Abstract

The complex scalar dark matter (DM) candidate in the gauged two Higgs doublet model (G2HDM), stabilized by a peculiar hidden parity (h-parity), is studied in detail. We explore the parameter space for the DM candidate by taking into account the most recent DM constraints from various experiments, in particular, the PLANCK relic density measurement and the current DM direct detection limit from XENON1T. We separate our analysis in three possible compositions for the mixing of the complex scalar. We first constrain our parameter space with the vacuum stability and perturbative unitarity conditions for the scalar potential, LHC Higgs measurements, plus Drell-Yan and electroweak precision test constraints on the gauge sector. We find that DM dominated by composition of the inert doublet scalar is completely excluded by further combining the previous constraints with both the latest results from PLANCK and XENON1T. We also demonstrate that the remaining parameter space with two other DM compositions can be further tested by indirect detection like the future CTA gamma-ray telescope.
I. INTRODUCTION

Dark Matter (DM) has become one of the most discussed topics in cosmology, astrophysics and particle physics. However, besides the indirect evidence from the power spectrum from the cosmic microwave background radiation (CMB) and the galaxy rotational curves which provide strong hints for the need of DM, current experiments for DM direct detection, indirect detection and collider searches still show no clue for the nature of DM. Currently, the best description of the early history of the Universe is given by the ΛCDM model which assumes the presence of dark energy and cold DM in addition to the ordinary matter. The leading hypothesis is that this cold DM is comprised of weakly interacting massive particle (WIMP) that was thermally produced just like the other Standard Model (SM) particles in the early universe. It is well known that the most compelling feature of WIMP DM is that, after freeze-out whence the DM reaction rates fell behind the Hubble expansion rate of the universe, it is possible to achieve the correct relic abundance with an electroweak sized annihilation cross section with a WIMP mass of a few hundreds GeV to a few TeV.

On the collider phenomenology side, we now know that all the major decay modes of the SM 125 GeV Higgs discovered on the fourth of July 2012 at the Large Hadron Collider (LHC) have been observed except the $Z\gamma$ and $\mu^+\mu^-$ modes. So far all the experimental results agree with the SM predictions within $10 \sim 15\%$. Nevertheless there are still some rooms for new physics. A particular class of models that extends simply the scalar sector of the SM to address new physics is quite popular. The most well known example is the general two Higgs doublet model (2HDM), which has several variants and resulted in very rich phenomenology. For a review of 2HDM and its phenomenology, see for example [1, 2]. One of the interesting variants of 2HDM is to impose a $Z_2$ symmetry in the model so that the second Higgs doublet
is $Z_2$-odd and then can be a DM candidate. This is the inert Higgs doublet model (IHDM) and many detailed phenomenological studies had been performed over the years. Furthermore, the idea that this $Z_2$ symmetry emerges accidentally in a renormalizable gauged two Higgs doublet model (G2HDM) has been explored recently in [28]. In G2HDM the two Higgs doublets are grouped together in an irreducible doublet representation of an extra non-Abelian $SU(2)_H$ gauge group. Besides the new hidden $SU(2)_H$, the SM gauge group is extended by including a new $U(1)_X$ symmetry. The scalar sector is further extended by including a new $SU(2)_H$ doublet and a triplet, both singlets under the SM gauge group.

Although any electrically neutral $Z_2$-odd particle in G2HDM can be considered a DM candidate, such as $W'$ or heavy new neutrinos, in this work we choose to concentrate on the phenomenology of the complex scalar DM candidate. The reason is mainly that we want to present this model as a viable alternative to IHDM and as such our setup is focused in providing a light, neutral and $Z_2$-odd complex scalar. Another reason is practicality, given that our setup is complicated enough to distinguish at least 3 main types of DM candidates coming only from the scalar sector due to mixing effects. We will study in detail the differences, similarities and results of these three possibilities. Phenomenologically, we expect all of them to communicate with the SM through Higgs portal type interactions. However, we will demonstrate that the SM $Z$ boson as well as its heavier siblings in G2HDM will also play non-negligible roles as mediators in various DM processes in relic density, direct and indirect detection, especially for the inert doublet-like DM case.

