level in the buffer zone, and to access an unoccupied level above the Fermi edge requires a large amount of energy. (b) Fermi gap \( \Delta E = E_{N+1} - E_N \) versus total particle number \( N \) for the anharmonic trap \( V(x) = m\alpha^2(x^2 + \lambda x^4)/2 \) for different anharmonicities \( \lambda \).

done at a different stage than the processing. Ultracold, spin-polarized Fermi gases, which are to first order non-interacting, are usually cooled to temperatures below the Fermi temperature through sympathetic cooling with a second component (either bosonic or fermionic) [25]. The second component is then removed and the experiment on the degenerate gas is carried out. Since no further sympathetic cooling is possible once the second component is removed, buffer fermions would allow one to protect the ground state.

The idea we present relies on the specific form of the energy spectrum around the Fermi edge [for example in anharmonic trapping potentials; see Fig. 1(b)], significant speedups can be obtained. In fact, in this limit the idea of Hilbert-space engineering through quantum statistics is largely independent of the potential shape, i.e., the exact form of the Hamiltonian.

Since the technique we discuss below will protect the lower motional energy states, and since the protection is done by the presence of a Fermi sea, it requires fermionic samples that are deep within the quantum degenerate regime. For neutral atoms these can be produced routinely in laboratories worldwide these days [26–28], and since the removal of the higher energy particles from a trap can also be done using standard techniques, we will concentrate in this paper on the control process itself.

In the following we will first introduce the system we investigate and define and discuss the process fidelity as our figure of merit. We will then apply the method in detail to three specific control tasks in Sec. III, and conclude in Sec. IV.

II. SYSTEM AND FIDELITY

A. Fermion state

We consider a gas of spin-polarized fermions that formally consists of \( N_p \) particles whose state we want to protect and \( N_b \) particles that form a buffer layer [see Fig. 1(a)], so that the overall number of particles is \( N = N_p + N_b \). Since at ultracold temperatures the dominant scattering interaction is of symmetric \( s \)-wave form, such gases can be efficiently described as noninteracting and they therefore form a perfect Fermi sea at zero temperature [29]. This also means that the time evolution of the many-particle wave function, \( |\Psi(t)\rangle \), can be obtained by solving the single-particle Schrödinger equations for each state within the Fermi sea:

\[
\frac{i\hbar}{\partial t} |\psi_i(t)\rangle = \left[ -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + V(x,t) \right] |\psi_i(t)\rangle,
\]

where the shape and time dependence of the potential, \( V(x,t) \), depend on the particular task that is to be implemented. The many-particle wave function then follows from calculating the Slater determinant as

\[
|\Psi(t)\rangle = \frac{1}{\sqrt{N!}} \sum_{\sigma \in \Pi[N]} \text{sgn}(\sigma) \prod_{i=1}^{N} |\psi_{\sigma(i)}(t)\rangle,
\]

where \( \Pi[N] \) consists of all the permutations of the set \( \{1, \ldots, N\} \).

B. Process fidelity

In the following we will consider processes where the \( N_p \) lowest eigenstates of an initial Hamiltonian are occupied by \( N_p \) relevant particles and we aim at having this subset of the fermionic subspace \( H^N \) of the Hamiltonian at the end of the process. In detail, we define the fidelity of the process as

\[
\mathcal{F} = \langle \Psi | \hat{\mathcal{M}} | \Psi \rangle,
\]

where \( |\Psi\rangle \) is an element of the fermionic subspace \( H^N \) and the measurement operator \( \hat{\mathcal{M}} \) is defined as

\[
\hat{\mathcal{M}} = \frac{1}{N!} \sum_{\tau \in \Pi[N]} \hat{M}^{(\tau(1))} \otimes \cdots \otimes \hat{M}^{(\tau(N))},
\]

\[
\hat{M}^{(i)} = \begin{cases} |\phi_i\rangle \langle \phi_i| & \text{if } i = 1, \ldots, N_p, \\ 1 & \text{if } i = N_p + 1, \ldots, N. \end{cases}
\]

The operator \( \hat{M}^{(i)} \) checks the occupation probability of the \( i \)th eigenstate of the Hamiltonian, provided that \( i \leq N_p \), and, as we are not interested in the population of levels above \( N_p \), \( \hat{M}^{(i)} \) acts as the identity for \( i > N_p \).

