Abstract

This article gives a contemporary and to some extent pedagogical review of the current theoretical understanding of the formation of the superconducting state in metallic systems with a variable density of carriers. We make an attempt to describe the crossover from the Bose-Einstein condensation type (small densities) to the Bardeen-Cooper-Schrieffer one (large densities). The functional methods are used throughout the treatment. The most of the results are considered in a review form for the first time. Some of them (in particular, the possible opening of a pseudogap) are used to explain the experimental data available for high-temperatures superconductors.

1 Introduction

1.1 The general formulation of the problem

It is well known that there are two fundamental limiting descriptions which allow us to understand the equilibrium low temperature "superphenomena", such as superconductivity and superfluidity, in 3D systems:

i) Bardeen-Cooper-Schrieffer (BCS) theory \([1]\), in which the normal state is a degenerate Fermi liquid that undergoes a cooperative pairing (Cooper) instability at the temperature \(T_P\). Here two processes, the formation of Cooper pairs and their condensation (macroscopic occupation of a single quantum state), occur simultaneously at the transition temperature, \(T_{c^{3D}} = T_P\).

ii) Bose-Einstein condensation (BEC) of bosons (see e.g. \([2]\)) in another single quantum state at the temperature \(T_B\). In fact, these bosons (for instance, \(^4\)He) are tightly bound (composite) particles made up of an even number of fermions. The bosonic particles are formed at some high temperature \(T_P\) of their binding (dissociation). However in contrast to the BCS case, these "pre-formed" bosons condense only at \(T_B \ll T_P\). The above-mentioned single quantum states as well as an intermediate case, which we will discuss below in details, are usually described by an order parameter which is homogeneous in the 3D case assuming that there are no external fields.

Most, if not all, of the real 3D systems clearly fall into either category i) or ii). For example, \(^3\)He and essentially all metallic superconductors that we now understand are Fermi superfluids described by the first category, whereas \(^4\)He is a Bose superfluid described by the second one.

Nevertheless, the general problem of the crossover (or interpolation) from the BCS scenario of superconductivity with cooperative Cooper pairing to the formation of composite (separate) bosons and their BEC has remained of great interest for a long time. It is connected primarily with a deeper understanding of the phenomenon of superconductivity even for 3D systems which are clearly closer to the BCS limit.

The significance of the problem increases when one tries to reduce the dimensionality of space from 3D to 2D. In such a case the problem acquires not only fundamental significance, but also practical importance. The latter, as we shall discuss below, is mainly related to the discovery of the high-temperature superconductors (HTSC) \([3]\). It is not the only reason for the widespread interest in the problem of the crossover. Even from the theoretical point of view the 2D crossover is far more mysterious than the 3D one. At first glance the BCS limit with weak attraction and high fermion density is completely different from the Bose limit with strong coupling and low boson density. Indeed, the simplest BCS theory predicts a finite value of \(T_{c^{2D}} = T_P^{2D}\) while the BEC is forbidden in 2D systems for massive bosons \([2]\) for which \(T_B^{2D} = 0\). This is the reason one might ask whether it is possible to obtain a 2D crossover.

It is worthwhile to note here that by virtue of the Coleman-Mermin-Wagner-Hohenberg theorem \([4]\) a "super-behaviour" \([1]\) with homogeneous order parameter (the latter related to breaking of some continuous symmetry) is not possible for pure 2D systems. This is

\(^{1}\)"Super-behaviour" refers to 2D ferro- or antiferromagnetism in the case of the Mermin-Wagner theorem and to superfluid behaviour in Hohenberg’s theorem, while the Coleman theorem is the field-theoretical generalization of the previous theorems (see e.g. \([3]\)).
due to the fluctuations of the order parameter (in particular of its phase) destroying the long-range order [3] (see also [3]). Therefore, the temperature $T^{2D}_c$ of establishing long-range order has to be zero. The statement that $T^{2D}_c = 0$ is in agreement with this general theorem. In fact the BCS result $T^{2D}_B$ does not contradict these theorems if one remembers that as a rule the BCS theory presupposes the mean field (MF) approach. Thus it does not take into account any fluctuations and the result only means that $T^{MF(2D)}_c = T^{2D}_P \neq 0$, while the temperature $T^{2D}_c$ of actually establishing the long-range order is zero in this case as well. Such a conclusion, however, results in a general question: how can one study 2D models of superconductors with finite $T_c$ values?

There are at least two ways to answer this question. First, 2D models are only a mathematical idealization and any real system must be at least quasi-two dimensional (quasi-2D). This immediately gives $T_c \neq 0$, although $T_c < T^{MF}_c$. Second, there is another interesting possibility for 2D systems to pass into the superfluid state at a temperature which is usually denoted by $T_{BKT}$. This corresponds to the so called Berezinskii-Kosterlitz-Thouless (BKT) phase transition. The BKT superfluid state has an inhomogeneous order parameter and is therefore not forbidden by the above-mentioned 2D theorems. The formation of this state is quite different from the ordinary superconducting transition and results in a new way of condensation (see Chapter 5).

The possibility for real systems to undergo the BKT transition crucially depends on their spatial anisotropy. Thus, one should study both 2D and quasi-2D cases.

Another important aspect of the crossover problem is related to the following unusual property of the HTSC compounds. Almost all the physical characteristics of HTSC’s ($T_c$ included) crucially depend on the itinerant carrier density. This means that the crossover in superconducting systems cannot be studied without taking into account the changing delocalized fermion density. We believe that many of the HTSC ”anomalies” are caused by the unusual (two-stage) formation of the superconducting state in 2D and (very probably) quasi-2D systems with an arbitrary carrier density [4].

Hopefully, this short introduction has convinced the potential readers that the superconducting condensate formation at the different densities of interacting fermions (in particular, in the BCS and Bose limiting cases) deserves a separate review.

1.2 History

The idea that the composite bosons (or, as they called, local pairs) exist and define the superconducting properties of metals is in fact more then 10 years older than the BCS theory. As early as 1946, a sensational communication appeared saying that the chemist-experimentator Ogg had observed superconductivity in the solution of Na in NH$_3$ at 77$K$ [10]. It is very interesting that the researcher made an attempt to interpret his own result in terms of the BEC of paired electrons. Unfortunately, the discovery was not confirmed and both it and his theoretical concept, were soon completely forgotten (for the details see e.g. [11]).

It is appropriate to note that the history of superconductivity has many similar examples. Probably, this explains why Bednorz and Müller named their first paper ”Possible high-$T_c$ superconductivity...” [3]. And even today there appear many unconfirmed communications about room-temperature superconducting transitions.

A new step, the development of the local pair concept, was taken in 1954 by Schafroth
who in fact re-discovered the idea of the electronic quasi-molecules [12]. This idea was further developed in the Schafroth, Blatt and Butler theory of quasi-chemical equilibrium [13], where superconductivity was considered versus the BEC. Such a scenario, unfortunately, could not compete with the BCS one due to some mathematical difficulties which did not allow the authors to obtain the famous BCS results. Then the triumph of the BCS theory replaced the far more obvious concept of the local pairs and their BEC by the Cooper ones and their instability which takes place in the necessary presence of a Fermi surface (more precisely a finite density of states at the Fermi level). In contrast for the local (i.e. separated) pairs the formation is not in principle connected to this density of electronic states. Also unlike the local pairs, the Cooper ones are highly overlapping in real space. Therefore, the Cooper pairing should be understood as a momentum space pairing.

Later experiment reminded us about the local pairs. It was Frederikse et al. [14] who found that the superconducting compound SrTiO$_3$ ($T_c \sim 0.3$K) has a relatively low density of carriers and, moreover, this density is controled by Zr doping. The first deep discussion of the possibility of the BCS-Bose crossover and pairing above the superconductivity transition temperature for a low density of carriers was carried out by Eagles [15] (see also his et al. relatively recent article [16]) in the context of SrTiO$_3$.

The further history of the investigation of the BCS-Bose crossover has been often cited in the current literature. So, we note only that the features of 3D crossover at $T = 0$ were considered in [17], and its extension to finite temperatures was first given by Nozieres and Schmitt-Rink [18].

The 2D crossover in superfluid $^3$He was studied in [19], where the very natural and convenient physical parameter $\varepsilon_b$, the bound pair state energy, was first used.

The discovery of HTSC significantly stimulated the interest in the problem of crossover and related phenomena. There are many articles dealing with its study and we can only mention some of them at this point [20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31] (see also the recent excellent review [32] devoted to other aspects of the BCS-Bose crossover, e.g. lattice models, time-dependent Ginzburg-Landau theory, numerical study of normal state crossover etc., which we because of this shall not discuss). We note only that some historical debates are associated with the parallel (and generally speaking independent) development of the macro- and microphysics of superfluidity and superconductivity since their discoveries were touched upon by Ginzburg in his new extremely comprehensive survey [33].

**1.3 Relevance to the high-temperature superconductors**

As we have already mentioned the crossover problem appears to be relevant to the general problem of the understanding of the HTSC. Indeed, these superconducting compounds have some peculiarities which place them much closer to the Bose or at least to the crossover region than majority of low temperature superconductors. We shall discuss the peculiarities in detail here.

Certainly, it is necessary to point out right away that the crossover phenomena do not (and cannot) address the problem of the mechanism for HTSC. The problem of HTSC itself is very difficult and controversial. Nevertheless the treatment of the crossover may shed light on some of the features of HTSC.
Almost all HTSC reveal following common properties:

- a relatively low and easily varied density of itinerant (appeared owing to the doping) carriers;
- a 2D, or more exactly quasi-2D, character of the conductivity and the magnetism;
- the block structure of the crystal lattices, i.e. from 1 to 6 superconducting CuO$_2$ layers per unit cell.

Let us consider these items. The ground state of the copper-oxide based materials forms due to the strong antiferromagnetic spin fluctuations in the proximity of the metal-insulator transition (see e.g. review [34]). It seems plausible that further doping of these materials results in the appearance of weakly interacting (i.e. non-strongly correlated) itinerant carriers (holes). However the exact nature of the ground state including the strong electron-electron correlations is in fact not yet established. The density $n_f$ of these holes is not as large as in ordinary metals, so the mean distance between them proves to be comparable with a pair size $\xi_0$ or a coherence length $\xi$. This situation is significantly different from the conventional BCS theory where the parameter $\xi_0$ greatly exceeds the mean distance between carriers which is $\sim n_f^{1/2}$. Experimentally the dimensionless value of $k_F\xi_0$ ($k_F$ is the Fermi momentum) which describes the ratio of the pair size and the distance between carriers is about $5 - 20$ for HTSC while for the low-temperature superconductors it is about $10^3 - 10^4$ [20, 34].

It follows from the above that the new materials are likely to be in an intermediate regime between the Cooper pairs and the composite bosons, at least when the doping is not large and the value of $T_c$ is far from the highest possible (optimal) one. Although there is some evidence [28] that HTSC at the optimal doping are closer to the BCS limit than to the Bose one.

Besides, because the coherence length is less than a lattice spacing in the direction perpendicular to the CuO$_2$ planes ($c$-direction), the superconductivity in the copper oxides takes place mainly in the isolated CuO$_2$ layers (or their blocks). This is the reason why pure 2D models of HTSC are commonly accepted. Undoubtedly these cuprate layers are connected even if they are situated in different unit cells. The mechanisms for this connection (by coherent or incoherent electronic transport) are not yet known exactly. There is no question, however, that one has to take into account the possibility of different (for instance, direct or indirect) interlayer hoppings to develop a full theory of HTSC. Therefore, strictly speaking, we need to consider quasi-2D models of these superconductors. Moreover, as we have already mentioned, it is necessary to extend the system into a third-dimension in order to have a finite value for $T_c$. It can be seen from the anisotropy of the conductivity that the influence of the third-dimension varies strongly from one family of cuprates to the other. For example, the anisotropy reaches $10^5$ for the Bi- and Tl-based cuprates, while its value for YBaCu$_3$O$_{6+\delta}$ compound is close to $10^2$. It seems plausible that in the Bi(Tl)-compounds where the transport in the $c$-direction is incoherent that the scenario with BKT transition is more probable. In the Y-ones this transport is rather

\footnote{It is well to bear in mind that the coherence length strictly speaking is distinguished from the pair size, especially at low carrier density (this question will be treated in Section 3.4).}
coherent and the superconducting state, at least at high doping, has a 3D character, with a homogeneous condensate which appears in the ordinary way.

In general, it is now evident that, depending on the crystal anisotropies (and/or the relationship between the intensity of c-transport and the doping value) the quasi-2D systems can undergo two or even three phase transitions. The first one is from the normal phase to another normal (with a pseudogap) phase with a finite density of incoherent pairs. The second one is from the latter phase to the BKT phase with an algebraic order. The third and final one is from the BKT phase to the superconducting phase with long-range order. These possibilities will be discussed below.

The role of interplanar effects inevitably increases when the superconducting planes are situated in the same unit cell so that the carriers in the adjacent layers are strongly coupled and can form interplanar pairs. This possibility together with the concentration effects brings about the simultaneous existence of the Cooper and local pairs in the system.

1.4 Outline

The remainder of this review is organized as follows. In Chapter 2 we first describe the model for studying the BCS-Bose crossover, especially in 3D systems. Then in Section 2.2 we introduce in detail the functional integral formalism which will be used throughout. The rest of this Chapter is devoted to applying the methods developed to the 3D crossover.

The zero temperature 2D crossover is discussed in Chapter 3. Considerable attention will be given to the effective potential (see also Appendix A), which allows one to obtain the main equations. The kinetic terms of the effective action are obtained in Section 3.4. This gives one the possibility to investigate the dependencies of the coherence length and the penetration depth on the carrier density.

In Chapter 4 the quasi-2D crossover is studied.

Finally, the finite temperature 2D crossover is addressed in Chapter 5. We describe how it proves necessary to modify the accepted methods to consider the BKT phase formation (refer also to Appendices B and C) and its dependence on carrier density correctly. An attempt to explain some observable normal state anomalies HTSC is also made.

Acknowledgments

We would like to thank Profs. V.P. Gusynin and V.A. Miransky, Drs. E.V. Gorbar, I.A. Shovkovy and V.M. Turkowskii for their fruitful collaboration and numberless discussions which helped to make clear some deep questions of the low dimensional phase transitions. We also indebted to Profs. V.G. Bar’yahtkar, P.I. Fomin and I.V. Stasyuk whose stimulating support at the different stages of the work allowed us to complete the review. Particularly we thank Prof. R.M. Carter and Dr. I.A. Shovkovy for many thoughtful comments on the earlier version of this manuscript. At last, one of us (S.G.Sh) is grateful to the members of the Department of Physics of the University of Pretoria, especially Prof. R.M. Carter and Dr. N.J. Davidson, for very useful points and hospitality.
2 3D crossover: critical temperature

It is most convenient for studying the crossover to start with the 3D case where there is no problem with establishing the long-range order below $T_{c}^{3D}$. We shall mainly follow here the paper [24] (see also the review [32]) in which the corresponding results were obtained by applying the more appropriate in this case the functional integral formalism rather than to the original paper [18].

2.1 Model

Let us introduce a continuum field model of fermions with an attractive two-body interaction. Our goal is to consider how the critical temperature $T_{c}^{3D}$ changes as a function of attraction and to establish the main factors which determine it in the BCS and Bose regimes.

The simplest model is described by the Hamiltonian density

$$H = -\psi_{\sigma}^{\dagger}(x) \left( \frac{\nabla^{2}}{2m} + \mu \right) \psi_{\sigma}(x) - V \psi_{\uparrow}(x) \psi_{\downarrow}(x) \psi_{\downarrow}(x) \psi_{\uparrow}(x),$$

(2.1)

where $x \equiv r, \tau$ ($r$ is a 3D vector); $\psi_{\sigma}(x)$ is the Fermi field; $m$ is the fermion effective mass; $\sigma = \uparrow, \downarrow$ is the fermion spin; $V > 0$ is the attraction constant. The chemical potential $\mu$ fixes the average density $n_{f}$ of the free (bare) carriers. We choose units in which $\hbar = k_{B} = 1$ and the system occupies the volume $v$.

Since we want to describe the Bose regime in terms of its constituent fermions, we have to allow the magnitude of the attraction $V$ to be arbitrary. In addition, we cannot use a simple BCS-like cutoff $\omega_{D} \ll \epsilon_{F}$ (usually $\omega_{D}$ is the Debye frequency) since we must allow the possibility for all the fermions to be affected by the interaction, not just for a small fraction ($\sim \omega_{D}/\epsilon_{F}$) in a shell around the Fermi energy $\epsilon_{F}$. We shall thus study a dilute Fermi gas in which the range of the attractive interactions can be characterized by a shape independent parameter, the scattering length $a_{s}$ in three dimensions. We shall describe in Section 2.3 how the ”renormalized” coupling $a_{s}^{-1}$ replaces ”bare” $V$.