In the past, some collider phenomenology of G2HDM has been studied. It was determined that Drell-Yan type signals may help detect the G2HDM $Z'$ in the high luminosity upgrade of the LHC and that enhancement of pair production of Higgs boson in the LHC is moderate compared to the SM. In a recent study it has been determined that G2HDM has a viable scalar sector parameter space.
compatible with vacuum stability and perturbative unitarity conditions, as well as Higgs phenomenology constraints from the LHC. The gauge sector is constrained by electroweak precision tests (EWPT) \cite{35}, setting limits on the masses of the new gauge bosons and the gauge sector parameter space. It is precisely this two recent studies on the scalar and gauge sectors constraints (SGSC) that we will take as starting point for our study, thus ensuring that the final constrained parameter space is consistent with previous studies and that our result has a stronger relevance.

This article is organized as follows. In Sec. II we briefly recall some salient features of the G2HDM model, in particular the scalar potential and mass spectra. In Sec. III we point out after spontaneous symmetry breaking there exists an accidental discrete $\mathbb{Z}_2$ symmetry in the whole Lagrangian of G2HDM. We classify all the particles in the model according to whether they are even or odd under this discrete symmetry, dubbed as $h$-parity. This residual symmetry forbids the lightest particle in the hidden sector to decay and hence it, if electrically neutral, may be a cold DM candidate in the model. We discuss further the compositions of complex scalar dark matter that is relevant in this work. In Sec. IV we discuss the DM constraints included in our analysis and how they are affected by our setup in more general terms. We describe how relic density (RD), direct detection (DD) and indirect detection (ID) measurements constrain each of the three different compositions of complex scalar DM considered. We also discuss the collider searches of DM from the mono-jet plus missing energy search and invisible Higgs decay. In Sec. V after a brief description of the methodology used in our numerical analysis we present the results of our analysis. Finally, in Sec. VI we summarize our findings and conclude, including a brief comment on future detectability. Some Feynman rules that are most relevant to the processes discussed in this work are collected in the Appendix A.
II. THE G2HDM MODEL

A. Matter Content

| Matter Fields   | $SU(3)_C \times SU(2)_L \times SU(2)_H \times U(1)_Y \times U(1)_X$ |
|----------------|---------------------------------------------------------------------|
| $H = (H_1, H_2)^T$ | $(1, 2, 2, 1/2, 1)$                                                  |
| $\Delta_H$       | $(1, 1, 3, 0, 0)$                                                   |
| $\Phi_H$         | $(1, 1, 2, 0, 1)$                                                   |
| $Q_L = (u_L, d_L)^T$ | $(3, 2, 1, 1/6, 0)$                                                |
| $U_R = (u_R, u_R^H)^T$ | $(3, 1, 2, 2/3, 1)$                                              |
| $D_R = (d_R, d_R^H)^T$ | $(3, 1, 2, -1/3, -1)$                                             |
| $L_L = (\nu_L, e_L)^T$ | $(1, 2, 1, -1/2, 0)$                                              |
| $N_R = (\nu_R, \nu_R^H)^T$ | $(1, 1, 2, 0, 1)$                                                |
| $E_R = (e_R^H, e_R)^T$ | $(1, 1, 2, -1, -1)$                                               |
| $\nu_L^H$        | $(1, 1, 1, 0, 0)$                                                   |
| $e_L^H$          | $(1, 1, 1, -1, 0)$                                                  |
| $u_L^H$          | $(3, 1, 1, 2/3, 0)$                                                 |
| $d_L^H$          | $(3, 1, 1, -1/3, 0)$                                                |

TABLE I. Matter contents and their quantum number assignments in G2HDM.