Let \( \hat{P}_F \) be the projector on the fermionic subspace \( H^N_p \). For \( |\Psi\rangle \in H^N_p \), we have \( \mathcal{F} = \langle \Psi | \hat{\mathcal{M}} | \Psi \rangle = \langle \Psi | \hat{P}_F \hat{\mathcal{M}} \hat{P}_F | \Psi \rangle \) where \( \hat{\mathcal{M}}_F := \hat{P}_F \hat{\mathcal{M}} \hat{P}_F \). One can show by using the fermionic number basis states \( |\phi_n\rangle \) that

\[
\hat{\mathcal{M}}_F = \sum_n |\phi_n\rangle \langle \phi_n|,
\]

where the sum is over all vectors \( n \) fulfilling \( n_j = 1 \) for \( j = 1, \ldots, N_p \) and \( \sum_{j=N_p+1}^{\infty} n_j = N_b \). From its structure it is clear that the operator \( \hat{\mathcal{M}}_F \) is a projector. This proves that always \( 0 \leq \mathcal{F} \leq 1 \) as it should be for a meaningful fidelity definition.
The fidelity (3) can then be rewritten as (see Appendix for details)
\[
\mathcal{F} = \sum_U \sum_{\sigma \in \Pi(N_p)} \text{sgn}(\sigma) \prod_{i=1}^{N_p} \langle \psi_{U(\sigma(i))}(T) | \phi_i \rangle^2,
\]
where the first sum \( U \) is over all mappings \( U : \{1, \ldots, N_p\} \rightarrow \{1, \ldots, N\} \) with \( U(i) < U(i+1) \) for \( i = 1, \ldots, N_p - 1 \) (which can be also viewed as all subsets of cardinality \( N_p \) of the set \( \{1, \ldots, N\} \). As mentioned above, the states \( |\psi_j(T)\rangle \) can be obtained from the single-particle Schrödinger equation (1).

From Eq. (7), it also follows that \( \mathcal{F}^{(N_p+1)} \geq \mathcal{F}^{(N_p)} \), i.e., that \( \mathcal{F} \) increases monotonically with the number of buffer particles \( N_b \). This can be seen because
\[
\Delta \mathcal{F} = \mathcal{F}^{(N_p+1)} - \mathcal{F}^{(N_p)} = \sum_{U \cup \tilde{U}} \sum_{\sigma \in \Pi(N_p)} \text{sgn}(\sigma) \prod_{i=1}^{N_p} \langle \psi_{U(\sigma(i))}(T) | \phi_i \rangle^2 \geq 0,
\]
where \( U \) are all a subset of cardinality \( N_p \) of the set \( \{1, \ldots, N+1\} \) and \( \tilde{U} \) are all a subset of cardinality \( N_p \) of the set \( \{1, \ldots, N\} \). Note that from this property and the fact that \( \mathcal{F} \) is bounded by 1, we know that the limit \( \lim_{N_b \rightarrow \infty} \mathcal{F}^{(N_p)} \) must exist, but it is not necessarily 1.