2.2 Formalism

As was already noted, the functional integral approach along with the Matsubara thermal technique is more appropriate for the problem that is studied here and in the subsequent Chapters. Thus, let us consider the formalism used.

First of all, introducing Nambu spinors for fermion fields [36] (see also [1])

$$\Psi(x) = \left( \begin{array}{c} \psi_{\uparrow}(x) \\ \psi_{\downarrow}(x) \end{array} \right), \quad \Psi^{\dagger}(x) = \left( \begin{array}{cc} \psi_{\uparrow}^{\dagger}(x) & \psi_{\downarrow}(x) \end{array} \right)$$

(2.2)

one has to rewrite (2.1) in a more suitable form:

$$H = -\Psi^{\dagger}(x) \left( \frac{\nabla^{2}}{2m} + \mu \right) \tau_{3} \Psi(x) - V \Psi^{\dagger}(x) \tau_{+} \Psi(x) \Psi^{\dagger}(x) \tau_{-} \Psi(x),$$

(2.3)

where $\tau_{3}, \tau_{\pm} \equiv (\tau_{1} \pm i\tau_{2})/2$ are Pauli matrices.
Now the partition function is expressed through the Hamiltonian (2.3) as:

\[ Z(v, \mu, T) = \int D\Psi D\Psi^\dagger \exp \left\{ - \int_0^\beta d\tau \int d\mathbf{r} \left[ \Psi^\dagger(x) \partial_\tau \Psi(x) + \mathcal{H}(\mathbf{r}) \right] \right\}, \quad (2.4) \]

where \( \beta \equiv 1/T \) and \( D\Psi D\Psi^\dagger \) denotes the measure of the integration over the Grassman variables \( \Psi \) and \( \Psi^\dagger \), satisfying the antiperiodic boundary conditions: \( \Psi(\tau, \mathbf{r}) = -\Psi(\tau + \beta, \mathbf{r}) \) and \( \Psi^\dagger(\tau, \mathbf{r}) = -\Psi^\dagger(\tau + \beta, \mathbf{r}) \).

If it was possible to calculate the partition function (2.4) one could, in principle, obtain all thermodynamical functions from the thermodynamical potential

\[ \Omega(v, \mu, T) = -T \ln Z(v, \mu, T). \quad (2.5) \]

Using now the auxiliary Hubbard-Stratonovich complex scalar field in the usual way one can represent (2.4) in an equivalent form:

\[ Z(v, \mu, T) = \int D\Phi D\Phi^\ast \exp \left\{ - \int_0^\beta d\tau \int d\mathbf{r} \left[ |\Phi(x)|^2 V + \Psi^\dagger(x) \left[ \partial_\tau \hat{I} - \tau_3 \left( \frac{\nabla^2}{2m} + \mu \right) - \tau_- \Phi(x) - \tau_+ \Phi^\ast(x) \right] \Psi(x) \right] \right\}. \quad (2.6) \]

The main virtue of this representation is a nonperturbative introduction of the composite fields \( \Phi(x) = V\Psi^\dagger(x)\tau_+\Psi(x) = V\psi_\uparrow(x)\psi_\uparrow^\dagger(x) \), \( \Phi^\ast(x) = V\Psi^\dagger(x)\tau_-\Psi(x) = V\psi_\downarrow(x)\psi_\downarrow^\dagger(x) \) and the possibility to develop a consistent approach. Specifically, the expression (2.6) turns out to be rather convenient for studying such a nonperturbative phenomenon as, for example, superconductivity. In this case the complex Hubbard-Stratonovich field naturally describes the order parameter arising due to the formation of the Cooper or the local pairs. The average value of \( |\Phi| (\equiv \Delta) \) is proportional to the density of pairs, on the one hand, and determines the gap in the one-particle Fermi-spectrum, on the other.

The integration over fermion fields in (2.6) can be done formally even though \( \Phi \) and \( \Phi^\ast \) depend on the spatial and temporal coordinates. Thus, one obtains (formally exactly)

\[ Z(v, \mu, T) = \int D\Phi D\Phi^\ast \exp \left\{ -\beta \Omega(v, \mu, T, \Phi(x), \Phi^\ast(x)) \right\}, \quad (2.7) \]

where

\[ \beta \Omega(v, \mu, T, \Phi(x), \Phi^\ast(x)) = \frac{1}{V} \int_0^\beta d\tau \int d\mathbf{r} |\Phi(x)|^2 - \text{Tr} \ln G^{-1} + \text{Tr} \ln G_0^{-1} \quad (2.8) \]

is the one-loop effective action. This action includes in itself a series of terms containing derivatives with respect to \( \Phi(x) \) and \( \Phi^\ast(x) \). In the lowest orders it corresponds to the Ginzburg-Landau effective action.

The operation \( \text{Tr} \) in (2.8) is taken with respect to the space \( \mathbf{r} \), the imaginary time \( \tau \) and the Nambu indices. The action (2.8) is expressed through the fermion Green function which obeys the equation:

\[ \left[ -\mathbf{\hat{I}} \partial_\tau + \tau_3 \left( \frac{\nabla^2}{2m} + \mu \right) + \tau_- \Phi(\tau, \mathbf{r}) + \tau_+ \Phi^\ast(\tau, \mathbf{r}) \right] G(\tau, \mathbf{r}) = \delta(\tau)\delta(\mathbf{r}) \quad (2.9) \]
with boundary condition
\[ G(\tau + \beta, \mathbf{r}) = -G(\tau, \mathbf{r}). \]  
\[ (2.10) \]

The free Green function
\[ G_0(\tau, \mathbf{r}) = G(\tau, \mathbf{r})|_{\Phi, \Phi^*, \mu=0} \]  
\[ (2.11) \]
in (2.8) is needed to provide the regularization in the calculation of
\[ \Omega(v, \mu, T, \Phi, \Phi^*). \]  
The representation (2.7), (2.8) is exact, although to perform the calculation in practice it is necessary to restrict ourselves to some approximation. Below we shall use the assumption, generally accepted in the 3D case (and in some quasi-2D systems), that the approximation including only the quadratic (Gaussian) fluctuations of the fields \( \Phi(x) \) and \( \Phi^*(x) \) (about their equilibrium values which will now also be denoted as \( \Phi \)) describes the system quite well.

The thermodynamical potential \( \Omega \) as well as the partition sum \( Z \) now depend on \( \Phi \) and \( \Phi^* \) which play the role of the order parameter. The order parameter appears due to the fact that one uses the effective potential \( \Omega(v, \mu, T, \Phi, \Phi^*) \) instead of the exact potential \( \Omega(v, \mu, T) \). Thus, it becomes necessary to write down the additional equations which determine the values of \( \Phi \) and \( \Phi^* \).

Moreover, in some cases it is sufficient to use the mean field approximation as is done in the original BCS theory. Here, however, we include the fluctuations also. Therefore, one obtains
\[ Z(v, \mu, T, \Phi, \Phi^*) = \exp[-\beta \Omega_{pot}(v, \mu, T, \Phi, \Phi^*)] \times \]
\[ \int \mathcal{D}(\Delta \Phi)\mathcal{D}(\Delta \Phi^*) \exp \left\{ -\int_0^\beta d\tau_1 \int_0^\beta d\tau_2 \int d\mathbf{r}_1 \int d\mathbf{r}_2 \times \right. \]
\[ \left( \Delta \Phi^*(\tau_1, \mathbf{r}_1) \frac{\beta \delta^2 \Omega(\Phi, \Phi^*)}{\delta \Phi^*(\tau_1, \mathbf{r}_1) \delta \Phi(\tau_2, \mathbf{r}_2)} \bigg|_{\Phi, \Phi^* = \text{const}} \right) \Delta \Phi(\tau_2, \mathbf{r}_2) + \]
\[ \Delta \Phi(\tau_1, \mathbf{r}_1) \frac{\beta \delta^2 \Omega(\Phi, \Phi^*)}{2 \delta \Phi(\tau_1, \mathbf{r}_1) \delta \Phi(\tau_2, \mathbf{r}_2)} \bigg|_{\Phi, \Phi^* = \text{const}} \Delta \Phi(\tau_2, \mathbf{r}_2) + \]
\[ \left. \Delta \Phi^*(\tau_1, \mathbf{r}_1) \frac{\beta \delta^2 \Omega(\Phi, \Phi^*)}{2 \delta \Phi^*(\tau_1, \mathbf{r}_1) \delta \Phi^*(\tau_2, \mathbf{r}_2)} \bigg|_{\Phi, \Phi^* = \text{const}} \Delta \Phi^*(\tau_2, \mathbf{r}_2) \right\}, \]  
\[ (2.12) \]

where
\[ \Omega_{pot}(v, \mu, T, \Phi, \Phi^*) = \left( \frac{1}{V} \int d\mathbf{r} |\Phi(x)|^2 - T\text{TrLn}G^{-1} + T\text{TrLn}G_0^{-1} \right) \bigg|_{\Phi = \Phi^* = \text{const}} \]  
\[ (2.13) \]
is the mean field thermodynamical potential; \( \Delta \Phi(x) = \Phi(x) - \Phi \) and \( \Delta \Phi^*(x) = \Phi^*(x) - \Phi^* \) are the fluctuation deviations from the equilibrium value of the order parameter.

In present review we restrict the consideration of the fluctuations to the critical line \( (\Phi = \Phi^* = 0) \) only. So, the partition function \( [2.12] \) after integration over \( \Delta \Phi \) and \( \Delta \Phi^* \) acquires the form
\[ Z(v, \mu, T) = \exp[-\beta \Omega_{pot}(v, \mu, T, 0, 0) - \text{TrLn}G^{-1}], \]  
\[ (2.14) \]
\[3\text{We note that this Gaussian approximation does not work in the 2D case at } T \neq 0 \text{ and, thus, we must modify it to analyze this case (see Chapter 5).} \]
where now
\[
\Gamma^{-1}(\tau, r) \equiv \left. \frac{\beta \delta^2 \Omega(\Phi, \Phi^*)}{\delta \Phi^*(\tau, r) \delta \Phi(0, 0)} \right|_{\Phi, \Phi^* = 0} = \frac{1}{V} \delta(\tau) \delta(r) + \text{tr}[G(\tau, r)\tau_+ G(-\tau, -r)\tau_+]|_{\Phi, \Phi^* = 0}
\]
(2.15)
is the inverse Green function of the order parameter fluctuations.

To avoid possible misunderstanding, we shall write down the formulae for the Fourier transformations which are used throughout the paper; they connect the coordinate and momentum representations in the usual manner:
\[
F(i\omega_n, k) = \int_0^\beta d\tau \int d\mathbf{r} F(\tau, \mathbf{r}) \exp(i\omega_n\tau - ik\mathbf{r}),
\]
(2.16)
\[
F(\tau, \mathbf{r}) = T \sum_{n=-\infty}^{+\infty} \int \frac{dk}{(2\pi)^d} F(i\omega_n, k) \exp(-i\omega_n\tau + ik\mathbf{r}),
\]
(2.17)
where \(\omega_n = \pi T(2n+1)\) are the fermion (odd) Matsubara frequencies and \(d\) is the dimensionality of the space (remember that in this Chapter \(d = 3\)). In the case of bosons the frequencies should be replaced by even ones: \(\Omega_n = 2\pi nT\).

For example, the Green function (2.9) has, in the momentum representation, the following form:
\[
G(i\omega_n, k) = -i\omega_n \hat{I} + \tau_\delta \Phi - \tau_+ \Phi^* \omega_n^2 + \xi^2(k) + |\Phi|^2,
\]
(2.18)
where \(\xi(k) = \varepsilon(k) - \mu\) with \(\varepsilon(k) = k^2/2m\) and \(\Phi\) and \(\Phi^*\) are already taken to be constants.

### 2.3 The mean field analysis

Substituting (2.18) into (2.13), one arrives at (see Appendix A)
\[
\Omega_{\text{pot}}(v, \mu, T, \Phi, \Phi^*) = v \left\{ \frac{|\Phi|^2}{V} - 2T \int \frac{dk}{(2\pi)^d} \left[ \ln \cosh \frac{\sqrt{\xi^2(k)} + |\Phi|^2}{2T} - \xi(k) \right] + 2T \int \frac{dk}{(2\pi)^d} \left[ \ln \cosh \frac{\varepsilon(k)}{2T} - \varepsilon(k) \right] \right\},
\]
(2.19)
where \(d = 3\).

The stationary condition
\[
\frac{\partial \Omega_{\text{pot}}(v, \mu, T, \Phi^* c, \Phi^* c)}{\partial \Phi} \bigg|_{\Phi = \Phi^* = 0} = 0
\]
(2.20)
results in the standard gap equation
\[
\frac{1}{V} = \int \frac{dk}{(2\pi)^3} \frac{1}{2\xi(k)} \tanh \frac{\xi(k)}{2T_c^{MF}}.
\]
(2.21)
Here we use the notation $T_{c}^{MF}$ rather than $T_{c}^{3D}$ because $\Omega_{\text{pot}}$ describes the system in the mean field approximation only. In such a case $T_{c}^{MF}$ does not depend significantly on the dimensionality of the space. Besides, as it will be seen, the value of $T_{c}^{MF}$ may significantly exceed $T_{c}^{3D}$ (or the temperature of real condensation) in the strong coupling regime.

Before proceeding further, we need to describe how we regulate the ultraviolet divergence in the gap equation (2.21). The idea is to replace the bare $V$ by the low energy limit of the two body $T$-matrix (in the absence of a medium). In the 3D case we use the formula

$$m/4\pi a_s = -1/V + \int \frac{dk}{(2\pi)^3} \frac{1}{2\varepsilon(k)}$$

(2.22)

which defines the above-mentioned $s$-wave scattering length $a_s$. As a function of the bare interaction, $a_s^{-1}$ increases monotonically from $-\infty$ for a very weak attraction to $+\infty$ for strong attractive interaction. Above the two-body bound state threshold in vacuum ($a_s^{-1} = 0$), $a_s$ in fact is the ”size” of this bound state with energy $E_b = -1/ma_s^2$. The dimensionless coupling constant in the dilute gas model is then $1/k_F a_s$, which ranges from $-\infty$ in the weak coupling (BCS) limit to $+\infty$ in the strong coupling (Bose) one.

Using (2.22) and (2.21) one obtains directly the equation for the introduced transition temperature $T_{c}^{MF}$ in terms of the renormalized coupling $a_s$:

$$-\frac{m}{4\pi a_s} = \int \frac{dk}{(2\pi)^3} \left[ \frac{1}{2\xi(k)} \tanh \frac{\xi(k)}{2T_{c}^{MF}} - \frac{1}{2\varepsilon(k)} \right].$$

(2.23)

There are two unknown quantities in this equation $T_{c}^{MF}$ and $\mu$, and thus we need another equation,

$$-\frac{1}{\nu} \frac{\partial \Omega_{\text{pot}}(v, \mu, T_{c}^{MF}, \Phi, \Phi^*)}{\partial \mu} \bigg|_{\Phi=\Phi^*=0} = n_f,$$

(2.24)

which, as was already said, fixes the chemical potential for a given density.

Note that unlike the BCS analysis in which one usually assumes that $\mu = \epsilon_F$ (the non-interacting Fermi energy), in the crossover problem $\mu$ will turn out to be a strongly dependent function of the coupling as one goes into the Bose regime where all the particles are affected by the attractive interaction. It directly follows from (2.24) and (2.19) that the number equation is given by

$$n_F(\mu, T_{c}^{MF}) = \int \frac{dk}{(2\pi)^3} \left[ 1 - \tanh \frac{\xi(k)}{2T_{c}^{MF}} \right] = n_f.$$

(2.25)

In the weak coupling limit, $1/k_F a_s \rightarrow -\infty$, we find from the system (2.23) and (2.25) the well-known BCS result

$$\mu = \epsilon_F, \quad T_{c}^{MF} = \frac{8\gamma}{\pi \epsilon_F^2} \epsilon_F \exp \left( -\frac{\pi}{2k_F |a_s|} \right),$$

(2.26)

where $\gamma \simeq 1.781$.

The equations can also be solved analytically in the strong coupling limit, where, however, one observes that the roles of the gap and number equations are reversed: the gap equation (2.23) determines $\mu$, while the number equation determines $T_{c}^{MF}$. In this limit $1/k_F a_s \rightarrow +\infty$ and one finds tightly bound (separate) pairs with the energy $|E_b| = $
1/ma^2 (and |E_b| \gg \epsilon_F). The non-degenerate Fermi system has here \( \mu \approx -|E_b|/2 \) and its \( T^{MF}_c \approx |E_b|/2 \ln(|E_b|/\epsilon_F)^{3/2} \). But really such a system can be hardly recognized as a Fermi system because all the fermions are bound in the pairs, so (at least at rather small temperatures) they in fact form Bose (local pair) system.

