Infarcted fibroadenoma of the breast: report of two new cases with review of the literature

Faruk Skenderi1, Fikreta Krakonja2 and Semir Vranic1*

Abstract

Introduction: Fibroadenomas are the most common benign breast tumors in young women. Infarction is rarely observed in fibroadenomas and when present, it is usually associated with pregnancy or lactation. Infarction can exceptionally occur as a complication of previous fine-needle aspiration biopsy or during lactation and pregnancy.

Materials and methods: Retrospective review of 650 cases of fibroadenomas diagnosed at our institution during the 8-years period identified two cases of fibroadenomas with infarction (rate ~0.3%).

Results: Two partially infarcted fibroadenomas were diagnosed on core biopsy and frozen section in an adolescent girl (13 years old) and in a young woman (25 years old), respectively. No preceding fine-needle aspiration biopsy was performed in these cases, nor were the patients pregnant or lactating at the time of the diagnosis.

Conclusion: Spontaneous infarction within fibroadenoma is a rare phenomenon in younger patients. The presence of necrosis on core biopsy or frozen section should be cautiously interpreted and is not a sign of malignancy.

Introduction

Fibroadenomas are the most common benign neoplasms of the breast usually affecting adolescents and young women [1,2]. Infarction in benign breast lesions is rare and may occur in various conditions, including fibroadenomas [1,3]. Infarction within a fibroadenoma was first described by Delarue and Redon in 1949 [4] and usually affects young women during pregnancy or lactation, but may occur at any age following fine-needle aspiration biopsy (FNA) [1,5-8].

Clinically, fibroadenoma typically presents as a palpable mass and may occasionally be mistaken for inflammatory lesions due to pain and tenderness or for malignancy due to hardness, fixation to the surrounding tissue or bloody nipple discharge [2,9,10].

Spontaneous infarction of fibroadenomas not related to previously mentioned causes occurs exceptionally and only a few cases are described in the available literature [2,7,9,11-14].

Herein, we describe a review of fibroadenomas of the breast with two new cases of spontaneous infarction, unrelated to any known risk factor.

Materials and methods

We did a retrospective search of our database for fibroadenomas of the breast that were diagnosed at our department during the 8 years period (2005–2012). Two cases of fibroadenoma with spontaneous infarction were identified. Paraffin-embedded tissue blocks and hematoxylin and eosin (H&E) slides were retrieved from the pathology archive and retrospectively reviewed (F.S. and S.V.).

In a case #1 immunohistochemical staining against estrogen receptor (ER, clone: 1D5, Dako, Glostrup, Denmark) and progesterone receptor (PR, clone: PgR636, DAKO, Glostrup, Denmark) was performed.

Clinical history was available for both cases along with radiologic images (ultrasound and magnetic resonance imaging [MRI]).
**Results**

Our search revealed 650 fibroadenomas during the period 2005–2012. Infarcted fibroadenomas were diagnosed in two patients (rate 0.3%): an adolescent girl (13 years old, Case #1) and in a young woman (25 years old, Case #2). Both patients had no previous history of pregnancy, lactation or previous FNA. No hormonal disturbances were present in the patients. Postoperative course was uneventful in both patients.

**Case 1**

A 13-year-old pubertal girl presented with a rapidly growing, mobile and painful mass in the right breast. Radiologic findings (ultrasound and MRI) indicated the presence of a well-circumscribed tumor of the right breast consistent with a juvenile fibroadenoma (BI-RADS Category 2) (Figure 1A-B).

Radiologist performed a core needle biopsy that revealed a fibroepithelial lesion exhibiting focal necrosis but without malignant cells (classified as B3 lesion) which led to the immediate excision biopsy, performed a week later (Figure 2A).

Grossly, the tumor was an encapsulated, soft yellow, measuring 40×35×25 mm with foci of hemorrhage and necrosis. The entire tumor was submitted for microscopic evaluation. Microscopic findings were consistent with partially infarcted benign fibroadenoma with focal increased stromal cellularity resembling that of benign phyllodes tumor (Figure 2B-C). Squamous metaplasia, observed in close proximity to the necrotic foci, was present and was reminiscent of the so-called necrotizing syringometaplasia in the skin or necrotizing sialometaplasia in salivary glands (Figure 2D).

In Case #1, both epithelial and stromal cells were focally positive for estrogen receptor (ER) and progesterone receptor (PR) (~20% of the cells with weak to moderate nuclear intensity).

**Case 2**

A 25-year-old gravida 0, para 0 woman presented to a breast radiologist with a short history of a rapidly growing palpable and painful tumor in the left breast. Clinical and radiologic findings (ultrasound) were suggestive of juvenile fibroadenoma or intraductal papilloma (BI-RADS Category 2) and the patient was referred to the breast surgeon. The excision biopsy was performed and intraoperative frozen section consultation was obtained which read as a benign fibroepithelial tumor with focal intratumoral hemorrhage without signs of malignancy.