### C. Adiabaticity and shortcuts

Let us first look at schemes which work perfectly in the adiabatic limit, i.e., for \( T \rightarrow \infty \). In this limit one gets \( |\psi_j(T)\rangle + e^{i\xi_j T} |\phi_i(T)\rangle \) where the \( \xi_j \) are phases. It immediately follows from Eq. (7) that \( \mathcal{F} = 1 \). To be more general, if \( T \) is large but finite, we get that \( |\psi_i(T)\rangle = e^{i\xi_j T} |\phi_i(T)\rangle + \frac{1}{T} |\hat{\chi}_j^{(1)}(T)\rangle + \frac{1}{T^2} |\hat{\chi}_j^{(2)}(T)\rangle + \ldots \) where the phase of \( |\phi_i(t)\rangle \) can be chosen in such a way that \( \langle \phi_i(T) | \hat{\chi}_j^{(1)}(T) \rangle = 0 \). Based on this, we can make a series expansion of the fidelity in the small parameter \( 1/T \) as
\[
\mathcal{F} \simeq 1 + \frac{1}{T^2} \left[ \omega^{(0)} + \sum_{\mu=1}^{N_b} \sum_{\lambda=1}^{N_b} \left| \langle \chi_{N_b+1,\lambda}(T) | \phi_\mu(T) \rangle \right|^2 \right],
\]
where \( \omega^{(0)} \) is an expression independent of \( N_b \). However, it can be seen that all terms which depend on \( N_b \) are always positive and therefore improve the fidelity. This coincides with the general monotonicity of the fidelity in \( N_b \) shown above.

Another special case is settings where shortcuts to adiabaticity techniques can be applied exactly, like for example the expansion of a harmonic trap [10] or the transport in a harmonic trap [30]. One can see from the above equation that one would obtain \( \mathcal{F} = 1 \) exactly for arbitrary numbers of particles on arbitrary time scales. In the following, we will therefore concentrate on settings where a shortcut to adiabaticity cannot be found easily, in particular anharmonic settings.

### D. Temperature effects

To extend this approach to the case of a finite temperature \( \tau \), the initial state is of canonical form and the probability for a specific occupation \( m \) at initial time is given by
\[
p_m = \frac{1}{Z} \exp \left[ -\frac{1}{k_B \tau} \sum_{j=1}^{N} (E_m(j) - E_j) \right].
\]
Here \( Z = \sum_m \exp \left[ -\sum_{j=1}^{N} (E_m(j) - E_j)/k_B \tau \right] \) is the partition function and \( k_B \) is the Boltzmann constant. The sum is over all functions \( m : \{1, \ldots, N\} \rightarrow \mathbb{N} \) with \( m(i) < m(i+1) \); i.e., \( (m(1), \ldots, m(N)) \) are the numbers of the energy eigenstates occupied by the \( N \) fermions and the \( E_j \) are the ordered eigenergies of the Hamiltonian at the initial time. The finite-temperature fidelity will then be the average over the fidelities of the different possible permutations of the particles
\[
\mathcal{F} = \sum_m p_m \mathcal{F}_m,
\]
where \( \mathcal{F}_m \) is the fidelity defined similarly to the one above with just the states in \( (m(1), \ldots, m(N)) \) initially occupied instead of \( (1, \ldots, N) \):
\[
\mathcal{F}_m = \sum_U \sum_{\sigma \in \Pi(N_p)} \text{sgn}(\sigma) \prod_{i=1}^{N_p} \langle \psi_{U(\sigma(i))}(T) | \phi_i \rangle^2.
\]
Note that while this sum is in principle infinite, we will truncate it for its numerical evaluation at a maximal energy level chosen such that the result is practically independent from the exact level of truncation.

### III. CONTROL TASKS

In this section we focus on particles trapped in potentials with significant anharmonicities, such that these cannot be treated as perturbations, and discuss three manipulation examples: expansion, transport, and splitting of the trap. For small (or zero) trap anharmonicity shortcuts for expansion and transport have been derived [5,30–33] and shortcuts related to the splitting can be found, for example, in [34,35].

This broad variety of tasks will show that, in contrast to other shortcut-to-adiabaticity protocols, the idea presented here is insensitive to the details of how the trap parameters are varied in time and does not require any specific time-dependence parameter functions which might be very complex and hard to implement experimentally. The only parameter is the number of buffer particles, \( N_b \), and we will show below how the fidelity depends on the size of the buffer for each of the three processes.