This unbounded growth of the ”transition temperature” is an artifact of the approximation and there is, in fact, no sharp phase transition at \( T^{MF}_c \) (outside of weak coupling where \( T^{MF}_c = T^{3D}_c \) ignoring the small effects of thermal fluctuations). The point is that the mean field approximation becomes progressively worse with increasing coupling: the effective potential (2.19) at \( \Phi = \Phi^* = 0 \) can only describe a normal state consisting of essentially non-interacting fermions.

While this is adequate for weak coupling, in the strong coupling limit unbound fermions exist in the normal state only at very high temperatures. In this limit, where the system is completely non-degenerate, a simple ”chemical equilibrium” analysis (boson \( \leftrightarrow \) 2 fermions) yields a dissociation (pairing) temperature \( T^{dissoc} = |E_b|/\ln(|E_b|/\epsilon_F)^{3/2}(\approx T_P) \). We thus get convinced that for strong coupling \( T^{MF}_c \) is related to the pair dissociation scale rather than the \( T^{3D}_c(\ll T^{MF}_c) \) at which the coherence is established. As it will be seen below the temperature \( T_P \) has an evident physical meaning in the 2D case: in the region \( T_{BKT} < T < T_P \) (further \( T_P \)) the system does not have a condensate (superconducting state) but its one-particle spectrum acquires some features (in particular, the pseudogap) of superconductivity.

### 2.4 Beyond the mean field approximation

As we have seen the mean field thermodynamical potential (2.13) (or its direct form (2.19)) cannot be used to access the strong coupling limit. Therefore, to achieve this limit we have to include the effects of the order parameter fluctuations. It was already shown in Section 2.2 that treating the fluctuations at the Gaussian level is done by the partition function (2.12). It allows to incorporate the fluctuation into both the gap (2.20) and number (2.24) equations by adding the fluctuation correction to \( \Omega_{\text{pot}}(v, \mu, T, \Phi, \Phi^*) \). As discussed in [18, 32] in the 3D case it is sufficient, however, to take into account the fluctuation effects through the number equation only. That is why we do not need the correction \( \partial(\Omega - \Omega_{\text{pot}})/\partial \Phi|_{\Phi=\Phi^*=0} = 0 \) to the gap equation.

Consequently, we can restrict ourselves to calculation of the partition function at the critical temperature given by (2.21) that follows from (2.14) only. This permits us to get the fluctuation correction to the number equation (2.24). Thus, one finally obtains from (2.14) that

\[
\Omega(v, \mu, T, \Phi = \Phi^* = 0) = \Omega_{\text{pot}}(v, \mu, T, 0, 0) + \frac{vT}{(2\pi)^3} \sum_{n=-\infty}^{\infty} \int dK \ln \Gamma^{-1}(i\Omega_n, K),
\]

where

\[
\Gamma^{-1}(i\Omega_n, K) = \frac{1}{V} - \frac{1}{2} \int \frac{dk}{(2\pi)^3} \frac{1}{\xi(k + K/2) + \xi(k - K/2) - i\Omega_n} \times \left[ \frac{\tanh \frac{\xi(k + K/2)}{2T} + \tanh \frac{\xi(k - K/2)}{2T}}{2T} \right].
\]

13
Further, one has to remove the ultraviolet divergences from (2.28) by applying the same regularization procedure using the scattering length $a_s$ (see definition (2.22)) as in case of the gap equation (2.21). With this substitution (2.28) transforms to the form:

$$\Gamma^{-1}(i\Omega_n, \mathbf{K}) = \frac{1}{2} \int \frac{d\mathbf{k}}{(2\pi)^3} \left[ \frac{1}{\varepsilon(\mathbf{k})} - \frac{1}{\xi(\mathbf{k} + \mathbf{K}/2) + \xi(\mathbf{k} - \mathbf{K}/2) - i\Omega_n} \right] \times \left( \frac{\tanh \frac{\xi(\mathbf{k} + \mathbf{K}/2)}{2T}}{2T} + \frac{\tanh \frac{\xi(\mathbf{k} - \mathbf{K}/2)}{2T}}{2T} \right) - \frac{m}{4\pi a_s}. \quad (2.29)$$

According to [18], it is convenient to rewrite $\Omega(v, \mu, T, \Phi = \Phi^* = 0)$ in terms of a phase shift defined by $\Gamma(\omega \pm i0, \mathbf{K}) = |\Gamma(\omega, \mathbf{K})| \exp(\pm i\delta(\omega, \mathbf{K}))$. Then the new number equation is given by the equality (“conservation law”)

$$n_F(\mu, T_c^{3D}) + 2n_B(\mu, T_c^{3D}) = n_f, \quad (2.30)$$

with

$$n_B(\mu, T_c^{3D}) \equiv \int \frac{d\mathbf{K}}{(2\pi)^3} \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} n_B(\omega) \frac{\partial \delta(\omega, \mathbf{K})}{\partial \mu}, \quad (2.31)$$

where $n_B(\omega) \equiv [\exp(\omega/T) - 1]^{-1}$ is the Bose distribution function.

One sees from (2.30) that the system of fermions is separated into two coexisting and dynamically bounded subsystems: Fermi particles, or unbound fermions with density $n_F(\mu, T_c^{3D})$, and local pairs, or bosons with density $n_B(\mu, T_c^{3D})$. Such an interpretation is possible and natural on the critical line only, when the finite density of condensate $|\Phi|$ is not included nonperturbatively in $n_F(\mu, T)$. Besides, as we shall demonstrate in Chapter 5, if the order parameter has a nonzero value, one can study the number equation without taking into account the bosonic contribution.

The temperature $T_c^{3D}$ at which homogeneous long-range order is established is defined by the solution of (2.23) together with (2.30). At weak coupling (large $n_f$), the results are essentially unaffected by the inclusion of Gaussian fluctuations in the number equation and $T_c^{3D}$ is the same as the mean field $T_c^{MF}$ obtained above (see (2.26)).

In fact the equations can be solved in the Bose limit too. From (2.23) we find $\mu(T_c^{3D}) = -|E_b|/2$, which is one-half the energy required to break a pair. Further, (2.31) can be simplified because the inequality $|\mu|/T \gg 1$ is satisfied. From this inequality it follows that the isolated pole of $\Gamma(\omega, \mathbf{K})$ on the real axis is situated far from the branch cut. The pole and the cut represent a two-body bound state with the center-of-mass momentum $\mathbf{K}$ and the continuum of two-particle fermionic excitations, respectively. The low energy physics for $T \ll T_c^{MF}$ is thus dominated by this pole, and one can approximate the phase at the pole by $\delta(\omega, \mathbf{K}) \simeq \pi \theta(\omega - K^2/4m + 2\mu + |E_b|)$, so that

$$n_B(\mu, T_c^{3D}) = \frac{1}{4\pi^3} \int d\mathbf{K} n_B \left( \frac{K^2}{4m} - 2\mu - |E_b| \right). \quad (2.32)$$

Finally, one gets

$$T_c^{3D} = \left( \frac{n_f}{2\zeta(3/2)} \right)^{2/3} \frac{\pi}{m} = 0.218 \epsilon_F, \quad (2.33)$$

which is simply the BEC result for bosons of mass $2m$ and density $n_f/2$. 

14
Summarizing the underlying physics in these limiting cases it is necessary to stress the following:

i) The value of $T_{c3D}$ in the weak coupling limit results from thermal excitations of individual particles.

ii) In strong coupling case, $T_{c3D}$ results from thermal excitations of collective modes. These excitations are outside the range of mean field theory. That is one of the reasons why we took into account the fluctuations.

The physics is thus quite different in the two limits considered: the pair breaking in the first case and the motion of bound pairs in the other.

The results of the numerical solution of the equations are presented in [26] (see also [32]). It may be worth commenting that the numerical result for $T_{c3D}$ is a non-monotonic function of $1/k_F a_s$ with a maximum value at intermediate coupling which is slightly larger than the BEC value. The last is independent of the coupling constant. The situation is completely different for the discrete (lattice) model of the 3D crossover [18] where $T_{c3D}$ decreases as the coupling increases. So, certainly there is an optimal value of the coupling for $T_{c3D}$. The latter will also take place for the quasi-2D model which is in fact discrete in the third direction. We shall discuss such a model in Chapter 4.

3 2D crossover: $T = 0$

As we discussed in Introduction the 2D case has attracted much attention partly because its possible relevance to the layered HTSC.

To avoid the above-mentioned problem of how to determine the $T_c$ value correctly in the strictly 2D system it is worthwhile to start with the zero temperature case. The problem thus becomes, due to the integration over frequency (which replaces the summation over Matsubara frequencies), effectively a 3D one. Therefore, the 2D theorems [4] are not applicable to this case and one can speak about long-range order in the 2D systems at $T = 0$.

We shall follow here the paper [24] (see also its extended version in [37, 38]) where the most general functional methods were used throughout. However, it is more convenient to go to the limit $T = 0$ in the expressions from the previous Chapter rather than use the zero temperature technique as it was done in [24].

3.1 Model

The model Hamiltonian that we shall consider coincides with (2.1) with one very important exception: the dimensionality of the space here $d = 2$. This fact is crucial in the choice of the parameter which one has to change to trace the crossover. The fact is that 3D bound states in vacuum are known to form only if the corresponding coupling constant $V$ exceeds some threshold. Thus, for the real cases one cannot achieve the Bose regime even at very low carrier densities if the attraction is not strong enough. This is the main reason why we have studied the 3D crossover as the function of the "renormalized" coupling $a_s^{-1}$ which corresponds to the "size" (radius) of the bound state at $a_s^{-1} \geq 0$ only.

A thresholdless bound state formation in the 2D space [39] leads us to the important conclusion that one can reach the Bose regime by decreasing the density $n_f$ of bare
fermions at any coupling. So, to study the 2D crossover it is convenient and quite natural to regulate the density of carriers, or the Fermi energy $\epsilon_F$, which is the same for 2D metals with the simplest quadratic dispersion law: $\epsilon_F = \pi n_f/m$. In doing so, the coupling $V$ should be replaced by its renormalized value $\epsilon_b$ which is the energy of the bound state in vacuum. We stress here once again that this parameter can be defined in the 2D case at any bare coupling $V$. The dimensionless coupling constant in the 2D case – the physical analog (see above) of $1/k_F$, in 3D – is thus given by the ratio $\epsilon_F/|\epsilon_b|$, which changes from 0 (in the Bose limit $n_f \to 0$) to $\infty$ (in the BCS limit when $n_f \to \infty$).

### 3.2 The Effective Action and Potential

As we have already noted in the general case, (2.8) is impossible for $\Phi$ dependent on $x$. However, if one assumes the gradients of $\Phi$ and $\Phi^*$ to be small the action (2.8) can be naturally divided into kinetic and potential parts

$$\Omega(v, \mu, \Phi(x), \Phi^*(x)) = \Omega_{kin}(v, \mu, \Phi(x), \Phi^*(x)) + \Omega_{pot}(v, \mu, \Phi, \Phi^*),$$

(3.1)

where the effective potential has been defined by (2.13) and calculated in Appendix A (its final expression is given by (2.19)). The terms $\Omega_{kin}(\Phi(x), \Phi^*(x))$ with derivatives in expansion (3.1) contains the important physical information, therefore we shall consider it in Section 3.4.

Let us return to the effective potential. Going to the limit $T \to 0$ one obtains from (2.19)

$$\Omega_{pot}(v, \mu, \Phi, \Phi^*) = v \left[ \frac{|\Phi|^2}{V} - \int \frac{d\mathbf{k}}{(2\pi)^2} \left( \sqrt{\xi^2(\mathbf{k}) + |\Phi|^2} - \xi(\mathbf{k}) \right) \right],$$

(3.2)

where the terms which do not depend on $\Phi, \Phi^*$ and $\mu$ are omitted.

It is interesting that, in virtue of the invariance of the partition function (2.6) with respect to the phase transformation of the group $U(1)$

$$\Psi(x) \to e^{i\alpha x_3} \Psi(x), \quad \Psi^\dagger(x) \to \Psi^\dagger(x) e^{-i\alpha x_3},$$

$$\Phi(x) \to e^{-2i\alpha} \Phi(x), \quad \Phi^*(x) \to \Phi^*(x) e^{2i\alpha},$$

(3.3)

with real $\alpha$ the potential $\Omega_{pot}(v, \mu, \Phi, \Phi^*)$ (2.13) (see also (2.19) and (3.2)) can only be dependent on the invariant product $\Phi^* \Phi$.

The analytic solution of the problem for the 2D case that we consider here is easier than the 3D one. Indeed, after performing the integration over $\mathbf{k}$ in (3.2) one directly obtains that

$$\Omega_{pot}(v, \mu, \Phi, \Phi^*) = v |\Phi|^2 \left\{ \frac{1}{V} - \frac{m}{4\pi} \left[ \ln \frac{W - \mu + \sqrt{(W - \mu)^2 + |\Phi|^2}}{\sqrt{\mu^2 + |\Phi|^2} - \mu} + \frac{W - \mu}{\sqrt{\mu^2 + |\Phi|^2} - \mu} \right] \right\},$$

(3.4)

There is another transformation (when the sign of the phase $\alpha$ is defined by the fermion spin rather than the charge) under which the Hamiltonian (2.1) (or (2.3)) is also invariant. Such a transformation proves to be important for fermion-fermion repulsion (i.e. $V < 0$), or for the fermion-antifermion (electron-hole) channel of pairing. Apart from this difference the physics for the case of a repulsive interaction is identical to that under consideration. The complete set of gauge transformations for the Hamiltonian under consideration were originally given by Nambu [6].
where the value $W = k_B^2/2m$ is the conduction bandwidth and $k_B$ is the Brillouin boundary momentum.

### 3.3 Main equations and analysis of solution

If the quantity $\Delta$ is defined as the average value of $|\Phi|$, then the equation for the extremum

$$\left. \frac{\partial \Omega_{\text{pot}}(v, \mu, \Phi, \Phi^*)}{\partial \Phi} \right|_{\Phi=\Phi^*=\Delta} = 0,$$

yields, according to (3.4)

$$\Delta \left[ \frac{1}{V} - \frac{m}{4\pi} \ln \frac{W - \mu + \sqrt{(W - \mu)^2 + \Delta^2}}{\sqrt{\mu^2 + \Delta^2 - \mu}} \right] = 0,$$

while the condition

$$-\frac{1}{v} \left. \frac{\partial \Omega_{\text{pot}}(v, \mu, \Phi, \Phi^*)}{\partial \mu} \right|_{\Phi=\Phi^*=\Delta} = n_f,$$

which sets the density of the particles in the system, takes the form

$$W - \sqrt{(W - \mu)^2 + \Delta^2} + \sqrt{\mu^2 + \Delta^2} = 2\epsilon_F,$$

where we made use of the relation between $\epsilon_F$ and $n_f$ in the 2D case.

Equations (3.6) and (3.8), which were obtained in the mean field approximation which is quite sufficient at $T = 0$, make up a set for finding the quantities $\Delta$ and $\mu$ as functions of $W$ and $\epsilon_F$ (or $n_f$). It differs from the similar set of [20] by the explicit dependence on $W$ that, in principle, can be important for the case of narrow or multi-band systems [35].

It should also be noted (see also the discussion after the equation (2.24)) that the necessity to utilize the system of equations in order to find self-consistently $\Delta$ and $\mu$ has been known for a long time (see [1]). However, the fermion density in real 3D metals is virtually unchanged in practice so that, as a rule, the equation for $\mu$ is trivialized to the equation $\mu = \epsilon_F$ and only the value $\Delta$ is regarded as unknown. The importance of the second equation for small particle densities was earlier pointed out in the papers [15, 17].

Equations (3.6) and (3.8) allow, along with the trivial solution ($\Delta = 0, \mu = \epsilon_F$) the nontrivial one:

$$\Delta^2 = \frac{\epsilon_F(W - \epsilon_F)}{\sinh^2(2\pi/mV)};$$

$$\mu = \epsilon_F \coth \frac{2\pi}{mV} \frac{W}{2} \left( \coth \frac{2\pi}{mV} - 1 \right),$$

which is valid for any physically reasonable values of the relevant parameters. It is also very interesting that for small $\epsilon_F$, there is a region where $\mu < 0$, and that the sign changeover occurs at a definite point $\tilde{\epsilon}_F = W/2[1 - \tanh(2\pi/mV)]$.

---

5This is the parameter that is responsible for the appearance of a new (ordered, or with lowered symmetry) phase (see Section 2.2.).
The expressions that are found in [19, 20] follow directly from (3.9) if, treating \( W \) as large and the attraction \( V \) as small, we introduce the 2D two-body binding energy 

\[
\varepsilon_b = -2W \exp\left(-\frac{4\pi}{mV}\right),
\]

(3.10) which does not include any many-particle effects. The introduction of the expression (3.10) enables one to take the limit \( W \gg \varepsilon_F \) and thus justifies to a certain degree the use of the parabolic dispersion law. Second the fitting parameter \( \varepsilon_b \) is more physically relevant. For example it is well-defined even for potentials with repulsion. We stress that the introduction of \( \varepsilon_b \) instead of \( V \) also allows us to regulate the ultraviolet divergence, which is in fact present in the gap equation (3.6). So, this step is quite similar to the step from equation (2.21) to (2.23).