The gauge symmetry group of G2HDM expands the SM gauge group $SU(2)_L \times U(1)_Y$ by adding a hidden sector of $SU(2)_H \times U(1)_X$. In the scalar sector we have the two $SU(2)_L$ Higgs doublets $H_1$ and $H_2$ both paired into an $SU(2)_H$ doublet $H$. The two scalar SM singlets, $\Delta_H$ and $\Phi_H$, have been put into the triplet and doublet representations of $SU(2)_H$, respectively. In order to construct gauge invariant Yukawa couplings, new right-handed heavy fermions have been added as $SU(2)_H$ compan-
ions of the SM right-handed fermions, pairing both of them together into $SU(2)_H$ doublets, but remaining $SU(2)_L$ singlets. Anomaly cancellation requires further that we add two pairs of left-handed heavy leptons and two pairs of left-handed heavy quarks for each family, all of them are singlets under both $SU(2)$ groups and under $U(1)_X$. We note that the $SU(2)_H$ is not the same as the $SU(2)_R$ in left-right symmetric models [37, 38]. The $W'^{(p,m)}$ in G2HDM does not carry electric charge, while the $W'^{\pm}$ in left-right symmetric models does. Thus we use the superscripts $p$ and $m$ to label them, instead of $+$ and $-$. We also note that non-sterile right-handed neutrinos $\nu_{iR}$ introduced in the mirror fermion models of electroweak scale right-handed neutrinos [39–41] are in a different manner. In the mirror fermion models, $\nu_{iR}$s are grouped with mirror charged leptons $l^M_{iR}$s to form $SU(2)_L$ doublets. Here in G2HDM, they are grouped with new heavy right-handed neutrinos $\nu^H_{iR}$ to form $SU(2)_H$ doublets instead. For other related ideas extending the 2HDM with extra gauge symmetries to address flavor problem, dark matter and neutrino masses, see for example [42–47]. The matter contents of the G2HDM model and their respective quantum numbers are listed in Table I.

B. Scalar Potential and Constraints

Scalar Potential

For this work we will be using the scalar potential from Ref. [34], that extends the original potential of Ref. [28] by adding two new terms with couplings $\lambda'_H$ and $\lambda'_{H\Phi}$. The most general scalar potential that respects the G2HDM symmetries can be divided into 4 different parts

$$V_T = V(H) + V(\Phi_H) + V(\Delta_H) + V_{\text{mix}}(H, \Delta_H, \Phi_H) .$$ (1)
The first term $V(H)$ in Eq. (1) consists of the two Higgs doublets $H_1$ and $H_2$ only and is given by

$$V(H) = \mu_H^2 \left( H^{\alpha i} H_{\alpha i} \right) + \lambda_H \left( H^{\alpha i} H_{\alpha i} \right)^2 + \frac{1}{2} \lambda' H^{\alpha i} H_{\alpha i} (H^{\beta j} H_{\beta j})$$

$$= \mu_H^2 \left( H_1^\dagger H_1 + H_2^\dagger H_2 \right) + \lambda_H \left( H_1^\dagger H_1 + H_2^\dagger H_2 \right)^2$$

$$+ \lambda' \left( -H_1^\dagger H_1 H_2^\dagger H_2 + H_1^\dagger H_2 H_2^\dagger H_1 \right) , \quad (2)$$

where greek and latin letters refer to $SU(2)_H$ and $SU(2)_L$ indices respectively, both of which run from 1 to 2, and we use the notation $H^{\alpha i} = H_{\alpha i}^*$. From the second line of Eq. (2), one can clearly see that $V(H)$ has the discrete $Z_2$ symmetry of $H_1 \rightarrow H_1$ and $H_2 \rightarrow -H_2$. Since $V(H)$ contains all the renormalizable terms constructed solely from $H_1$ and $H_2$, this discrete symmetry is automatically present. Recall that in general 2HDM, one needs to impose this discrete symmetry to avoid unwanted terms that may lead to flavor changing neutral current in the Higgs-Yukawa interactions at the tree level. The second term $V(\Phi_H)$ is for the $SU(2)_H$ doublet $\Phi_H$ only and given by

$$V(\Phi_H) = \mu_H^2 \Phi_H^\dagger \Phi_H + \lambda_H \left( \Phi_H^\dagger \Phi_H \right)^2$$

$$= \mu_H^2 (\Phi_1^* \Phi_1 + \Phi_2^* \Phi_2) + \lambda_H (\Phi_1^* \Phi_1 + \Phi_2^* \Phi_2)^2 , \quad (3)$$