#### A. Trap expansion

We first consider the expansion of the trapping potential, which we choose to be of the form
\[
V(x,t) = \frac{m}{2} \omega(t)^2 (x^2 + \lambda x^4),
\]
and in which the anharmonicity is quantified by the parameter \( \lambda \). We set \( \lambda = m \omega_i / \hbar \) such that the anharmonicity is significant and far from being just a small perturbation.

For the control task the trapping frequency \( \omega(t) \) is changed from \( \omega_i \) at \( t = 0 \) to \( \omega_f \) at \( t = T \) and we consider two different forms of the time dependence, linear and sinusoidal,
respectively given by

\[
\omega_{\text{sin}}(t) = \omega_i + (\omega_f - \omega_i) \frac{t}{T},
\]

\[
\omega_{\text{cos}}(t) = \omega_i + (\omega_f - \omega_i) \sin^2 \left( \frac{\pi t}{2T} \right).
\]

The resulting fidelities \( \mathcal{F} \) for both schemes are shown in Fig. 2(a) for \( N_p = 2 \). One can clearly see that adding just a small number of buffer particles leads to significantly larger \( \mathcal{F} \), even at total times for which the fidelity without buffer particles was very low. We also see that this is independent of the control scheme, underlining the fact that our method does not depend on the precise time dependence of the control parameters. Nonetheless, it can be seen that the sinusoidal scheme generally results in larger \( \mathcal{F} \) than the linear scheme for fixed \( T \) and \( N_p \). Since both schemes yield roughly similar results we will in the following focus on the sinusoidal scheme only.

The dependence of the fidelity on the number of buffer particles for different numbers of protected particles \( N_p \) is shown in Fig. 2(b) for a fixed process time of \( T = 25/\omega_i \). The fidelity increases monotonically with increasing \( N_b \) (for fixed \( N_p \)), agreeing with the general property of the fidelity derived in Sec. II.

In addition, it is interesting to note that adding an even number of particles is more effective than adding an odd number. This can be understood by first considering the extreme case of \( N_p = 1 \) [red line in Fig. 2(b)], where it can be seen that, if one adds a single buffer particle to an even number of buffer particles, the process fidelity does not change. The reason for this is that expansion is a symmetric operation with respect to the center of the trap; i.e., the Hamiltonian commutes with the parity operator. Therefore states of different parity do not couple and for \( N_p = 1 \) the subspace of buffer particles in odd eigenstates completely decouples from the subspace of the single, protected particle (as the ground state is even) and also from the buffer particles in even eigenstates. The fidelity then depends only on the even subspace and adding an additional odd buffer particle has no effect. For larger \( N_p \), both subspaces are involved in the fidelity, making the situation more complex and the effect less prominent.

Figure 2(b) also illustrates the effect of the OC, as one can see that fidelities decrease dramatically with larger system sizes (larger \( N_p \)). However, it is also worth pointing out that in our situation this is slightly surprising, as due to the trap anharmonicity, the Fermi gap is bigger for larger \( N_p \), see Fig. 1(b), and one could therefore expect the OC to be suppressed for larger systems at fixed \( T \). Nevertheless, Fig. 2(b) clearly shows that adding more particles to the system increases the fidelity of the relevant, lower-lying many-body state, and therefore allows us to beat the OC.

In all cases a fidelities \( \mathcal{F} \geq 0.95 \) can be achieved by adding a large enough number of buffer particles and Fig. 2(c) shows the relation between the process time \( T \) and the minimal number of buffer particles \( N_b, \text{min} \) needed for achieving \( \mathcal{F} \geq 0.95 \) for all process times larger than \( T \). It can clearly be seen that smaller \( T \) must be combined with a larger number of buffer particles, \( N_b, \text{min} \), to result in the desired threshold fidelity.