It should be mentioned that, in a dilute gas model, the existence of a two-body bound state in vacuum is a necessary (and sufficient) condition for a Cooper instability [19, 20, 32]. This statement becomes nontrivial if one considers two-body potentials \( V(r) \) with short-range repulsion (e.g., hard-core plus attraction), so that one has to cross a finite (but really very weak [39]) threshold in the attraction before a bound state forms in vacuum.

Thus, by making use of (3.10) it is easy to simplify (3.9) [19, 20, 32]:

\[
\Delta = \sqrt{2|\varepsilon_b|\varepsilon_F}; \quad \mu = -\frac{|\varepsilon_b|}{2} + \varepsilon_F,
\]

(3.11) with \( \bar{\varepsilon}_F = |\varepsilon_b|/2 \).

To understand the physical significance of these remarkably simple results we look at the two limits of this solution. For very weak attraction (or high density) the two-particle binding energy is extremely small, i.e. \( |\varepsilon_b| \ll \varepsilon_F \), and it is seen that we recover the well-known BCS results with strongly overlapping in \( r \)-space Cooper pairs. The chemical potential \( \mu \approx \varepsilon_F \), and the gap function \( \Delta \ll \varepsilon_F \).

In the opposite limit of very strong attraction (or a very low particle density) we have a deep two-body bound state \( |\varepsilon_b| \gg \varepsilon_F \), and find that we are in a regime in which there is BEC of composite bosons, or "diatomic molecules". The chemical potential here \( \mu \approx -|\varepsilon_b|/2 \), which is one half the energy of pair dissociation for tightly bound (local) pairs.

It should also be kept in mind that in the local pair regime (\( \mu < 0 \)) the gap \( \varepsilon_{gap} \) in the quasiparticle excitation spectrum equals not \( \Delta \) (as in the case \( \mu > 0 \)) but rather \( \sqrt{\mu^2 + \Delta^2} \) (see [17] and the review [32]).

Leaving aside the analysis of \( \Omega_{pot} \) for arbitrary values of the parameters (see [37]), let us consider the most interesting case \( W \to \infty, V \to 0 \) with finite \( \varepsilon_b \). Then finding from (3.10) the expression for \( 4\pi/mV \) and substituting it into (3.4) we obtain 

\[
\Omega_{pot}(v, \mu, \Phi, \Phi^*) = v \frac{m}{4\pi} |\Phi|^2 \left( \ln \frac{\sqrt{\mu^2 + |\Phi|^2} - \mu}{|\varepsilon_b|} - \frac{\mu}{\sqrt{\mu^2 + |\Phi|^2} - \mu} - \frac{1}{2} \right),
\]

(3.12) whence we arrive at the expressions near point \( \Phi, \Phi^* \to 0 \):

\[
\Omega_{pot}(v, \mu, \Phi, \Phi^*) \mid_{\Phi, \Phi^* \to 0} \approx
\]
\[
\begin{cases}
  v \frac{m}{4\pi} |\Phi|^2 \left( \ln \frac{2|\mu|}{|\varepsilon_b|} + \frac{|\Phi|^2}{8\mu^2} \right), & \mu < 0 \\
  v \frac{m}{4\pi} |\Phi|^2 \left( \ln \frac{|\Phi|^2}{2\mu|\varepsilon_b|} - \frac{1}{2} \right) - 2\mu^2, & \mu > 0
\end{cases}
\] (3.13)

Equations (3.6) and (3.8) can be written as
\[
\sqrt{\mu^2 + \Delta^2} - \mu = |\varepsilon_b|; \quad \sqrt{\mu^2 + \Delta^2} + \mu = 2\epsilon_F,
\] (3.14)
respectively; their solution, (3.11), is quoted above. As it is evident from (3.13), the potential term \(\Omega_{\text{pot}}\) in the region \(\mu < 0\) corresponds to particles with repulsion, which accounts for their BEC. We note here that for the 3D case this repulsion was obtained in [25] using a diagrammatic technique. In the region of high \(n_f\), where \(\mu > 0\), the \(\Omega_{\text{pot}}\) cannot be represented as a series even for small \(\Phi\), which reflects the specific properties of the effective potential in 2D systems.

If, proceeding from (3.4) and (3.9), we find the thermodynamic potential difference of the trivial and non-trivial solutions, we can easily obtain the result that it takes form
\[
\Omega_{\text{pot}}(v, \mu, \Delta) - \Omega_{\text{pot}}(v, \mu, 0) = -v \frac{m}{2\pi} \left[ \epsilon_F^2 \coth \frac{2\pi}{mV} \mu - \mu^2 \theta(\mu) \right],
\] (3.15)
which demonstrates (for various \(\mu \leq \epsilon_F \leq W/2\)) that at \(T = 0\) the nontrivial solution is always more favorable than the trivial one, and the point \(\Phi = \Phi^* = 0\) is unstable since here \(\partial^2 \Omega_{\text{pot}}/\partial \Phi^2 \partial \Phi^* < 0\) for all allowed values of the parameters.

As follows from (3.12), both \(\Omega_{\text{pot}}(\mu, \Delta)\) and \(\Omega_{\text{pot}}(\epsilon_F, 0)\) are equal to \(-v m \epsilon_F^2 / 2\pi\), i.e. the potentials of the superconducting and normal phases turn out to be equal in the limit \(W \to \infty, V \to 0\). Nevertheless, it can be shown, just as in [20], that the superconducting phase has the lowest internal energy. In addition, the relevant difference is proportional to \(v \rho(\epsilon_F) \Delta^2 \) (\(\rho(\epsilon_F) = m/2\pi\)) being the density of states, which is energy independent in the 2D case; in other words, we arrive at the standard result of the BCS theory [1], which is clearly valid for all values of the ratio \(\epsilon_F/|\varepsilon_b|\).

### 3.4 The gradient terms of the effective action

Now we calculate the terms \(\Omega_{\text{kin}}\) which contain the derivatives in expansion (3.1). As before, we shall assume the inhomogeneities of \(\Phi\) and \(\Phi^*\) to be small having restricted ourselves only to the terms with lowest derivatives. For simplicity we shall also consider the stationary case and calculate the terms with the second-order spatial derivatives only, which makes it possible to determine the coherence length \(\xi\) and the penetration depth \(\lambda_H\) of the magnetic field in a 2D superconductor.

With these restrictions, taking into account the invariance of \(\Omega(v, \mu, \Phi, \Phi^*)\) (see equation (2.8)) with respect to the phase transformations (3.3) one can write a general form for the kinetic part of the action:
\[
\Omega_{\text{kin}}(v, \mu, T, \Phi(x), \Phi^*(x)) = T \int_0^\beta d\tau \int d\mathbf{r} T_{\text{kin}}(\Phi, \Phi^*, \nabla \Phi, \nabla \Phi^*) =
\]
\[
T \int_0^\beta d\tau \int d\mathbf{r} \left[ T_1(|\Phi|^2)|\nabla \Phi|^2 + \frac{1}{2} T_2(|\Phi|^2)(\nabla |\Phi|^2)^2 \right],
\] (3.16)
where there are no items with a total derivative since the boundary effects are regarded as unessential, and the coefficients $T_{1,2}(|\Phi|^2)$ are assumed to be unknown quantity. It follows from (3.16) that in the second approximation in derivatives the variations in both the direction (phase) of the field $\Phi$ and its absolute value are taken into account.

To calculate the coefficients $T_{1,2}(|\Phi|^2)$ we shall follow the paper [40] according to which one can determine the variation derivatives

$$\frac{\delta^2 \Omega_{\text{kin}}(\Phi, \Phi^*)}{\delta \Phi^*(\mathbf{r}) \delta \Phi(0)}|_{\Phi, \Phi^* = \text{const}} = -T \int_0^\beta d\tau [T_1(|\Phi|^2) + |\Phi|^2 T_2(|\Phi|^2)] \nabla^2 \delta(\mathbf{r});$$

$$\frac{\delta^2 \Omega_{\text{kin}}(\Phi, \Phi^*)}{\delta \Phi(\mathbf{r}) \delta \Phi(0)}|_{\Phi, \Phi^* = \text{const}} = -T \int_0^\beta d\tau (\Phi^*)^2 T_2(|\Phi|^2) \nabla^2 \delta(\mathbf{r}). \quad (3.17)$$

Multiplying both equations (3.17) by $\mathbf{r}^2$ and integrating over $d\mathbf{r}$ one can obtain

$$\int d\mathbf{r} \mathbf{r}^2 \frac{\delta^2 \Omega_{\text{kin}}(\Phi, \Phi^*)}{\delta \Phi^*(\mathbf{r}) \delta \Phi(0)}|_{\Phi, \Phi^* = \text{const}} = -4T \int_0^\beta d\tau [T_1(|\Phi|^2) + |\Phi|^2 T_2(|\Phi|^2)];$$

$$\int d\mathbf{r} \mathbf{r}^2 \frac{\delta^2 \Omega_{\text{kin}}(\Phi, \Phi^*)}{\delta \Phi(\mathbf{r}) \delta \Phi(0)}|_{\Phi, \Phi^* = \text{const}} = -4T \int_0^\beta d\tau (\Phi^*)^2 T_2(|\Phi|^2), \quad (3.18)$$

which allows one to determine the coefficients required. Indeed, let us define the correlation functions

$$K_{ij}(\mathbf{q}) \equiv \int d\mathbf{r} \exp(-i\mathbf{qr}) \frac{\delta^2 \Omega_{\text{kin}}(\Phi, \Phi^*)}{\delta \Phi_i(\mathbf{r}) \delta \Phi_j(0)}|_{\Phi, \Phi^* = \text{const}}, \quad \Phi_1 \equiv \Phi^*, \Phi_2 \equiv \Phi. \quad (3.19)$$

It is then readily seen from (3.18) and (3.19) that $T_{1,2}(|\Phi|^2)$ are determined from the derivatives of the correlators $K_{ij}(\mathbf{q})$ in components of the vector $\mathbf{q}$ at $\mathbf{q} = 0$:

$$T_1(|\Phi|^2) = \frac{1}{4} \left[ \frac{\partial^2 K_{12}(\mathbf{q})}{\partial \mathbf{q}^2} - \Phi \frac{\partial^2 K_{22}(\mathbf{q})}{\partial \mathbf{q}^2} \right]|_{\mathbf{q} = 0};$$

$$T_2(|\Phi|^2) = \frac{1}{4(\Phi^*)^2} \frac{\partial^2 K_{22}(\mathbf{q})}{\partial \mathbf{q}^2}|_{\mathbf{q} = 0}, \quad (3.20)$$

it being apparently sufficient to know $K_{12}(\mathbf{q})$ and $K_{22}(\mathbf{q})$ only. Thus, the problem has been simply reduced to calculating the correlators.

On the other hand, the effective action for the case of the imaginary time-independent fields can be written (see (2.8)) in the following form:

$$\Omega(v, \mu, T, \Phi(\mathbf{r}), \Phi^*(\mathbf{r})) = T \int_0^\beta d\tau \int d\mathbf{r} \left\{ \frac{1}{V} |\Phi(\mathbf{r})|^2 - T \sum_{n = -\infty}^{+\infty} \text{tr}(\mathbf{r} | \text{Ln} \left[ -i\omega_n \hat{I} + \tau_3 \left( \nabla^2 - \frac{m^2}{2m} + \mu \right) + \tau_- \Phi(\mathbf{r}) + \tau_+ \Phi^*(\mathbf{r}) \right] | \mathbf{r}) \right\}. \quad (3.21)$$

where the operation tr refers to Pauli matrices, and the normalization term with $G_0^{-1}$ is omitted. Comparing (3.19) and (3.21) and using the definition (2.9) after the Fourier-transformation (2.17) we obtain directly:

$$K_{12}(\mathbf{q}) = T \sum_{n = -\infty}^{+\infty} \int \frac{d\mathbf{k}}{(2\pi)^2} \text{tr}[G(i\omega_n, \mathbf{k})\tau_+ G(i\omega_n, \mathbf{k} + \mathbf{q})\tau_-];$$

$$0
\[ K_{22}(q) = T \sum_{n=-\infty}^{+\infty} \frac{dk}{(2\pi)^2} \text{tr}[G(i\omega_n, k)\tau_- G(i\omega_n, k + q)\tau_-], \] (3.22)

where \( G(i\omega_n, k) \) is the Green’s function defined by (2.18). Calculating the traces in (3.22) it is easy to arrive at the final expression for the correlators:

\[ K_{12}(q) = T \sum_{n=-\infty}^{+\infty} \frac{dk}{(2\pi)^2} \left( \frac{i\omega_n + k^2/2m - \mu}{\omega_n^2 + \mathcal{E}^2(k)} \right) \left( \frac{i\omega_n - (k + q)^2/2m + \mu}{\omega_n^2 + \mathcal{E}^2(k + q)} \right); \]

\[ K_{22}(q) = T \sum_{n=-\infty}^{+\infty} \frac{dk}{(2\pi)^2} \left( \frac{\mathcal{E}(q)^2}{\mathcal{E}(k)\mathcal{E}(k + q)} \right). \] (3.23)

where we used the notation \( \mathcal{E}^2(k) \equiv \xi^2(k) + |\Phi|^2 \).

Summing over the Matsubara frequencies and then going to the limit \( T = 0 \) one can obtain the final formulae:

\[ K_{12}(q) = -\int \frac{dk}{8\pi^2} \frac{1}{\mathcal{E}(k) + \mathcal{E}(k + q)} \left\{ 1 + \frac{\left( k^2/2m - \mu \right)}{\mathcal{E}(k)\mathcal{E}(k + q)} \right\}; \]

\[ K_{22}(q) = \int \frac{dk}{8\pi^2} \frac{\mathcal{E}(q)^2}{\mathcal{E}(k)\mathcal{E}(k + q)}. \] (3.24)

A somewhat tedious but otherwise straightforward calculation (see [37, 38]) now yields for the desired coefficients of (3.16):

\[ T_1(|\Phi|^2) = \frac{1}{16\pi} \int_{-\mu}^{W-\mu} \frac{2|\Phi|^2 - u^2}{(u^2 + |\Phi|^2)^{5/2}} (u + \mu) + \frac{u}{(u^2 + |\Phi|^2)^{3/2}} \left. \right|_{u=-\mu}^{u=W-\mu}; \] (3.25)

\[ T_2(|\Phi|^2) = \frac{1}{16\pi} \int_{-\mu}^{W-\mu} \frac{5u^2(u + \mu)}{(u^2 + |\Phi|^2)^{7/2}} - \frac{3(2u + \mu)}{2(u^2 + |\Phi|^2)^{5/2}} \left. \right|_{u=-\mu}^{u=W-\mu} = \frac{1}{16\pi} \frac{2|\Phi|^6 - 4|\Phi|^4u^2 - 2u^5\mu - 5u^3|\Phi|^2 - 9u\mu|\Phi|^4}{|\Phi|^4(u^2 + |\Phi|^2)^{5/2}} \left. \right|_{u=-\mu}^{u=W-\mu}. \] (3.26)

The expressions (3.25) and (3.26) together with (3.4) complete the calculation of all the terms of the effective action (3.1) for the 2D metal with attraction between fermions.

### 3.5 Correlation length and penetration depth versus doping

Knowing \( T_1(|\Phi|^2) \) and \( T_2(|\Phi|^2) \) one can find the values for different observables. For practical purposes it suffices to restrict ourselves to considering the coefficients obtained at the point \( |\Phi| = \Delta \) of the effective potential minimum. Besides, instead of (3.26)
it is convenient to introduce the combination $\tilde{T}_2(|\Phi|^2) \equiv T_1(|\Phi|^2) + 2\Delta^2 T_2(|\Phi|^2)$ which determines the change in the $|\Phi|$ value only and arises as the coefficient at $(\nabla|\Phi|)^2$.

The analysis of (3.23) and (3.26) reveals that at $|\Phi| = \Delta$ both these functions are positive for $\epsilon_F \leq W/2$ where they change their sign, which simply reflects the necessity to go over the antiparticle (from electron to hole or vice versa) picture for the region $\epsilon_F > W/2$. On the other hand, in the region $\epsilon_F \leq W/2$ the positiveness of these functions demonstrates the stability of the homogeneous ground state of the model concerned.

One can succeed in simplifying (3.25) and (3.26) if takes into account that, as a rule, $\epsilon_F \ll W$ (for example, in HTSC metal-oxides $\epsilon_F \sim 0.1W$ [21, 34]). Then, using (3.10) and (3.11), one can rewrite $T_1(\Delta^2)$ and $\tilde{T}_2(\Delta^2)$ in the very simple form:

$$T_1(\Delta^2) = \frac{1}{16\pi\hbar|\epsilon_b|}; \quad \tilde{T}_2(\Delta^2) = \frac{1}{24\pi\hbar^2} \left(\frac{2\epsilon_F - |\epsilon_b|}{2\epsilon_F + |\epsilon_b|}\right)^3,$$

(3.27)

where for completeness we have restored the Planck constant again.