Gross examination revealed a nodular, circumscribed tumor, measuring 25×20×17 mm that was soft, yellow with peripheral areas of hemorrhage. The entire tumor was submitted for histopathologic evaluation which revealed juvenile (cellular) fibroadenoma with foci of hemorrhage and necrosis (Figure 3A-B). No evidence of malignancy was found.

**Discussion**

Fibroadenomas are the most common benign tumors of the breast that usually affect premenopausal women but may occur at any age. Diagnosis of fibroadenoma rarely poses a diagnostic dilemma, even on core biopsy, FNA or frozen section. We presented here two rapidly growing infarcted fibroadenomas that were causing pain. Infarction within fibroadenoma is a very rare event and the frequency of infarction in our study is in line with a study of Haagensen [15] who found only five infarcted cases among 1,000 reviewed breast fibroadenomas (rate: 0.5%). Another two studies based on the series of fibroadenomas in West African women revealed a slightly higher incidence of spontaneous infarction (0.9%) [16,17]. The highest frequency (3.6%) was reported in a recent study of Al-Atrooshi [18].

The presence of infarction and necrosis are usually worrisome signs in breast pathology although spontaneous

Infarction can be seen in variety of benign breast lesions including fibroadenoma, phyllodes tumor, lactating adenoma, and intraductal papilloma [3,19-23]. Spontaneous infarction in fibroadenomas is a rare phenomenon and usually associated with pregnancy, lactation or a recent FNA [5-7]. Exceptionally, spontaneous infarction may affect multiple fibroadenomas in the same patient [24]. Infarction may also be associated with the use of oral contraceptives [25]. Rarely, it can be seen in young patients without any associated risk factors, as illustrated in our two cases. The cause and mechanism of infarction are largely unknown. One of the possible explanations is that infarction represents a spectrum of regressive changes that also may include calcification and hyalinization, both of which are much more commonly seen in fibroadenomas [26]. Newman et al. [27] also found thrombo-occlusive vascular changes as a possible cause of infarction within fibroadenomas.

In our first case, a focus of necrosis was seen on core biopsy which prompted excision biopsy while in the second case clinical suspicion for malignancy prompted an intra-operative frozen section consultation which also revealed the presence of intratumoral hemorrhage and necrosis. A meticulous histopathologic evaluation of the entire tumors, however, revealed no signs of malignancy despite the presence of necrosis. Of note, case #1 also

Figure 2 (A): Hematoxylin & Eosin (H&E) slide of a core biopsy showing a classical fibroadenoma with an area of necrosis (arrow) (5x); (B): An excision biopsy revealing a fibroadenoma with a focal morphologic features of benign phyllodes tumor (H&E, 10x); (C): A zone of necrosis (H&E, 10x); (D): Squamous metaplasia, observed in close proximity of necrotic foci, reminiscent of the so-called necrotizing syringometaplasia in the skin or necrotizing sialometaplasia in salivary glands (H&E, 10x).

Figure 3 (A): A classical cellular (juvenile) fibroadenoma (H&E, 10x); (B): An area with hemorrhage and necrosis (H&E, 5x).
showed areas of squamous metaplasia resembling so-called necrotizing syringometaplasia in the skin or sialometaplasia in salivary glands. This phenomenon has already been described in infarcted breast fibroadenomas [28] and can also be seen in other benign breast lesions in a close proximity to the area of infarction (e.g. intraductal papilloma, [20]).

Fibroadenomas, particularly in older women, may be affected by various proliferative changes including malignant epithelial lesions [29,30]. The most frequent are in situ carcinomas (both ductal and lobular), and their invasive counterparts [30-32]. Exceptionally, sarcomas may also develop within fibroadenomas (e.g. angiosarcoma, osteosarcoma) [33,34]. Little is known about the molecular mechanisms that drive the development and progression of malignant tumors within fibroadenomas. Comparative studies that analyzed various molecular markers in fibroadenomas and breast carcinomas failed however to identify the potential drivers [35,36]. However, a clonality study of Kuijper et al. [37] indicated that fibroadenomas possessed a potential to progress in an epithelial direction (carcinoma) or in a stromal direction (phyllodes tumor).

We conclude that partial spontaneous infarction is a rare event in breast fibroadenomas and may not be associated with any known risk factor. The presence of necrosis on core biopsy or intra-operative frozen section should be cautiously interpreted and is not itself a sign of malignancy.

Consent
The case reports were shared with the local ethical committee whose policy is not to review case reports.

Competing interests
The authors declare no conflict of interest.

Authors’ contributions
SV and FK have been directly involved in diagnosis and interpretation of patient’s diagnosis. FS and SV conceived the study design. All authors wrote and approved the final manuscript.

Acknowledgment
The authors thank Dr. Zoran Gatalica, MD, DSc, Caris Life Sciences, Phoenix, Arizona, United States of America for proof reading the manuscript and critical comments.

The preliminary results of the study were in part presented at the XXIX International Congress of the International Academy of Pathology, Cape Town, South Africa, 2012.