Next, we study the effects of the potential shape and the temperature on our scheme and start by considering the dependence on \( \mathcal{F} \) for different (relevant, nonperturbative) anharmonicities \( \lambda \). The results shown in Fig. 3(a) confirm that this method does not require a detailed knowledge of the trapping potential, as for \( N_b \geq 8 \) the fidelity stays always above the threshold fidelity of 0.95 for the whole range of \( \lambda \) values shown. In fact, we note that the fidelity increases with \( \lambda \) as our scheme takes advantage of the increased energy gap at the Fermi energy for larger \( \lambda \) [see again Fig. 1(b)].

Finite-temperature results are shown in Fig. 3(b) for different numbers of buffer particles \( N_b \) (with fixed \( T = 25/\omega_i \), \( N_p = 2 \), \( \lambda = m\omega_i/h \)), and it can be seen that the scheme is quite stable under temperature perturbations. Increasing temperatures can be compensated by increasing the number of buffer particles to achieve the same target fidelity: \( N_b \) should be increased by 1 to compensate for an increase in temperature of the order of \( \hbar \omega_i/k_B \) [see the dots in Fig. 3(b)]. This is also what one would expect heuristically as the “width” of the edge in the Fermi-Dirac distribution is of the order of \( k_B T \) and the energy gap is of the order \( \hbar \omega_i \). As one might expect, the increase of the fidelity is again monotonic with increasing \( N_b \) with finite temperature for the shown parameter range.
FIG. 3. Trap expansion with a sinusoidal scheme for different number of buffer particles $N_b$. The order of the legend corresponds to the order lines on the graph. (a) Fidelity $F$ versus anharmonicity $\lambda$ at temperature $\tau = 0$; the vertical line indicates $\lambda = m\omega_i/h$, to allow easy comparison to Fig. 2. (b) Fidelity $F$ versus temperature $\tau$; $\lambda = m\omega_i/h$. In both panels $\omega_f/\omega_0 = 0.01$, $N_p = 2$ with $T = 25/\omega_i$; the horizontal line indicates a fidelity of $F = 0.95$; in (b) the dots on the horizontal axis indicate when the corresponding line crosses this threshold fidelity.

B. Transport

The second dynamical scheme we examine is the spatial translation of the trapping potential described by

$$V(x,t) = \frac{1}{2}m\omega^2[x - x_0(t)]^2 + \lambda(x - x_0(t))^4,$$

and we choose the movement of the trap center $x_0(t)$ between $x_i = x_0(0)$ and $x_f = x_0(T)$ to be of the form

$$x_0(t) = x_i + (x_f - x_i)\sin^2\left(\frac{\pi t}{2T}\right).$$

(17)

Let $d = \sqrt{\hbar/m\omega}$, and we set $\lambda = 1/d^2$. The resulting fidelities $F$ are shown in Fig. 4(a) for $N_p = 2$ and one can see that, similarly to the expansion scheme, fidelities of $F \geq 0.95$ can be achieved by increasing the number of buffer particles $N_b$ instead of increasing the total time $T$. In this case, however, the fidelities exhibit oscillations for shorter $T$, giving high fidelities for some specific final times. This is directly related to the single-particle behavior where magic times exist, for which the transport of the wave packet becomes optimal [36,37].

In Fig. 4(b) we examine how the fidelity depends on the number of buffer particles for different numbers of protected particles $N_p$ (for a fixed process time $T = 11.5/\omega$). As expected, adding buffer particles $N_b$ always increases the fidelity (see again also Sec. II). However, it is worth pointing out certain differences compared to the expansion scheme [see Fig. 2(a)]. First, adding a single buffer particle always has a significant effect and second, the fidelity is now not monotonic in $N_p$ [for fixed $N_b$ and $T$, compare to Fig. 2(b)]: all fidelity lines for the different $N_p$ cross the threshold line of $F = 0.95$ given enough $N_b$.