The explicit form of $T_1(\Delta^2)$ and also $a \equiv v^{-1}\partial^2\Omega_{pot}(\Phi, \Phi^*)/\partial\Phi\partial\Phi^*|_{\Phi^2=\Delta^2}$ allows one to calculate the coherence length and the penetration depth. Since (see (3.4))

$$a = \frac{m}{\pi\hbar^2} \frac{\epsilon_F(W - \epsilon_F) \coth \frac{2\pi\hbar^2}{mV}}{W^2 \coth^2 \frac{2\pi\hbar^2}{mV} - (W - 2\epsilon_F)^2}$$

$$\rightarrow \frac{m}{2\pi\hbar^2} \frac{\epsilon_F}{2\epsilon_F + |\epsilon_b|} \quad (W \to \infty, V \to 0),$$

(3.28)

then, according to general theory of fluctuation phenomena [41], one gets that

$$\xi = \hbar \left[\frac{T_1(\Delta^2)}{a}\right]^{1/2} = \hbar \left(\frac{2\epsilon_F + |\epsilon_b|}{8m\epsilon_F|\epsilon_b|}\right)^{1/2}.$$

(3.29)

This formula shows the dependence of $\xi$ on $\epsilon_F$ (or $n_f$). It is very interesting and useful to compare (3.29) with the definition of the pair size [28, 29] (also incorrectly referred to as the coherence length [20, 27]), namely

$$\xi_0^2 = \frac{ds \int d\mathbf{r}g(\mathbf{r})r^2}{\int d\mathbf{r}g(\mathbf{r})},$$

(3.30)

where

$$g(\mathbf{r}) = \frac{1}{n_f^2} \langle \Psi_{BCS}|\psi_{\uparrow}^\dagger(\mathbf{r})\psi_{\downarrow}^\dagger(0)|\Psi_{BCS}\rangle$$

(3.31)

is the pair-correlation-function for opposite spins and $|\Psi_{BCS}\rangle$ is the usual BCS trial function. For the 2D model under consideration the general expression (3.30) gives [20, 28]

$$\xi_0^2 = \frac{\hbar^2}{4m} \left[ \frac{\mu^2 + 2\Delta^2}{\mu^2 + 2\Delta^2} \left(\frac{\pi}{2} + \tan^{-1}\frac{\mu}{\Delta}\right)^{-1} \right],$$

(3.32)

where $\Delta$ and $\mu$ were given by (3.11). So, we are ready now to compare (3.29) and (3.32). For high carrier densities $\epsilon_F \gg |\epsilon_b|$ one finds that $\xi \sim \xi_0 \sim \bar{v}_F/\Delta$, i.e.
the well-known Pippard’s result is reproduced correctly. Moreover, if, according to [19], we introduce the pair size \( \xi_b = \hbar (m|\varepsilon_b|)^{-1/2} \) in vacuum, then it is clear that \( \xi \sim \xi_0 \ll \xi_b \) when \( |\varepsilon_b| \lesssim \epsilon_F \). Therefore, both \( \xi \) and \( \xi_0 \) prove to be close to the pair size which is much larger than the interparticle spacing. The latter statement one can see from the value of the dimensionless parameter \( \xi k_F \sim \xi_0 k_F \sim \epsilon_F / \Delta \gg 1 \).

In the opposite limit \( |\varepsilon_b| \gg \epsilon_F \) of very low density one can see that \( \xi_b \ll \xi \sim k_F^2 \) while \( \xi_0 \sim \xi_b \). Consequently the correct interpretation of \( \xi_0 \) is the pair size (in presence of the Fermi sea (3.30)) rather than the coherence length. The former in the extreme Bose regime is much smaller than the mean interparticle spacing, since \( \xi_0 k_F \ll 1 \), while always \( \xi k_F \sim 1 \). The meaning of \( \xi \) is indeed the coherence length because it remains finite and comparable with the mean interparticle spacing even when \( |\varepsilon_b| \) goes to infinity.

Calculations of the \( \lambda_H \) value require one to introduce the external magnetic field \( H \) and also the usual extension of the derivatives \( \hbar \nabla \to \hbar \nabla - (2ie/c)A \) (\( e \) is the electron charge, \( c \) is the light velocity, \( A \) is the vector potential). Adding then the energy of the magnetic field \( \int d\tau \int d\mathbf{r} H^2 / 8\pi z \) to the effective action (3.1) by direct calculation one gets

\[
\lambda_H = \left[ \frac{\epsilon^2}{32\pi e^2 T_1 (\Delta^2) z \Delta^2} \right]^{1/2}.
\]

Note that in (3.33) and (3.34) \( z \) is the number of superconducting layers per unit length taking into account the 3D character of the external field action. Hence, Ginzburg-Landau parameter (see (3.29), (3.34)) is equal to

\[
\kappa = \frac{\lambda_H}{\xi} = \frac{1}{\hbar} \left[ \frac{\epsilon^2 a}{32\pi e^2 T_1 (\Delta^2) z \Delta^2} \right]^{1/2}.
\]

Substituting here the accurate expressions (3.11), (3.27) and (3.28) for \( \Delta \), \( T_1 (\Delta^2) \) and \( a \) it is easy to find that (3.33) takes a simple enough form

\[
\kappa = \frac{c}{\epsilon} \sqrt{\frac{m}{z}} \frac{2|\varepsilon_b|}{2\epsilon_F + |\varepsilon_b|},
\]

from which the explicit dependence of this parameter versus the ratio between \( \epsilon_F \) and \( |\varepsilon_b| \) follows immediately. So, for \( z \sim (10^7 - 10^9) \text{cm}^{-1} \) (as occurs in real cuprates) the formula (3.34) for a large range of values for \( \epsilon_F \) gives \( \kappa \sim 10^2 \). This means that 2D metals with low \( \epsilon_F \) (so called underdoped case) turn out to be very strongly type-II superconductors. However, it follows from the same formula that with increasing \( \epsilon_F \) the
parameter $\kappa$ decreases and in the limit $\epsilon_F \gg |\epsilon_b|$ (strongly overdoped case) it is possible (in principle) to obtain the value $\kappa \lesssim 1$ or in the other words, to change the type of the superconductor.

We estimate finally the value of the second critical field $H_{c2}$. Indeed, equating the energy gain (see (3.15)) of the state with $\Delta \neq 0$ and the field energy one can show that

$$H_{c2} = \frac{2}{\hbar} \epsilon_F \sqrt{m_z}.$$ 

For the same parameters we find that $H_{c2} \sim (10^5 - 10^6)\text{Oe} = 10 - 10^2\text{T}$ which also corresponds to the critical magnetic field values for the HTSC metal-oxides [42, 43]. Finally, note that the concentration dependence of $\partial H_{c2}/\partial T$ was studied also [44].

4 Crossover in the quasi-2D systems

As we have already mentioned in the introduction there are many ways which allow one to extend the zero-temperature analysis of the 2D model from the previous Chapter to the case $T \neq 0$. Every way has some advantages as well as disadvantages. So, different generalizations of the model are to be investigated. Here we shall study a quasi-2D extension, which might be relevant for HTSCs with a relatively low anisotropy of the conductivity as, for example, is present in the Y-based cuprates. On the other hand, the quasi-2D model can be considered as an extension of the 3D model from Chapter 2. Our treatment is based on the paper [31] (see also its detailed versions [45, 46]).

4.1 Model

The simplest model Hamiltonian density for the carriers in the quasi-2D system reads

$$\mathcal{H} = - \psi_\sigma^\dagger(x) \left[ \frac{\nabla_\perp^2}{2m_\perp} - \frac{1}{m_z d_z^2} \cos (\nu \nabla_z d_z) + \mu \right] \psi_\sigma(x) - V \psi_\uparrow^\dagger(x) \psi_\downarrow^\dagger(x) \psi_\downarrow(x) \psi_\uparrow(x), \quad (4.1)$$

where $x \equiv \tau, r_\perp, r_z$ (with $r_\perp$ being a 2D vector); $\psi_\sigma(x), \mu$ and $V$ are already determined; $m_\perp$ is an carrier effective mass in the planes (for example, CuO$_2$ ones); $m_z$ is an effective mass in the $z$-direction; $d_z$ is the interlayer distance.

The Hamiltonian proposed proves to be very convenient for study of fluctuation stabilization by weak 3D one-particle inter-plane tunnelling. The extension of the 2D system in the third-direction could give rise to a possibility that it may undergo the 3D superconducting transition with the establishment of homogeneous long-range order. This transition does not contradict the 2D theorems [4]. We omitted in (4.1) the two-particle (Josephson) tunnelling considering it here to be smaller than the one-particle already taken into account. There can however be situations when Josephson tunnelling becomes more essential then the one-particle coherent one. In addition some authors consider that the most important mechanism for HTSC is the incoherent inter-plane hopping (through, for instance, the impurity (localized) states or due to the assistance of phonons.)

It is significant that the large anisotropy of the conductivity cannot be identified with the similar anisotropy of the effective masses $m_z$ and $m_\perp$. In particular, HTSC with
rather large anisotropy in z-direction do not display the usual metal behaviour at low temperatures. It means that interplane motion of the fermions is incoherent and the BKT transition could take place before the 3D superconducting transition (see the next Chapter). But, as will be seen, for justification of approximations used below the modest value of the ratio \( m_z/m_\perp \geq 10^2 \) is already sufficient. Such a value is present for instance in the HTSC YBa\(_2\)Cu\(_3\)O\(_{6+\delta}\) (1-2-3). Because of this we shall study the simplest case of tunnelling which is described by the second term in (4.1).

The method for the study of the Hamiltonian (4.1) mainly coincides with that used for the 3D model (2.1). So, we shall often refer to the similar formulae from Chapter 2.

### 4.2 The mean field approximation

The effective potential (2.19) obtained in Appendix A is in fact model independent. Thus, one has to use it together with the dispersion law

\[
\xi(k) = \varepsilon(k) - \mu = \frac{k^2}{2m_\perp} + \frac{1}{m_z d_z^2} \cos k z d_z - \mu
\]  

(4.2)

in accordance with the Hamiltonian (1.1).

Again the stationary condition (2.20) results in the gap equation (2.21) where now \( \xi(k) \) is determined by (4.2).

It is necessary to emphasize that for the temperatures of interest, the band width in the z-direction is \( m_z^{-1} d_z^{-2} \ll T_{c}^{MF} \), i.e. the system is really a quasi-2D one. As for the last inequality, it is easy to see, that at \( m_z \approx 10^2 m_e \) and \( d_z = 10 \AA \) the value \( \hbar^2/(m_z d_z^2 k_B) \sim 10K \) is really far less than the usual critical temperatures in HTSC compounds.

Now we need to describe how one can regulate the ultraviolet divergence in the gap equation (2.21). As has been already noted in Section 2.1 for the case of the local-pair superconductivity the cutoff of BCS type cannot be applied. Moreover, the regularization by the 3D scattering length \( a_s \) (see the definition (2.22)) is unsuitable for the quasi-2D system. It turns out that in order to eliminate the divergences in (2.21) it is convenient to introduce, as in the 2D case, the energy of the two-particle bound state (compare with (3.10))

\[
\varepsilon_b = -2W \exp \left( -\frac{4\pi d_z}{m_\perp V} \right),
\]  

(4.3)

where \( W = k_{\perp B}^2/2m_\perp \) is the bandwidth in the plane\(^6\). The factor \( d_z \) in the index of the exponent is necessary to preserve the dimensionlessness.

Again, contrary to the usual BCS approach, the value of the chemical potential should be consistently defined from the equation (2.24), which leads to the second, or number, equation (2.25).

Taking into account the above-mentioned inequality \( m_z^{-1} d_z^{-2} \ll T_{c}^{MF} \) the number equation (2.25) in the limit \( W \to \infty \) takes the following final form:

\[
2T_{c}^{MF} \ln \left[ 1 + \exp \left( \frac{\mu}{T_{c}^{MF}} \right) \right] = 2\epsilon_F,
\]  

(4.4)

\(^6\text{Note that in the region of the parameters considered these bound states are formed without any threshold.}\)
where (here) $\epsilon_F = \pi n_f d_z/m_\perp$ is the Fermi energy of free quasi-2D fermions with $\epsilon(k) \sim k^2$.

So, one needs to solve simultaneously the system of the equations (2.21) with the dispersion law (4.2) and (4.4) with two unknown variables, $T_c^{MF}$ and $\mu$, respectively.

At high carrier concentrations $n_f$, such that $\mu \gg T_c^{MF}$, the equality $\mu \simeq \epsilon_F$ is indeed the solution of (4.4). Than taking into account the regularization procedure, it follows from (2.21) that (compare with (2.26))

$$T_c^{MF} \simeq \frac{\gamma}{\pi} \sqrt{2|\epsilon_b| \epsilon_F} = \frac{2\gamma}{\pi} \sqrt{W\epsilon_F} \exp \left( -\frac{2\pi d_z}{m_\perp V} \right).$$

(4.5)

This is just the well-known BCS result for a 2D metal [37].

In the opposite case of small $n_f$, such as $-\mu \gg T_c^{MF}$, the roles of the gap (2.21) and number (4.4) equations are as above in some sense reversed: the equation (2.21) determines $\mu$, while the (4.4) determines the value of $T_c^{MF}$. Now, using the definition (4.3) one obtains from (2.21)

$$\ln \frac{2W}{|\epsilon_b|} = \frac{1}{2\pi} \int_0^{2\pi} dt \int_0^{2W} dx \left[ \frac{1}{x - 2\mu + (2/m_z d_z^2) \cos t} \right].$$

(4.6)

Integrating the right side of (4.6) and in the limit $W \to \infty$ we immediately arrive at the final expression

$$\mu = -\frac{|\epsilon_b|}{2} - \frac{1}{2(m_z d_z^2)^2|\epsilon_b|}.$$  

(4.7)

This expression, except for the second term, is identical to the result described in Section 2.3. The second term is directly connected to the quasi-2D character of the model and, despite its far smaller magnitude, is very important when the fluctuations are taken into account. At $|\epsilon_b| \gg \epsilon_F$ the equation (4.4) transforms into the transcendental one:

$$\frac{|\epsilon_b|}{2T_c^{MF}} = \ln \frac{T_c^{MF}}{\epsilon_F}.$$  

(4.8)

It follows from (1.8) that we obtain a similar result to that in Section 2.3: for fixed $\epsilon_F$, the value of $T_c^{MF}$ grows rapidly as the coupling constant $V$ increases. Thus, for the case of small carrier density, the temperature $T_c^{MF}$ is not connected to the critical one $T_c$, but in fact corresponds to the temperature of composite boson dissociation (compare with Section 2.3).

### 4.3 The role of Gaussian fluctuations

In order to investigate the effects of composite bosons formed in the system, one should again take into account the order parameter fluctuations. As was discussed in the previous Section, one can simply use the expressions from Chapter 2 with $\xi(k)$ determined by (4.2). Thus, the expressions (2.27) and (2.28) may be used directly if one applies the ultraviolet regularization by the energy (4.3) as has been done in Section 4.2. Once again, from (2.27), we arrive at the "conservation law" (2.30).
Let us consider now the influence of \( n_B(\mu, T) \) determined by (2.31) on the behaviour of the system as the carrier density changes. We should solve self-consistently the system of equations (2.21) and (2.31).

At high enough carrier density the contribution of \( n_B(\mu, T) \) to (2.31) is negligible, and one arrives at the equality \( T_c \simeq T_c^{MF} \), where \( T_c^{MF} \) is given by (1.3).

Recall (see Section 2.4) that in a more consistent scheme one should take into consideration the correction \( \partial(\Omega - \Omega_{pot})/\partial \Phi \) to the gap equation (2.21), and consequently the fluctuations modify the equation. This correction may be especially important in the quasi-2D case. However, because of the conditions \( \mu \simeq \epsilon_F \gg T_c \) and \( m_z d_z^2 T_c \gg 1 \), one can convince oneself that this correction changes \( T_c \) rather weakly (17) (see also [48]).

Note that the consideration of the correction to the gap equation (2.20) should be very interesting because based on the general 2D theorems one knows that \( T_c \rightarrow 0 \) when \( m_z \rightarrow \infty \) (2D case) even though \( \mu \simeq \epsilon_F \). To trace this limit the above-mentioned correction must be taken into account. From the other side, when \( m_z \rightarrow \infty \) the BKT scenario will take place at any density \( n_f \) and we have to modify the approach from Chapter 2 used here to study the formation of the inhomogeneous BKT phase. The latter will be accurately done in the next Chapter.

Turning back to the equality \( T_c \simeq T_c^{MF} \) one can see, using (1.3) (the \( T_c^{MF} \) coincides with the expression obtained in [37], for a pure 2D superconductor due to the band narrowness in the \( k_z \)-direction), that \( T_c \) increases with the growth of coupling constant \( V \). This behaviour of \( T_c \) is just as in the 3D case (see (2.21)).