where $\Phi_H = (\Phi_1, \Phi_2)^T$. The third term is for the $SU(2)_H$ triplet $\Delta_H$ and is given by

$$V(\Delta_H) = -\mu_\Delta \text{Tr} \left( \Delta_H^2 \right) + \lambda_\Delta \left( \text{Tr} \left( \Delta_H^2 \right) \right)^2$$

$$= -\mu_\Delta \left( \frac{1}{2} \Delta_3^2 + \Delta_p \Delta_m \right) + \lambda_\Delta \left( \frac{1}{2} \Delta_3^2 + \Delta_p \Delta_m \right)^2 , \quad (4)$$

where

$$\Delta_H = \begin{pmatrix} \Delta_3 / 2 & \Delta_p / \sqrt{2} \\ \Delta_m / \sqrt{2} & -\Delta_3 / 2 \end{pmatrix} = \Delta_H^\dagger \text{ with } \Delta_m = (\Delta_p)^* \text{ and } (\Delta_3)^* = \Delta_3 . \quad (5)$$
Furthermore, unlike other models with $SU(2)_L$ triplet Higgs, the off-diagonal components $\Delta_{p,m}$ do not carry electric charge. We use the subscripts $p$ and $m$ to label them instead of $+ \text{ and } -$ in the same way as the new gauge bosons $W'_{(p,m)}$. Finally, the last term $V_{\text{mix}}$ consists all three scalars $H$, $\Phi_H$ and $\Delta_H$

$$V_{\text{mix}}(H, \Delta_H, \Phi_H) = + M_{H\Delta} \left( H^\dagger \Delta_H H \right) - M_{\Phi \Delta} \left( \Phi_H^\dagger \Delta_H \Phi_H \right) + \lambda_{H\Phi} \left( H^\dagger H \right) \left( \Phi_H^\dagger \Phi_H \right) + \lambda_H \left( H^\dagger H \right) \left( \Phi_H^\dagger \Phi_H \right) \frac{\text{Tr} \left( \Delta_H^2 \right)}{2} + \lambda_{\Phi \Delta} \left( \Phi_H^\dagger \Phi_H \right) \frac{\text{Tr} \left( \Delta_H^2 \right)}{2} .$$

(6)

Eq. (6) can be expanded further in terms of the component fields of $H$, $\Delta_H$ and $\Phi_H$ as follows

$$V_{\text{mix}}(H, \Delta_H, \Phi_H) = + M_{H\Delta} \left( \frac{1}{\sqrt{2}} H_1^\dagger H_2 \Delta_p + \frac{1}{2} H_1^\dagger H_1 \Delta_3 + \frac{1}{\sqrt{2}} H_2^\dagger H_1 \Delta_m - \frac{1}{2} H_1^\dagger H_2 \Delta_3 \right) \right)$$

$$- M_{\Phi \Delta} \left( \frac{1}{\sqrt{2}} \Phi_1^* \Phi_2^* \Delta_p + \frac{1}{2} \Phi_1^* \Phi_1 \Delta_3 + \frac{1}{\sqrt{2}} \Phi_2^* \Phi_1 \Delta_m - \frac{1}{2} \Phi_2^* \Phi_2 \Delta_3 \right)$$

$$+ \lambda_{H\Phi} \left( H_1^\dagger H_1 + H_2^\dagger H_2 \right) \left( \Phi_1^* \Phi_1 + \Phi_2^* \Phi_2 \right)$$

$$+ \lambda_H \left( H_1^\dagger H_1 \Phi_1^* \Phi_1 + H_2^\dagger H_2 \Phi_2^* \Phi_2 + H_1^\dagger H_2 \Phi_2^* \Phi_1 + H_2^\dagger H_1 \Phi_1^* \Phi_2 \right)$$

$$+ \lambda_{\Phi \Delta} \left( \Phi_1^* \Phi_1 + \Phi_2^* \Phi_2 \right) \left( \frac{1}{2} \Delta_3^2 + \Delta_p \Delta_m \right) \frac{\text{Tr} \left( \Delta_H^2 \right)}{2} .$$