Figure 4(c) shows the relation between the process time $T$ and the minimal number of buffer particles $N_{b,\text{min}}$ required to reach $F \geq 0.95$ for all process times larger than or equal to $T$. Similarly to the expansion scheme, $N_{b,\text{min}}$ goes to 0 for large enough $T$ and the required buffer is increasing for shorter process times $T$. In addition, $N_{b,\text{min}}$ does not have a strong dependence on $N_p$ in the transport case.

The relation between $F$ and temperature $\tau$, for different values of $N_b$ (with fixed $T = 11.5/\omega$, $N_p = 2$), is shown in Fig. 5(a). One can see that the scheme is again stable against temperature perturbation; however, for increasing temperature the number of buffer particles $N_b$ has to be increased to still achieve a fidelity $F \geq 0.95$. Again, from the dots on the horizontal axis it can be seen that $N_b$ has to be increased by 1 if the temperature increases by an order of $\hbar\omega_0/k_B$. Again, we note that for the temperatures shown there is still the monotonic increase of the fidelity with increasing $N_b$.

It is also interesting to note that the fidelity in general does not always decrease monotonically with increasing tempera-
leads to a splitting of the atomic cloud. For this we choose
\[ V(x,t) = \frac{1}{2}m\omega^2 x^2 + h(t) e^{-x^2/d^2}, \]
where again \( d = \sqrt{\hbar/m\omega}. \) The time dependence of the barrier height chosen is
\[ h(t) = h_i + (h_f - h_i) \sin^2 \left( \frac{\pi t}{2T} \right), \]
where \( h_i \) is the initial height of the barrier at \( x = 0 \) before the splitting and \( h_f \) after the process. Similarly to the case of expansion, splitting is a symmetric operation; i.e., the Hamiltonian is commuting with the parity operator. As such it is expected that even numbers of additional particles are more effective than odd numbers. Splitting is also quite distinct from the other manipulations in that it affects higher-energy states in the trap less, whereas transport or expansion affect the whole spectrum of states in the trap. In the following, we set \( h_i = 0 \) and \( h_f = 20\hbar \omega \), which leads to a final separation in two wells for approximately the 18 lowest-energy eigenstates.

In Fig. 6(a) one can see that, as expected, increasing \( N_b \) gives higher fidelities \( \mathcal{F} \) on shorter time scales and \( \mathcal{F} \) increases monotonically with \( T \). In fact, the process is very robust and already for \( N_b = 3 \) a fidelity of \( \mathcal{F} \geq 0.95 \) can be achieved for almost instant time scales.

The dependence of the fidelity on \( N_b \) is shown for different \( N_p \) in Fig. 6(b). For odd numbers of particle \( N_p \), one can see an effect similar to the one observed in the expansion process, where an even number of buffer particles \( N_b \) is needed to see an increase in fidelity. This can again be understood by considering the symmetric nature of the splitting dynamics. However, while one would naively expect the same for states with even numbers of particles \( N_p \), it is absent in this case. The reason for this can be found in the specific structure of the eigenspectrum of the split trap, where for our parameters successive even and odd eigenstates are effectively energetically degenerate. An even number of particles in the system therefore has two particles with energies close to the Fermi edge and adding any number of buffer particles will lead to an increase in fidelity as one possible transition is blocked.

Finally, from Fig. 6(c), one can see that the splitting is slightly more sensitive to temperature than the previous two operations. The dots on the horizontal axis show heuristically that an additional buffer particle is required for every increase
in temperature of about $0.25k_B/h\omega$, while in the previous two schemes this was about $k_B/h\omega$.

**IV. CONCLUSION**

In this work we have explored the idea of using Pauli blocking for speeding up adiabatic evolution by using an additional layer of buffer particles to protect the lowest-energy fermions when the system parameters are dynamically changed. We have presented a thorough investigation, both analytical and numerical, showing that the presence of this additional layer allows the speedup of adiabatic manipulations without exciting unwanted transitions. By discussing three different examples, we have demonstrated that this method is robust and applicable to a wide range of scenarios.