At small concentrations, such that \( |\mu|/T_c \gg 1 \) taking into account the definition (1.3) in the limit \( W \rightarrow \infty \) one obtains from (2.28) that

\[
\Gamma^{-1}(i\Omega_n, \mathbf{K}) = \frac{m_\perp}{4\pi d_z} \times \\
\ln \frac{K_\perp^2}{4m_\perp} - 2\mu - i\Omega_n + \sqrt{\left( \frac{K_\perp^2}{4m_\perp} - 2\mu - i\Omega_n \right)^2 + \left( \frac{2}{m_z d_z^2} \cos K_z d_z \right)^2} - \frac{2|\varepsilon_b|}{2|\varepsilon_b|}.
\]

After introducing the phase \( \delta(\omega, \mathbf{K}) \equiv -\arg \Gamma^{-1}(\omega + i0, \mathbf{K}) \) it can again be written as:

\[
\delta(\omega, \mathbf{K}) = \pi \theta \left( \omega - \frac{K_\perp^2}{4m_\perp} + \frac{1}{2|\varepsilon_b|(m_z d_z^2)^2} \cos K_z d_z + 2\mu + |\varepsilon_b| \right)
+ \frac{1}{2|\varepsilon_b|(m_z d_z^2)^2}.
\]  

At last, after substitution of the expression (17) for the chemical potential into (4.10) one arrives at the final equation for \( T_c \), namely:

\[
n_B(\mu, T) \equiv \int \frac{d\mathbf{K}}{(2\pi)^3} n_B \left( K_\perp^2 + \frac{1}{2|\varepsilon_b|(m_z d_z^2)^2} (1 - \cos K_z d_z) \right) \simeq \frac{n_f}{2}.
\]

It is easy to see that the boson effective mass for its motion in the plane retains the value \( 2m_\perp \). As for the motion between the planes, the effective boson mass increases considerably:

\[2|\varepsilon_b|m_z^2d_z^2(\gg m_z)\].

It can be stressed that this increase has a dynamical character as is testified simply by the presence of \( |\varepsilon_b| \). Physically, it is ensured by the
one-particle character (see equation (4.1)) of the tunnelling between planes which only takes place through the virtual breakup of a pair for which the energy loss is of the order $|\varepsilon_b|$.

Now, using the formula for the BEC of an ideal quasi-2D Bose-gas [39] (see also the review [43]), it is easy to write down an equation for $T_c$, which here takes the simple form

$$T_c \simeq \frac{\pi n_f d_z}{2 m_{\perp} \ln (2T_c |\varepsilon_b|m^2 d^4)} = \frac{\epsilon_F}{2 \ln (2T_c |\varepsilon_b|m^2 d^4)}.$$  \hfill (4.12)

The last equation describes the characteristic properties of a quasi-2D superconductor with small carrier density:

i) firstly, the critical temperature $T_c \sim \epsilon_F$, or (see above) $T_c \sim n_f/2$, or the number of the composite bosons, as it should be in 2D case (recall that in a 3D one $T_c \sim n_f^{2/3}$ (see (2.33)), in contrast to the MF approximation 2D $T_c^{MF} \sim \sqrt{n_f} \gg T_c$ [37] (see also (3.11) because usually $T_c^{MF} \sim \Delta$);

ii) secondly, contrary to the case of the 3D superconductor where $T_c$ does not depend on $V$ at all (see (2.33)), in a quasi-2D system $T_c$ does depend on $V$, namely: $T_c$ decreases with the growth of $V$. As was stated above, the reason for this is the dynamical increase of the composite boson mass along the third direction. Thus, the growth of $|\varepsilon_b|$ (or of $V$, which is the same) “makes” the system more and more two-dimensional even for the simplest case of a quasi-2D metal with a local four-fermion interaction.

It is interesting to note that a decreasing $T_c$ can also take place in the case when the local pairs are bipolarons [50]; then, the increasing of coupling with phonons, which makes the pairs more massive, also leads to $T_c$ decreasing, (rather than increasing) as the electron-phonon coupling grows.

The main results here are not only the expressions (4.5) and (4.12) for $T_c$ in the different limiting cases, namely the cases of large and small $V$. No less important is the comparison of these expressions which show that for a given density of fermions (i.e. a given $\epsilon_F$) there are two essential regions. If $|\varepsilon_b| \ll \epsilon_F$, then even in the case of small (by absolute value $n_f$) densities the BCS formula is valid and $T_c$ grows with increasing $|\varepsilon_b|$ (see (4.5)). In the opposite case, $|\varepsilon_b| \gg \epsilon_F$, $T_c$ decreases with the growth of $|\varepsilon_b|$. It shows that in the case of quasi-2D systems (it seems that the HTSC belong to this case) $T_c(|\varepsilon_b|)$ has a maximum. Consequently, there is a region (for fixed $|\varepsilon_b|$) of values of $\epsilon_F$ for which $T_c$ increases. If we also take into account the two-particle tunnelling in (4.1), then the previous result will only be a lower bound for $T_c$ for large $|\varepsilon_b|$. The region of $\epsilon_F \approx |\varepsilon_b|$ needs special study (see e.g. [3, 5]) because of the presence of both strongly developed fluctuations and the possible distinction of properties of such a Fermi-liquid from the Fermi-liquid of Landau type.

## 5 2D crossover: finite temperature

We have already studied the finite temperature (or more exactly $T_c$) crossover for the 3D and quasi-2D models. The 2D crossover at $T = 0$ crossover was addressed also. So, we are ready to discuss the 2D crossover at $T \neq 0$. As was stressed in the Introduction (see also [32]) an analytical treatment of the finite $T$ crossover problem in 2D is quite a difficult task. This is primarily related to the necessity to treat $T_c$ as the BKT temperature $T_{BKT}$ below...
which there is an algebraic (power decay) order and a finite superfluid density \[8\] (see also the review \[52\] and the book \[53\]). Nevertheless, some insight into the peculiarities of the formation of the BKT has been gained \[9\].

5.1 Model and Formalism

Most of previous analyses \[54, 55, 56\] of the behaviour of the 2D systems at \( T \neq 0 \) have been based on a Nozieres-Schmitt-Rink approach \[18\]. As shown above, this is simply the Gaussian approximation to the functional integral which perhaps explains the difficulties faced in these calculations. On the one hand, Gaussian fluctuations destroy long-range order in 2D and if one searches for the \( T_{c}^{2D} \) at which the order sets in one should get zero in accordance with the above-mentioned theorems \[4\]. On the other hand, taking into account Gaussian fluctuations is completely inadequate to describe the BKT transition.

Nonetheless, several steps have been made even in this direction. For example, the BKT transition in the relativistic 2 + 1-theory was studied in \[57\], and even the crossover from superconductivity to superfluidity was considered in \[22\] (see also \[58\]) according to the value of the carrier density \( n_{f} \) (recall that \( n_{f} = m\epsilon_{F}/\pi \)). However, the method employed in \[22\] to the temperature \( T_{BKT} \) has a number of drawbacks.

Specifically, the equation for \( T_{BKT} \) was obtained neglecting the existence of a neutral (real) order parameter \( \rho \), whose appearance at finite \( T \), being due to the breaking of only a discrete symmetry, is consistent with Coleman-Mermin-Wagner-Hohenberg theorem \[4\]. As we shall see below, \( \rho \) gives the modulus of a multivalued complex order parameter of a 2D system as a whole, and only the modulus determines the possibility of the formation of nonuniform (including vortex) configurations in the system.

However, as a result of allowing for a neutral order parameter, a region where \( \rho \) decays gradually to zero appears in the phase diagram of the system. This region separates the standard normal phase with \( \rho = 0 \) from the BKT phase, where there is the power decay of correlations. Despite of the exponential decay of the correlations in it, this new region of states very likely possesses unusual properties, since \( \rho \) appears in all expressions in the same manner as does the energy gap \( \Delta \) in the theory of ordinary superconductors, though to calculate the observed single-particle spectrum, of course, the carrier losses due to scattering of carriers by fluctuations of the phase of the order parameter and, in case of real systems, by dopants must be taken into account \[59\]. The possible existence of such a phase, which is also in some sense normal, might shed light of the frequently anomalous (see, for example, the reviews \[34, 60\]) behaviour of the normal state of HTSC, specifically, the temperature dependencies of the spin susceptibility, resistivity, specific heat, photoemission spectra, and so on \[61, 62, 21\], for the explanation of which the idea of a pseudogap (and also spin gap) in the region \( T > T_{c} \) is now widely employed.

Thus, our objective in this Chapter is to calculate \( T_{BKT} \) and \( T_{\rho} \) (\( T_{\rho} \) is the temperature at which \( \rho \rightarrow 0 \)) as functions of \( n_{f} \) and to establish a form of this new region, which lies in the temperature interval \( T_{BKT} < T < T_{\rho} \). Besides, we will try to demonstrate using the example of the static spin susceptibility that this phase may really be used to explain the above-mentioned anomalous properties of the HTSC. That is the reason why the phase was called the "anomalous normal" phase.

There is no need to write down the model Hamiltonian which is studied here, because it is identical with that of described in Chapter 3.1.
The desired phase diagram consisting from normal, anomalous and superconducting phases was calculated firstly in [9] employing the Hubbard-Stratonovich method (see Section 2.2, the equations (2.6) – (2.8)). In the 2D case, however, instead of using the accepted method for calculation the partition function \( Z(v, \mu, T) \) (see (2.7)), one must to perform the calculation in modulus-phase variables. This prevents us from the subsequent treatment of the phase fluctuations at Gaussian level only. Thus, we will be able to take into account the phase degree of freedom with needed accuracy.

The modulus-phase variables were introduced in accordance with [63], where the parametrization \( \Phi(x) = \rho(x) e^{-2i\theta(x)} \), \( \Phi^\ast(x) = \rho(x) e^{2i\theta(x)} \), (5.1) was used. One can easily see that (5.1) corresponds to the obvious transformation of the initial Fermi-fields, namely

\[
\psi_\sigma(x) = \chi_\sigma(x) e^{i\theta(x)}, \quad \psi_\sigma^\dagger(x) = \chi_\sigma^\dagger(x) e^{-i\theta(x)},
\]  

(5.2)

where the field operator \( \chi_\sigma(x) \) describes neutral fermions and \( e^{i\theta(x)} \) corresponds to the charge degree of freedom. In Nambu variables (2.2) the transformation (5.2) takes the following form

\[
\Psi(x) = e^{i\tau_3 \theta(x)} \Upsilon(x), \quad \Psi^\dagger(x) = \Upsilon^\dagger(x) e^{-i\tau_3 \theta(x)}.
\]  

(5.3)

Making corresponding substitutions (5.3) in the representation (2.6) and integrating over the fermi-fields \( \Upsilon \) and \( \Upsilon^\dagger \) we arrive at the expression (compare with (2.7) and (2.8))

\[
Z(v, \mu, T) = \int \rho \mathcal{D}\rho \mathcal{D}\theta \exp \left[ -\beta \Omega(v, \mu, T, \rho(x), \partial \theta(x)) \right],
\]  

(5.4)

where

\[
\beta \Omega(v, \mu, T, \rho(x), \partial \theta(x)) = \frac{1}{V} \int_0^\beta d\tau \int d\rho^2(x) - \text{Tr} \ln G^{-1} + \text{Tr} \ln G_0^{-1}
\]  

(5.5)

is as (2.8) the one-loop effective action, which, however, depends on the modulus-phase variables. The action (5.3) is expressed through the Green function of the initial (charged) fermions that has in the new variables the following operator form

\[
G^{-1} = -\hat{I} \partial_\tau + \tau_3 \left( \frac{\nabla^2}{2m} + \mu \right) + \tau_1 \rho(\tau, \mathbf{r}) -
\]

\[
\tau_3 \left( i\partial_\tau \theta(\tau, \mathbf{r}) + \frac{(\nabla \theta(\tau, \mathbf{r}))^2}{2m} \right) + \hat{I} \left( \frac{i\nabla^2 \theta(\tau, \mathbf{r})}{2m} + \frac{i \nabla \theta(\tau, \mathbf{r}) \nabla}{m} \right).
\]  

(5.6)

The free fermion Green function \( G_0 \) that provides the convenient regularization in the process of calculation was defined in (2.11). It is important that neither the smallness nor slowness of the variation of the phase of the order parameter was assumed in obtaining expression (5.6).

\( ^7 \)It may be obtained as a solution of some differential equation with the antiperiodic boundary conditions (see (2.9) and (2.10)).
Since the low-energy dynamics in the phases in which \( \rho \neq 0 \) is determined mainly by the long-wavelength fluctuations of \( \theta(x) \), only the lowest order derivatives of the phase need be retained in the expansion of \( \Omega(v, \mu, T, \rho(x), \partial \theta(x)) \):

\[
\Omega(v, \mu, \rho(x), \partial \theta(x)) \simeq \Omega_{\text{kin}}(v, \mu, T, \rho, \partial \theta(x)) + \Omega_{\text{pot}}(v, \mu, T, \rho) \tag{5.7}
\]

where

\[
\Omega_{\text{kin}}(v, \mu, T, \rho, \partial \theta(x)) = T \text{Tr} \left[ \sum_{n=1}^{\infty} \frac{1}{n} (G \Sigma)^n \right] \bigg|_{\rho=\text{const}} \tag{5.8}
\]

and (see (2.13))

\[
\Omega_{\text{pot}}(v, \mu, T, \rho) = \left( \frac{1}{V} \int d\rho \rho^2 - T \text{Tr} \ln G^{-1} + T \text{Tr} \ln G_0^{-1} \right) \bigg|_{\rho=\text{const}}. \tag{5.9}
\]

The kinetic \( \Omega_{\text{kin}} \) and potential \( \Omega_{\text{pot}} \) parts are expressed through the Green function of the neutral fermions which obeys the equation (compare with (2.9))

\[
\left[ -\hat{I} \partial_\tau + \tau_3 \left( \frac{\nabla^2}{2m} + \mu \right) + \tau_1 \rho \right] G(\tau, r) = \delta(\tau) \delta(r) \tag{5.10}
\]

and the operator

\[
\Sigma(\partial \theta) \equiv \tau_3 \left( i \partial_\tau \theta + \frac{(\nabla \theta)^2}{2m} \right) - \hat{I} \left( \frac{i \nabla^2 \theta}{2m} + \frac{i \nabla \theta(\tau, r) \nabla}{m} \right). \tag{5.11}
\]

The representation (5.7) allows one to get a full set of the equations which are necessary to find out \( T_{BKT}, \rho(T_{BKT}) \) and \( \mu(T_{BKT}) \) at given \( \epsilon_F \) (or, for example, \( \rho(T) \) and \( \mu(T) \) at given \( T \) and \( \epsilon_F \)). While the equation for \( T_{BKT} \) will be written using the kinetic part (5.8) of the effective action, the equations for \( \rho(T_{BKT}) \) and \( \mu(T_{BKT}) \) (or \( \rho(T) \) and \( \mu(T) \)) could be obtained using the mean field potential (5.9). It turns out that in the phase where \( \rho \neq 0 \) the mean-field approximation for the modulus variable describes the system quite well. This is mainly related with a nonperturbative character of the Hubbard-Stratonovich method, i.e. most of effects are taken over by a nonzero value of \( \rho \).

### 5.2 The equation for \( T_{BKT} \)

If our model were reduced to a some known model describing the BKT phase transition, we would be easily write the equation for \( T_{BKT} \). Indeed, in the lowest orders the kinetic term (5.8) coincides with so called classical XY model \([52, 53]\) which has the following continuum Hamiltonian

\[
H = \frac{J}{2} \int d\mathbf{r} (\nabla \theta(\mathbf{r}))^2. \tag{5.12}
\]

Here \( J \) is the some constant (in the original classical discrete XY model it is the value of spin) and \( \theta \) is the angle (phase) of the two-component vector in plane.

The temperature of the BKT transition is, in fact, known for this model, namely

\[
T_{BKT} = \frac{\pi}{2} J. \tag{5.13}
\]
Despite the very simple form of the equation (5.13), it was derived (see also [52, 53]) using the renormalization group technique, which takes into account the non-single-valuedness of the phase $\theta$. Thus, the fluctuations of the phase are taken into account at a higher approximation than the Gaussian one.