(7)

Interestingly, $V_{\text{mix}}(H, \Delta_H, \Phi_H)$ is invariant under the combined discrete symmetry $H_1 \rightarrow H_1$, $H_2 \rightarrow -H_2$, $\Phi_1 \rightarrow -\Phi_1$, $\Phi_2 \rightarrow \Phi_2$, $\Delta_3 \rightarrow \Delta_3$, and $\Delta_{p,m} \rightarrow -\Delta_{p,m}$. Since the complete scalar potential $V_T$ consists of all renormalization terms constructed out of $H$, $\Delta_H$ and $\Phi_H$, this discrete symmetry can be viewed as an accidental one in the scalar sector of the model. In fact one can extend this discrete symmetry to the whole renormalizable Lagrangian of G2HDM. We will discuss this further in Sec III.
Spontaneous Symmetry Breaking (SSB)

The gauge symmetry of G2HDM is broken spontaneously by the vacuum expectation values (VEVs) of \( \langle H_1 \rangle = (0, v/\sqrt{2})^T \), \( \langle \Phi_2 \rangle = v_\phi/\sqrt{2} \), and \( \langle \Delta_3 \rangle = -v_\Delta \). In Ref. [28], we demonstrated that \( v_\Delta \) satisfies a cubic equation with all coefficients expressed in terms of the fundamental parameters in the scalar potential. Solutions of \( v_\Delta \) can be found either analytically or numerically and plug into the linear coupled equations for \( v_2^2 \) and \( v_\phi^2 \) that can then be solved straightforwardly. Since \( v_\Delta \) has three different roots in general, the correct one will be picked by minimum energy requirement. Thus, the symmetry breaking of \( SU(2)_L \times U(1)_Y \times U(1)_X \) in G2HDM is induced or triggered by the triplet VEV \( v_\Delta \) which breaks \( SU(2)_H \). Note that the sign of \( \mu_2^2 \) is negative with respect to \( \mu_\phi^2 \) and \( \mu_H^2 \). If \( \mu_\Delta^2 > 0 \), \( SU(2)_H \) is spontaneously broken by the VEV \( v_\Delta \neq 0 \). After \( SU(2)_H \) symmetry breaking is triggered, the vacuum alignment of \( \Phi_H \) is controlled by the quadratic terms for \( \Phi_1 \) and \( \Phi_2 \) given by

\[
\mu_\Phi^2 + \frac{1}{2} M_{\Phi \Delta} v_\Delta + \frac{1}{2} \lambda_{\Phi \Delta} v_\Delta^2 + \frac{1}{2} (\lambda_{H \Phi} + \lambda'_{H \Phi}) v_\phi^2 ,
\]

\[
\mu_\Phi^2 - \frac{1}{2} M_{\Phi \Delta} v_\Delta + \frac{1}{2} \lambda_{\Phi \Delta} v_\Delta^2 + \frac{1}{2} \lambda_{H \Phi} v_\phi^2 ,
\]

respectively. The parameters \( M_{\Phi \Delta} \), \( \lambda_{\Phi \Delta} \), \( \lambda_{H \Phi} \) and \( \lambda'_{H \Phi} \) can be either positive or negative independent of the sign of \( \mu_\phi^2 \), meaning that Eqs. (8) and (9) can be positive and negative, respectively. One can achieve \( \langle \Phi_1 \rangle = 0 \) and \( \langle \Phi_2 \rangle \neq 0 \) by making judicious choices of the parameters. Furthermore, \( SU(2)_L \) symmetry breaking is controlled by the quadratic terms of \( H_1 \) and \( H_2 \). After expanding the potential, the coefficients for them are

\[
\mu_H^2 - \frac{1}{2} M_{H \Delta} v_\Delta + \frac{1}{2} \lambda_{H \Delta} v_\Delta^2 + \frac{1}{2} \lambda_{H \Phi} v_\phi^2 ,
\]