The proposed technique is particularly well suited to protect ground states during changes of the external potential, resulting in a speedup of ground-state preparation in potentials for which these states cannot easily be prepared directly with high fidelity. The method does not require precise knowledge of the shape of the trap or the energy spectrum of the system. It is also insensitive to the details of how the trap parameters are varied in time and no specific time dependence of the parameter functions is necessary, which might be very complex and hard to implement experimentally. All this makes it a very robust and readily applicable technique.

In this work we have discussed an ideal fermion system without interactions. In fact, this is a good approximation for spin-polarized, ultracold Fermi gases where the short-range without interactions. In fact, this is a good approximation for

and readily applicable technique.

All this makes it a very robust and applicable technique.

Finally, we would like to stress again that our study gives a deep insight into the phenomenon of the orthogonality catastrophe. We have shown that the fidelity of a subsystem can be much larger than the one of the full many-body system and in particular, that the particles close to the Fermi edge play a much stronger role in the effect of the many-body state becoming orthogonal.

We are grateful to D. Rea for useful discussion and commenting on the manuscript. T.D. acknowledges support by the Irish Research Council (GOIPG/2015/3195). This work was supported by the Okinawa Institute of Science and Technology Graduate University.

**APPENDIX: CALCULATION OF THE FIDELITY**

We calculate the fidelity of the final state, $\mathcal{F} = \langle \Psi | \hat{M} | \Psi \rangle$, with the measurement operator defined by Eq. (4), where $|\Psi\rangle$ is the state of our $N$-fermion wave function after some unitary time evolution. We want to calculate $\mathcal{F}$ as a function of the single-particle states $|\psi_i\rangle$; cf. Eq. (2). Expanding the definitions of $\hat{M}$ and $|\Psi\rangle$, we get

$$\mathcal{F} = \frac{1}{N!N!} \sum_{\sigma, p, q} \text{sgn}(p) \text{sgn}(q) \prod_{i=1}^{N_p} \langle \psi_p(i) | \phi_{\sigma(i)} \rangle \langle \phi_{\sigma(i)} | \psi_q(i) \rangle \prod_{j=N_p+1}^{N} \langle \psi_p(j) | \psi_q(j) \rangle$$

$$= \frac{1}{N!N!} \sum_{\sigma, p, q} \text{sgn}(p) \text{sgn}(q) \prod_{i=1}^{N_p} \langle \psi_p(\sigma^{-1}(i)) | \phi_{i} \rangle \langle \phi_{i} | \psi_q(\sigma^{-1}(i)) \rangle \prod_{j=N_p+1}^{N} \langle \psi_p(\sigma^{-1}(j)) | \psi_q(\sigma^{-1}(j)) \rangle.$$
This fidelity is independent of \( \mu(N_p + 1), \ldots, \mu(N) \). Therefore, for each \( \mu \) we can define a mapping \( U : \{1, \ldots, N_p\} \rightarrow \{1, \ldots, N\} \) by \( U(i) = \mu(i) \) for \( i = 1 \ldots N_p \) such that \( U(i) < U(i+1) \) for \( i = 1 \ldots N_p - 1 \). Note that each \( U \) can also be viewed as a subset of cardinality \( N_p \) of the set \( \{1, \ldots, N\} \). As \( N_p! \) different \( \mu \) result in the same \( U \), this allows us to write the fidelity as

\[
\mathcal{F} = \sum_U \sum_{\pi_P} \sum_{\pi_Q} \text{sgn}(\pi_P) \text{sgn}(\pi_Q) \prod_{i=1}^{N_p} \left| \langle \psi_{\mu(\pi(i))} | \phi_i \rangle \right|^2 = \sum_U \sum_{\pi_P} \text{sgn}(\pi_P) \prod_{i=1}^{N_p} \left| \langle \psi_{\mu(\pi(i))} | \phi_i \rangle \right|^2,
\]

which corresponds to Eq. (7).