To expand $\Omega_{\text{kin}}$ up to $\sim (\nabla \theta)^2$, it would be sufficient to restrict ourselves to terms with $n = 1, 2$ in the expansion (5.8). The procedure of calculation (see Appendix B) is similar to that employed in [64], where the case of large densities $n_f$ at $T = 0$ was considered, and gives

$$
\Omega_{\text{kin}} = \frac{T}{2} \int_0^\beta d\tau \int d\mathbf{r} \left[ J(\mu, T, \rho(\mu, T))(\nabla \theta)^2 + K(\mu, T, \rho(\mu, T))(\partial_r \theta)^2 \right],
$$

where

$$
J(\mu, T, \rho) = \frac{1}{m} n_F(\mu, T, \rho) - \frac{T}{\pi} \int_{-\mu/2T}^\infty dx \frac{x + \mu/2T}{\cosh^2 \sqrt{x^2 + \rho^2 / 4T^2}}
$$

characterizes the stiffness of neutral condensate,

$$
K(\mu, T, \rho) = \frac{m}{2\pi} \left( 1 + \frac{\mu}{\sqrt{\mu^2 + \rho^2}} \tanh \frac{\sqrt{\mu^2 + \rho^2}}{2T} \right),
$$

and a value

$$
n_F(\mu, T, \rho) = \frac{m}{2\pi} \left\{ \sqrt{\mu^2 + \rho^2} + \mu + 2T \ln \left[ 1 + \exp \left( -\frac{\sqrt{\mu^2 + \rho^2}}{T} \right) \right] \right\}
$$

has a sense of fermi-quasiparticles density (for $\rho = 0$ the expression (5.17) is simply the density of the free fermions). Note that $J(\mu, T, \rho = 0) = 0$.

A direct comparison of the expression (5.14) with the Hamiltonian of XY model (5.12) makes it possible to write an equation for $T_{BKT}$:

$$
\frac{\pi}{2} J(\mu, T_{BKT}, \rho(\mu, T_{BKT})) = T_{BKT}.
$$

(5.18)

Although mathematically the problem reduces to a well-known problem, the analogy is incomplete. Indeed, in the standard XY model (as well as the nonlinear $\sigma$ model) the vector (spin) subject to ordering is assumed to be a unit vector with no dependence on $T$. In our case this is fundamentally not the case, and a self-consistent calculation of $T_{BKT}$ as a function of $n_f$ requires additional equations for $\rho$ and $\mu$, which together with (5.18) form a complete system.

---

8 The exponentially small correction is omitted here.
9 A total derivative with respect to $\tau$ is omitted.
10 There is no doubts that in certain situations (for example, very high $T$) it also can become a thermodynamical variable, i.e. dependent on $T$, as happens in problems of phase transitions between ordered (magnetic) and disordered (paramagnetic) phases when the spin itself vanishes. Specifically, for quasi-2D spin systems it is virtually obvious that as one proceeds from high-$T$ regions, at first a spin modulus forms in 2D clusters of finite size and only then does global 3D ordering occur.
5.3 The effective potential and the equations for $\rho$ and $\mu$

There is no need to repeat the calculation of the effective potential. The point is that the effective potential (2.19) calculated in Appendix A depends on (see Section 3.2) the invariant product $\Phi \Phi^* = \rho^2$ only. Thus, one may immediately write

$$\Omega_{pot}(v, \mu, T, \rho) = v \left[ \frac{\rho^2}{V} - \int \frac{dk}{(2\pi)^2} \left( 2T \ln \cosh \frac{\sqrt{\xi^2(k) + \rho^2}}{2T} - \xi(k) \right) \right],$$

(5.19)

where $\xi(k) = k^2 / 2m - \mu$. Then the desired missing equations are the condition $\partial \Omega_{pot}(\rho) / \partial \rho = 0$ that the potential (5.19) be minimum and the equality $v^{-1} \partial \Omega_{pot} / \partial \mu = -n_f$, which fixes $n_f$. For them we have, respectively:

$$\frac{1}{V} = \int \frac{dk}{(2\pi)^2} \frac{1}{2\sqrt{\xi^2(k) + \rho^2}} \tanh \frac{\sqrt{\xi^2(k) + \rho^2}}{2T},$$

(5.20)

$$n_F(\mu, T, \rho) = n_f.$$  

(5.21)

The equations (5.20) and (5.21) obtained above comprise a self-consistent system for determining the modulus $\rho$ of the order parameter and the chemical potential $\mu$ in the mean-field approximation for fixed $T$ and $n_f$.

As we have already discussed in Section 3.3, the energy of two-particle bound states $\varepsilon_b$ (see its definition (3.10)), is more convenient to use than the four-fermi constant $V$. For example, using the identity

$$\tanh \frac{x}{2} = 1 - \frac{2}{\exp x + 1}$$

one may easily go to the limits $W \to \infty$ and $V \to 0$ in the equation (5.20), which after this renormalization becomes

$$\ln \frac{|\varepsilon_b|}{\sqrt{\mu^2 + \rho^2} - \mu} = 2 \int_{-\mu/T}^{\infty} \frac{du}{\sqrt{u^2 + (\frac{\rho}{T})^2}} \left[ \exp \sqrt{u^2 + (\frac{\rho}{T})^2} + 1 \right],$$

(5.22)

Thus, in practice, we will solve numerically the system of the equations (5.18), (5.22) and (5.21) to study $T_{BKT}$ as function of $n_f$.

It is easy to show that at $T = 0$ the system (5.22), (5.21) transforms into the system (3.14) which was already addressed. Recall that its solution is $\rho = \sqrt{2|\varepsilon_b|} \varepsilon_F$ and $\mu = -|\varepsilon_b| / 2 + \varepsilon_F$. This will be useful for studying the concentration dependencies of $2\Delta / T_{BKT}$ and $2\Delta / T_\rho$, where $\Delta$ is the zero-temperature gap in the quasiparticle excitation spectrum [17, 20, 32]

$$\Delta = \begin{cases} \rho, & \mu > 0; \\
\sqrt{\mu^2 + \rho^2}, & \mu < 0.
\end{cases}$$

(5.23)

Setting $\rho = 0$ in the equations (5.20) and (5.21), we arrive (in the same approximation) at the equations for the critical temperature $T_\rho$ and the corresponding value of $\mu$:

$$\ln \frac{|\varepsilon_b|}{T_\rho \pi} = - \int_0^{\mu / 2T_\rho} \frac{du}{u} \tanh \frac{u}{\pi} \quad (\gamma = 1.781),$$

(5.24)
\[
T_\rho \ln \left[ 1 + \exp \left( \frac{\mu}{T_\rho} \right) \right] = \epsilon_F.
\]

(5.25)

Note that these equations coincide with the system which determines \( T_{c(2D)}^{MF} \) and \( \mu(T_{c(2D)}^{MF}) \) (see [37]). This is evidently related with mean-field approximation used here. There is, however, a crucial difference between these values. Namely, if one takes into account the fluctuations, the value of \( T_{c2D} \) should go to zero, while the value of \( T_\rho \) should stay finite.

That is the reason why the temperature \( T_\rho \) has its own physical meaning: the incoherent (local or Cooper) pairs begin to be formed formed below \( T_\rho \). At higher temperatures there are these pair fluctuations only (see e.g. [21]).

5.4 The phase diagram

The numerical investigation of the systems (5.18), (5.22), (5.21) and (5.24), (5.25) gives the following very interesting results, which are displayed graphically.

![Phase diagram](image)

Figure 1: \( T_{BKT} \) and \( T_\rho \) versus the free fermion density. The dots represent the function \( \rho(\epsilon_F) \) at \( T = T_{BKT} \). The regions of the normal phase (NP), anomalous normal phase (ANP) and BKT phase are indicated.

**a)** The anomalous phase region (see Fig.1) in the present model is commensurate with the BKT region. But it has not been ruled out that in the case of the quasi-2D model this region will disappear as \( n_f \) increases. For example, in the case of an indirect interaction it was shown [65] that the anomalous phase region really exists at the low carrier density only, i.e. it shrinks when the doping increases.

**b)** For low \( \epsilon_F (\ll |\epsilon_b|) \) the function \( T_{BKT}(\epsilon_F) \) is linear, as it also confirmed by the analytical solution of the system (5.18), (5.22) and (5.21), which gives \( T_{BKT} = \epsilon_F / 2 \). Surprisingly such behaviour (although for \( T_c \)) is copied in different families of non-conventional ("exotic") superconductors (HTSC including) with comparatively small Fermi energy [21].

We note that in this limit the temperature \( T_c \) of formation of a homogeneous order parameter for the quasi-2D model (see Chapter 4, the equation (4.13)) can be written in the following form [65] (see also [21])

\[
T_c \approx \frac{T_{BKT}}{\ln(\epsilon_F |\epsilon_b|/4t_||^2)}.
\]

(5.26)
where $t_{\parallel} = 1/(m_z d_z^2)$ is the inter-plane hopping (coherent tunnelling) constant. This shows that when $T_c < T_{BKT}$ the weak three-dimensionalization can preserve (in any case, for low $n_f$) the regions of the anomalous and BKT phases, which, for example, happens in the relativistic quasi-2D model \[\text{[60]}\]. At the same time, as the three-dimensionalization parameter $t_{\parallel}$ increases, when $T_c > T_{BKT}$ the BKT phase can vanish, provide, however, that the anomalous phase region and both temperatures $T_{\rho}$ and $T_c$ are preserved. It follows from (5.26) that the BKT phase vanishes when $t_{\parallel} > \sqrt{2|\epsilon_b|\epsilon_F} (= \Delta)$.

![Figure 2](image_url)

**Figure 2:** $\mu(T)$ for different values of $\epsilon_F/|\epsilon_b|$: 1 — 0.05; 2 — 0.2; 3 — 0.45; 4 — 0.6; 5 — 1; 6 — 2; 7 — 5. (For $\mu > 0$ and $\mu < 0$ the chemical potential was scaled to $\epsilon_F$ and $|\epsilon_b|$, respectively.) The thick lines bound regions of the BKT, anomalous normal and normal phases.

c) Figure 2 shows the values $n_f$ for which $\mu$ differs substantially from $\epsilon_F$ and, in other words, the Landau Fermi-liquid theory becomes inapplicable for metals with low or intermediate carrier density. As expected, the kink $\mu$ at $T = T_{\rho}$, experiments on observation which were discussed in \[\text{[67]}\] and have been interpreted for the 1-2-3 cuprate \[\text{[68]}\], becomes increasingly less pronounced as $\epsilon_F$ increases. But in the present case it is interesting that in the approximation employed it happens at the normal-anomalous phases boundary or before superconductivity really appears. Therefore it would be of great interest to perform experiments which would reveal the temperature dependence $\mu(T)$ especially for strongly anisotropic and relatively weakly doped cuprates.

d) It follows from curve 3 in Fig. 2 that the transition (change in sign of $\mu$) from local to
Cooper pairs is possible not only as $\epsilon_F$ increases, which is more or less obvious, but also (for some $n_f$) as $T$ increases.

![Figure 3: $2\Delta/T_{BKT}$ and $2\Delta/T_\rho$ versus the free fermion density.](image)

e) Finally the calculations showed (see Fig. 3) that the ratio $2\Delta/T_{BKT}$ is always greater than 4.4. The value $2\Delta/T_\rho (= 2\Delta/T_c^{MF})$ is, however, somewhat lower and reaches the BCS theory limit of 3.52 only for $\epsilon_F \gg |\epsilon_b|$. It is interesting that this concentration behaviour is consistent with numerous measurements of this ratio in HTSC [69, 70]. Note that the divergencies of $2\Delta/T_{BKT}$ and $2\Delta/T_\rho$ at $\epsilon_F \to 0$ are directly related with the definition (5.23).

Discussing the phase diagram obtained it can be emphasized that the qualitative ideas about the crucial importance of phase fluctuations for underdoped HTSC was, to our knowledge, first discussed by Emery and Kivelson [6]. These authors, starting from the experimental data of Uemura et al. [21] and some others (see the Refs. cited in [6]), and from the well-known general observation the superconducting state is characterized by a complex order parameter, introduced the temperature $T_\theta$ at which phase order can occur. They have also argued that at low superconducting carrier density and poor screening (i.e. in bad metals) phase fluctuations become more significant than all other fluctuations, so that the classical XY-model is suitable for underdoped cuprate oxides. When $T_c \ll T_\theta^{max}$ ($T_\theta^{max}$ is the temperature at which the phase order disappears if the disordering effects of all the other degrees of freedom are ignored), phase fluctuations must be relatively unimportant and the observable $T_c$ will be close to the $T_c^{MF}$ predicted by BCS-Bogolyubov theory. Otherwise, $T_c \simeq T_\theta^{max} < T_c^{MF}$, and $T_c^{MF}$ is simply the temperature at which local pairing occurs.

Undoubtedly, the approach developed in this Chapter is self-consistent and a more-or-less complete (in the hydrodynamical approximation) extension of the semiquantitative results presented in [6, 21]. At the same time there is only one difference (but in our opinion an essential one) between the behaviour of the function we obtain for $T_c^{MF}(n_f) \equiv T_\rho(n_f)$ in the limit $n_f \to 0$ and the function sketched for $T_c^{MF}$ in [6]. It is clear from the figure (see Fig.1) (and can be shown analytically) that in our case the zero density limit is $T_\rho(0) = 0$, in contrast to Refs. [6, 21] where $T_c^{MF}$ grows when $n_f$ decreases.

On the other hand, the limit $T_\rho(n_f \to 0) \to 0$ (the same argument also applies to $T_{dissoc}$ in Section 2.3) cannot be considered sufficiently regular due to the strong increase,
for small \( n_f \), of the neutral order parameter fluctuations which were not taken into account in the approximation used. From the physical point of view perhaps the most consistent limit for this, extremely low (when \( \mu < 0 \)) fermion density, region is: \( T_\rho(n_f \to 0) \to T_P \approx 2\sqrt{\rho^2 + \mu^2} \sim |\varepsilon_b| \) (see \( \text{(5.23)} \) and Fig.2).

5.5 “Spin-gap” behaviour in the anomalous normal phase

It would be very interesting to study how a nonzero value of the neutral order parameter affects the observable properties of the 2D system. Does this really resemble the gap opening in the traditional superconductors, except that it happens in the normal phase? Or, in other words, does the pseudogap open?

We shall demonstrate this phenomenon taking, as a case in point, the paramagnetic susceptibility of the system \( \text{[8]} \).

To study the system in the magnetic field \( H \) one has to add the paramagnetic term

\[
\mathcal{H}_{PM} = -\mu_B H \left[ \psi_+^\dagger(r) \psi_+(r) - \psi_+^\dagger(r) \psi_+(r) \right],
\]

to the Hamiltonian \( \text{(2.1)} \). Here \( \mu_B = e\hbar/2mc \) is the Bohr magneton. Note that, using the isotropy in the problem, we chose the direction of field \( H \) to be perpendicular to the plane containing the vectors \( r \). (Recall that in this Chapter \( d = 2 \) and \( r \) is the 2D vector.)

It is a very simple matter to rewrite \( \mathcal{H}_{PM} \) in the Nambu variables \( \text{(2.2)} \), namely

\[
\mathcal{H}_{PM} = -\mu_B H \Psi^\dagger(r) \Psi(r).
\]

Then, adding the corresponding term to the equation \( \text{(5.10)} \) for the neutral fermion Green function, it is easy to obtain that of in the momentum representation (compare with \( \text{(5.2)} \))

\[
G(i\omega_n, k, H) = \frac{1}{(i\omega_n + \mu_B H)\hat{I} - \tau_3 \xi(k) + \tau_1 \rho} = \frac{(i\omega_n + \mu_B H)\hat{I} + \tau_3 \xi(k) - \tau_1 \rho}{(i\omega_n + \mu_B H)^2 - \xi^2(k) - \rho^2}.
\]

The static paramagnetic susceptibility is expressed through the magnetization

\[
\chi(\mu, T, \rho) = \frac{\partial M(\mu, T, \rho, H)}{\partial H}\bigg|_{H=0},
\]

which in the mean-field approximation may be derived from the effective potential

\[
M(\mu, T, \rho, H) = -\frac{1}{\nu} \frac{\partial \Omega_{\text{pot}}(\nu, \mu, T, \rho, H)}{\partial H}.
\]

Thus from \( \text{(5.31)} \) one obtains \( \text{[7]} \)

\[
M(\mu, T, \rho, H) = \mu_B T \sum_{n=-\infty}^{\infty} \int \frac{d\mathbf{k}}{(2\pi)^2} \text{tr}[G(i\omega_n, \mathbf{k}, H)\hat{I}]\]

\[11\text{That was done with V.P. Gusynin.}
\[12\text{Note that one should use the first part of \( \text{(5.29)} \) to get this formula.}

37
Then using the definition (5.30) one arrives at

$$\chi(\mu, T, \rho) = \mu_B^2 \int \frac{dk}{(2\pi)^2} 2T \sum_{n=-\infty}^{\infty} \frac{\xi^2(k) + \rho^2 - \omega_n^2}{[\omega_n^2 + \xi^2(k) + \rho^2]^2}. \quad (5.33)$$

The sum in (5.33) is calculated in Appendix C (see the equation (C.3)) and, thus, we obtain the final result

$$\chi(\mu, T, \rho) = \chi_{\text{Pauli}} \frac{1}{2} \int_{-\mu/2T}^{\infty} \frac{dx}{\cosh^2 \sqrt{x^2 + \rho^2/4T}}, \quad (5.34)$$

where $\chi_{\text{Pauli}} \equiv \mu_B^2 m/\pi$ is the Pauli paramagnetic susceptibility for the 2D system.