\[
\mu_H^2 + \frac{1}{2} M_{H \Delta} v_\Delta + \frac{1}{2} \lambda_{H \Delta} v_\Delta^2 + \frac{1}{2} (\lambda_{H \Phi} + \lambda'_{H \Phi}) v_\phi^2 ,
\]
respectively. Similar to the $\Phi_H$ case, the parameters involved can be either positive or negative independently of the sign of $\mu^2_H$, but this time Eqs. (10) and (11) would be negative and positive, respectively. In this case, the gauge symmetry $SU(2)_L$ is broken by the vacuum alignment $\langle H_1 \rangle \neq 0$ and $\langle H_2 \rangle = 0$. In our numerical scan for the parameter space in Sec. V, we will search for parameters such that Eqs. (8) and (11) are positive while Eqs. (9) and (10) are negative in order to achieve the desired vacuum alignment. The $\mu^2_H$, $\mu^2_\Phi$ and $\mu^2_\Delta$ parameters will be fixed using the VEV equations (Eqs. (18) to (20) of Ref. [28]). Since $H_1$, $\Phi_2$ and $\Delta_3$ are all even under $Z_2$, the discrete symmetry is not broken by their VEVs. Therefore the $Z_2$-odd $H_2$ can become a DM candidate as long as it is lighter than all other $Z_2$-odd particles in the model.

**Theoretical and Phenomenological Constraints on the Scalar Potential**

We will begin our analysis by considering the conditions determined in Ref. [34] for the scalar sector parameter space. Namely, we want to start with a parameter space that leaves the scalar potential bounded from below, with couplings that remain within perturbative unitarity ranges and make sure that we can actually achieve a sufficiently SM-like Higgs with a $\sim 125$ GeV mass and that can pass the limits set by the LHC.

While for the minimum of the potential one checks the quadratic terms, to ensure that the scalar potential is bounded from below for large-field values one is mainly concerned with the quartic terms. In Ref. [34] it was show that copositivity criteria [48–50] is enough to find conditions for the potential to be bounded from below and have a stable vacuum. The copositive conditions are

$$\tilde{\lambda}_H(\eta) \geq 0, \quad \lambda_\Phi \geq 0, \quad \lambda_\Delta \geq 0,$$

(12)
\[ \Lambda_{H\Phi}(\xi, \eta) \equiv \tilde{\lambda}_{H\Phi}(\xi) + 2\sqrt{\tilde{\lambda}_H(\eta)}\lambda_{\Phi} \geq 0 , \]
\[ \Lambda_{H\Delta}(\eta) \equiv \lambda_{H\Delta} + 2\sqrt{\tilde{\lambda}_H(\eta)}\lambda_{\Delta} \geq 0 , \]
\[ \Lambda_{\Phi\Delta} \equiv \lambda_{\Phi\Delta} + 2\sqrt{\tilde{\lambda}_{\Phi}(\eta)}\lambda_{\Delta} \geq 0 , \]

where the parameters \( \xi \) and \( \eta \) can have any value in the ranges \( 0 \leq \xi \leq 1 \) and \( -1/4 \leq \eta \leq 0 \).

On the other hand we have to make sure that our parameter space remains within perturbative limits. Again we look only at quartic couplings since \( 2 \to 2 \) scattering processes induced by cubic couplings are suppressed by their propagators while quartic couplings are not. After checking all the possible \( 2 \to 2 \) scattering processes the final ranges allowed by perturbative unitarity are

\[ |\lambda_i(\mathcal{M}_i)| \leq 8\pi , \forall i = (1, \cdots, 10) , \]
\[ |\lambda_H| \leq 4\pi , |\lambda'_{H}| \leq 8\sqrt{2}\pi , |2\lambda_H \pm \lambda'_{H}| \leq 8\pi , |\lambda_{\Phi}| \leq 4\pi , |\lambda_{\Delta}| \leq 4\pi , \]
\[ |\lambda_{H\Phi}| \leq 8\pi , |\lambda_{H\Phi}'| = |\lambda_{H\Phi} + \lambda'_{H\Phi}| \leq 8\pi , |\lambda'_{H\Phi}| \leq 8\sqrt{2}\pi , \]
\[ |\lambda_{H\Delta}| \leq 8\pi , |\lambda_{\Phi\Delta}| \leq 8\pi , \]