To study $\chi$ as a function of $T$ and $\nu_f$ (or $\epsilon_F$) the formula (5.34) should be used together with the equations (5.22) and (5.21).

For the case of the normal phase ($\rho = 0$) one can investigate the system analytically. Thus (5.34) takes form

$$\chi(\mu, T, \rho = 0) = \chi_{\text{Pauli}} \frac{1}{1 + \exp(-\mu/T)}, \quad (5.35)$$

while $\mu$ is already determined by (5.25). This system has the solution

$$\chi(\epsilon_F, T, \rho = 0) = \chi_{\text{Pauli}}[1 - \exp(-\epsilon_F/T)], \quad (5.36)$$

which coincides with that known from the literature [2].

![Graph](image)

Figure 4: $\chi(T)$ for different values of $\epsilon_F/|\epsilon_b|$: 1 — 0.2; 2 — 0.6; 3 — 1; 4 — 5; 5 — 10; 6 — 20.

The results of numerical study of the system (5.34), (5.22) and (5.21) are presented in Fig. 4. One can see that the kink in $\chi$ happens at $T = T_\rho$ as in the dependence of $\mu$ on $T$. Below $T_\rho$ the value of $\chi(T)$ decreases, although the system is still normal. This means that the spin-gap (pseudogap) opens. The size of the pseudogap region depends strongly on the doping ($\epsilon_F/|\epsilon_b|$), as it takes place for the real HTSC [61, 62, 60]. For small values of $\epsilon_F/|\epsilon_b|$ this region is large ($T_\rho > 2T_{BKT}$), while for the large ratio it is small.
6 Concluding remarks

To summarize we have discussed the crossover in the superconducting transition between BCS- and Bose-like behaviour for the simplest 3D, quasi-2D and 2D models with s-wave direct non-retarded attractive interaction. It has been pointed out that optimally doped HTSC are still on the BCS side of this crossover, although they are certainly far away from the standard BCS description.

Above we emphasized the model description which in our opinion proves to be the most suitable for the clarification of the diverse physical properties peculiar to electronic systems with changeable carrier density in any dimension. While there is still no generally accepted microscopic theory of HTSC compounds and their basic features (including the pairing mechanism), it seems to us that this approach, although in a sense phenomenological, is of great interest since it is able to cover the whole region of carrier concentrations (and consequently the whole range of coupling constants), temperatures and crystal anisotropies. It, as we tried to demonstrate, allows one not only to propose a reasonable interpretation for the observed phenomena caused by doping but also to predict new phenomena (for example, pseudogap phase formation as a new thermodynamically equilibrium normal state of low dimensional conducting electronic systems).

Evidently there are a number of important open questions. They may be divided into two classes: the first one concerns the problem of a better and more complete treatment of the models themselves. The second class is related to the problem of to what extent these model are applicable to HTSC compounds and what are the necessary ingredients for a more realistic description.

Regarding our treatment of the 3D and quasi-2D models, it is obvious that one has to take into account the interaction between the bosons also. In particular the Gaussian approximation is not sufficient to give reliable results for $T_c$ at intermediate coupling when the "size" of the bosons is comparable with the mean distance between them. As for the 2D model, there is some unconfirmed numerical result \[71\] based on a fully self-consistent determination of a phase transition to a superconducting state in a conserving approximation, which state that the superconducting transition is not the BKT transition. Besides, it would be very interesting to obtain the spectrum of the anomalous normal phase.

Concerning the question to which the models considered are really applicable to HTSC, it is obvious that most of the complexity of these systems is neglected here. We did not take into account an indirect nature of the interaction between the fermions and d-wave pairing. Note, however, that some attempts to study the crossover for these cases were made \[72, 73, 78\] (for general review see \[74\]).

A lot of peculiarities of HTSC are now connected with stripe structure of CuO$_2$ planes, which, according to many experiments (see \[74\] and references therein), are divided onto bands of the normal and superconducting bands. There is interesting and important problem how to investigate these systems.

The problem of the crossover from BEC to BCS (especially for 2D systems) is such a rich one that without doubt will bring us a lot of surprises in the near and far future. One of them is perhaps the unified theory of superconductivity and magnetism \[75\] which has already excited a lot of interest and criticism (e.g. \[76\]).
A The effective potential

Let us derive the effective potential (2.19). To obtain it one should write down the formal expression (2.13) in the momentum representation, so that

$$\Omega \text{pot}(v, \mu, T, \Phi, \Phi^*) = v \left\{ \left| \Phi \right|^2 \frac{V}{V} - T \sum_{n=-\infty}^{+\infty} \int \frac{dk}{(2\pi)^d} \frac{1}{\det G^{-1}(i\omega_n, k)} \right\}, \quad \delta \to +0,$$

(A.1)

where

$$G^{-1}(i\omega_n, k) = i\omega_n I - \tau_3\xi(k) + \tau_+\Phi + \tau_-\Phi^* = \begin{pmatrix} i\omega_n - \xi(k) & \Phi \\ \Phi^* & i\omega_n + \xi(k) \end{pmatrix}$$

(A.2)

and

$$G_0^{-1}(i\omega_n, k) = G^{-1}(i\omega_n, k) \bigg|_{\Phi = \Phi^* = \mu = 0} = \begin{pmatrix} i\omega_n - \varepsilon(k) & 0 \\ 0 & i\omega_n + \varepsilon(k) \end{pmatrix}$$

(A.3)

are the inverse Green functions. The exponential factor $e^{i\delta\omega_n\tau_3}$ is added into (A.1) to provide a right regularization which is necessary to perform the calculation with the Green functions (see [77]). For instance, one obtains that

$$\lim_{\delta \to +0} \sum_{n=-\infty}^{+\infty} \frac{1}{\omega_n} \left( \sum_{n=-\infty}^{+\infty} \frac{1}{\omega_n} \right) \cos \delta\omega_n + i \sum_{\omega_n > 0} \sin \delta\omega_n \left( \ln G^{-1}(i\omega_n, k) - \ln G^{-1}(-i\omega_n, k) \right) \tau_3 \right\} =$$

$$= \sum_{n=-\infty}^{+\infty} \frac{1}{\omega_n} \left( \sum_{n=-\infty}^{+\infty} \frac{1}{\omega_n} \right) - \frac{\xi(k)}{T},$$

(A.4)

where the properties that

$$\ln G^{-1}(i\omega_n, k) = -\tau_3\frac{\xi(k)}{i\omega_n}, \quad \omega_n \to \infty$$

and

$$\sum_{\omega_n > 0} \frac{\sin \delta\omega_n}{\omega_n} \approx \frac{1}{2\pi T} \int_0^\infty dx \frac{\sin \delta x}{x} = \frac{1}{4T} \text{sign} \delta$$

were used.

To calculate the sum in (A.4) one have to firstly use the identity $\text{tr} \ln \hat{A} = \ln \det \hat{A}$, so that (A.1) takes the following form

$$\Omega \text{pot}(v, \mu, T, \Phi, \Phi^*) = v \left\{ \left| \Phi \right|^2 \frac{V}{V} - T \sum_{n=-\infty}^{+\infty} \int \frac{dk}{(2\pi)^d} \ln \frac{\det G^{-1}(i\omega_n, k)}{\det G_0^{-1}(i\omega_n, k)} \right\}.$$

(A.5)
Calculating the determinants of the Green functions (A.2) and (A.3) one gets

\[
\Omega_{pot}(v, \mu, T, \Phi, \Phi^*) = v \left\{ \frac{|\Phi|^2}{V} - T \sum_{n=-\infty}^{+\infty} \int \frac{dk}{(2\pi)^d} \ln \frac{\omega_n^2 + |\Phi|^2}{\omega_n^2 + \epsilon^2(k)} \right. \\
- \left. \int \frac{dk}{(2\pi)^d} \left[-\xi(k) + \epsilon(k) \right] \right\}, \tag{A.6}
\]

where the role of \( G_0(i\omega_n, k) \) in the regularization of \( \Omega_{pot} \) is evident now. The summation in (A.6) can be done if one uses the following representation

\[
\ln \frac{\omega_n^2 + a^2}{\omega_n^2 + b^2} = \int_0^\infty dx \left( \frac{1}{\omega_n^2 + a^2 + x} - \frac{1}{\omega_n^2 + b^2 + x} \right). \tag{A.7}
\]

Then, the sum

\[
\sum_{k=0}^{\infty} \frac{1}{(2k+1)^2 + c^2} = \frac{\pi}{4c} \tanh \frac{\pi c}{2} \tag{A.8}
\]

may be now applied and one obtains

\[
\ln \frac{\omega_n^2 + a^2}{\omega_n^2 + b^2} = \\
\int_0^\infty dx \left( \frac{1}{2\sqrt{b^2 + x}} \tanh \frac{\sqrt{b^2 + x}}{2T} - \frac{1}{2\sqrt{a^2 + x}} \tanh \frac{\sqrt{a^2 + x}}{2T} \right). \tag{A.9}
\]

Integrating (A.9) over \( x \) one thus arrives to the expression:

\[
T \sum_{n=-\infty}^{+\infty} \int \frac{dk}{(2\pi)^d} \ln \frac{\omega_n^2 + \xi(k)^2 + |\Phi|^2}{\omega_n^2 + \epsilon^2(k)} = \\
2T \int \frac{dk}{(2\pi)^d} \ln \frac{\cosh[\sqrt{\xi^2(k)} + |\Phi|^2/2T]}{\cosh[\epsilon(k)/2T]}. \tag{A.10}
\]

Finally, substituting (A.10) into (A.6) we get (2.19).

**B Low energy kinetic part of the effective action**

Here we derive the kinetic part (5.8) of the effective action (5.7). To obtain it one should calculate directly the first two terms of the series in (5.8) which are formally written as

\[
\Omega_{kin}^{(1)} = T \text{Tr}(G\Sigma) \quad \text{and} \quad \Omega_{kin}^{(2)} = \frac{1}{2} T \text{Tr}(G\Sigma G\Sigma). \tag{B.1}
\]

The straightforward calculation of \( \Omega_{kin}^{(1)} \) gives

\[
\Omega_{kin}^{(1)} = T \int_0^\beta d\tau \int \frac{dr}{(2\pi)^2} \sum_{n=-\infty}^{+\infty} \int dk tr[G(i\omega_n, k)\tau_3] \left( i\partial_n + \frac{(\nabla \theta)^2}{2m} \right), \tag{B.1}
\]

where

\[
G(i\omega_n, k) = -\frac{i\omega_n \hat{I} + \tau_3 \xi(k) - \tau_1 \rho}{\omega_n^2 + \xi^2(k) + \rho^2} \tag{B.2}
\]

is the Green function of the neutral fermions in the frequency-momentum representation (compare with (2.18)). The summation over Matsubara frequencies \( \omega_n = \pi(2n+1)T \) and
integration over \( k \) in \((B.1)\) can be easily performed using the sum \((A.8)\) and thus one obtains

\[
\Omega^{(1)}_{\text{kin}} = T \int_0^\beta d\tau \int d\mathbf{r} n_F(\mu, T, \rho) \left( i \partial_\tau \theta + \frac{(\nabla \theta)^2}{2m} \right),
\]

where \( n_F(\mu, T, \rho) \) is determined by \((5.17)\). We note that \( \Sigma \) has the following structure

\[
\Sigma = \tau \Omega_1 + \hat{I} \Omega_2
\]

where \( \Omega_1 \) and \( \Omega_2 \) are some differential operators (see \((5.11)\)). One can see, however, that the part of \( \Sigma \), proportional to the unit matrix \( \hat{I} \), does not contribute in \( \Omega^{(1)}_{\text{kin}} \).

For the case \( T = 0 \) \cite{[63, 64]} when real time \( t \) replaces imaginary time \( \tau \), one can argue from the Galilean invariance that the coefficient of \( \partial_\tau \theta \) is rigidly related to the coefficient at \( (\nabla \theta)^2 \). So it does not appear in \( \Omega^{(2)}_{\text{kin}} \). We wish, however, to stress that these arguments can not be used to exclude the appearance of the term \( (\nabla \theta)^2 \) from \( \Omega^{(2)}_{\text{kin}} \) when \( T \neq 0 \), thus we must calculate it explicitly.

The \( \Omega_1 \) term in \( \Sigma \) yields

\[
\Omega^{(2)}_{\text{kin}}(\Omega_1) = \frac{T}{2} \int_0^\beta d\tau \int d\mathbf{r} \frac{T}{(2\pi)^2} \sum_{n=-\infty}^{\infty} \int d\mathbf{k} \text{tr}[\mathcal{G}(i\omega_n, \mathbf{k})\tau_3 \mathcal{G}(i\omega_n, \mathbf{k})\tau_3] \times
\]

\[
\left( i \partial_\tau \theta + \frac{(\nabla \theta)^2}{2m} \right)^2,
\]

And from \((B.4)\) we find that

\[
\Omega^{(2)}_{\text{kin}}(\Omega_1) = -\frac{T}{2} \int_0^\beta d\tau \int d\mathbf{r} \mathcal{K}(\mu, T, \rho) \left( i \partial_\tau \theta + \frac{(\nabla \theta)^2}{2m} \right)^2,
\]

where \( \mathcal{K}(\mu, T, \rho) \) was defined in \((5.16)\). It is evident that \( \Omega_1 \) term does not affect the coefficient of \( (\nabla \theta)^2 \). Further, it is easy to make sure that the cross term from \( \Omega_1 \) and \( \Omega_2 \) in \( \Omega^{(2)}_{\text{kin}} \) is absent. Finally, the calculations of the \( \Omega_2 \) term contribution to \( \Omega^{(2)}_{\text{kin}} \)\footnote{The higher than \( (\nabla \theta)^2 \) derivatives were not found here.} give

\[
\Omega^{(2)}_{\text{kin}}(\Omega_2) = T \int_0^\beta d\tau \int d\mathbf{r} \frac{T}{(2\pi)^2} \sum_{n=-\infty}^{\infty} \int d\mathbf{k} \text{tr}[\mathcal{G}(i\omega_n, \mathbf{k})\hat{I} \mathcal{G}(i\omega_n, \mathbf{k})\hat{I}] \times
\]

\[
\frac{(\nabla \theta)^2}{4m^2}.
\]

Thus, after summation over Matsubara frequencies (see Appendix C)

\[
\Omega^{(2)}_{\text{kin}}(\Omega_2) = -\int_0^\beta d\tau \int d\mathbf{r} \frac{1}{32\pi^2 m^2} \int d\mathbf{k} \frac{k^2}{\cosh^2 \sqrt{\xi^2(k) + \rho^2/2T}} (\nabla \theta)^2.
\]

As expected this term vanishes when \( T \to 0 \) but at finite \( T \) it is comparable with \((B.3)\).

Combining \((B.3)\), \((B.5)\) and \((B.7)\) we obtain \((5.14)\).
C Summation over Matsubara frequencies

Here we perform the summation over Matsubara frequencies in the following expression

\[ T \sum_{n=-\infty}^{\infty} \text{tr}[G(i\omega_n, k) \hat{I} G(i\omega_n, k) \hat{I}] \], \hspace{1cm} (C.1) \]

where the Green function \( G(i\omega_n, k) \) is given by (B.3). At first, using the elementary properties of the Pauli matrices one obtains

\[ \text{tr}[G(i\omega_n, k) \hat{I} G(i\omega_n, k) \hat{I}] = 2\left[\xi^2(k) + \rho^2 - \omega_n^2\right]\left[\omega_n^2 + \xi^2(k) + \rho^2\right]^2. \hspace{1cm} (C.2) \]

Then, the summation can be easily carried out, if one uses the following sums [78]

\[ \sum_{k=0}^{\infty} \frac{1}{(2k+1)^2 + a^2} = \frac{\pi}{8a^2} \tanh \frac{\pi a}{2} - \frac{\pi^2}{16a^2 \cosh^2 \frac{2a}{2}} \hspace{1cm} (C.3) \]

and

\[ \sum_{k=0}^{\infty} \frac{(2k+1)^2}{(2k+1)^2 + a^2} = \frac{\pi}{8a} \tanh \frac{\pi a}{2} + \frac{\pi^2}{16 \cosh^2 \frac{2a}{2}} \hspace{1cm} (C.4) \]

Assuming that \( a^2 \equiv \left(\xi^2(k) + \rho^2\right)/\pi^2 T^2 \) one directly arrives to the final result

\[ 2T \sum_{n=-\infty}^{\infty} \frac{\xi^2(k) + \rho^2 - \omega_n^2}{[\omega_n^2 + \xi^2(k) + \rho^2]^2} = -\frac{1}{2T} \frac{1}{\cosh^2 \sqrt{\xi^2(k) + \rho^2}/2T}. \hspace{1cm} (C.5) \]