where

\[ \lambda_1 = 2\lambda_H , \quad \lambda_2 = 2\lambda_{\Phi} , \quad \lambda_3 = 2\lambda_{\Delta} , \quad \lambda_{1,5} = 2\lambda_H \pm \lambda'_{H} , \]
\[ \lambda_{6,7} = \tilde{\lambda}_H^+ + \lambda_{\Phi} \pm \sqrt{2\lambda^2_{H\Phi} + (\tilde{\lambda}_H^+ - \lambda_{\Phi})^2} , \]

with \( \tilde{\lambda}_H^+ \equiv \lambda_H + \lambda'_{H}/2 \) and \( \lambda_{8,9,10} \) given by the three roots of the equation \( \lambda^3 + a\lambda^2 + \ldots \)
\[ b\lambda + c = 0 \text{ with} \]

\[
\begin{align*}
    a &= -5\lambda_\Delta - 6\lambda_\Phi - 10\lambda_H + \lambda_H' , \\
    b &= -6\lambda_{H\Delta}^2 - 3\lambda_{H\Phi}^2 + 5\lambda_\Delta(10\lambda_H - \lambda_H' + 6\lambda_\Phi) + 6\lambda_\Phi(10\lambda_H - \lambda_H') \\
        &\quad - 8(\lambda_{H\Phi} + \lambda_{H\Phi}'/2)^2 , \\
    c &= 36\lambda_\Phi\lambda_{H\Delta}^2 - 24\lambda_{H\Delta}\lambda_\Phi(\lambda_{H\Phi} + \lambda_{H\Phi}'/2) + 40\lambda_\Delta(\lambda_{H\Phi} + \lambda_{H\Phi}'/2)^2 \\
        &\quad + (3\lambda_{H\Phi}^2 - 30\lambda_\Delta\lambda_\Phi)(10\lambda_H - \lambda_H') .
\end{align*}
\]

On the phenomenological side, we will require the presence of a SM Higgs with a mass of \( 125.09 \pm 0.24 \) GeV and a signal strength for the Higgs decay into two photons of \( \mu^\gamma = 0.81^{+0.19}_{-0.18} \) as found by the ATLAS experiment [51]. For more details about the theoretical conditions described here, we encourage the interested reader to consult Ref. [34].

C. Mass Spectra

\textit{Higgs-like (Z}_2\text{-even) Scalars}

Expanding the scalar potential in terms of the VEVs and taking the second derivatives with respect to the scalar fields, one can obtain the mass terms and the mixing terms of the scalar fields. The SM Higgs is extracted from the mixing of three real scalars \( h, \phi_2 \) and \( \delta_3 \).\footnote{We follow the notations of [28] shifting the scalar fields as: \( H_1 = \begin{pmatrix} G^+ \\ \frac{v + \delta_3}{\sqrt{2}} + iG^0 \end{pmatrix} , H_2 = \begin{pmatrix} H^+ \\ H_2^0 \end{pmatrix} \), \[ \Phi_H = \begin{pmatrix} G_H^0 \\ \frac{v\phi + \phi_2}{\sqrt{2}} + iG_H^0 \end{pmatrix} , \text{ and } \Delta_H = \begin{pmatrix} -\frac{v_\Delta + \delta_3}{2} & \frac{\Delta_\Phi}{\sqrt{2}} \\ \frac{\Delta_\Phi}{\sqrt{2}} & \frac{v_\Delta - \delta_3}{2} \end{pmatrix} . \]}

The mixing matrix of these \( Z_2\)-even neutral real scalars written
in the basis of \( S = \{ h, \phi_2, \delta_3 \}^T \) is given by

\[
\mathcal{M}^2_0 = \begin{pmatrix}
2\lambda_H v^2 & \lambda_H \phi v \phi & \frac{v}{2} (M_{H\Delta} - 2\lambda_{H\Delta} v_{\Delta}) \\
\lambda_H \phi v \phi & 2\lambda_{\phi} v_{\phi}^2 & \frac{v_{\phi}}{2} (M_{\phi\Delta} - 2\lambda_{\phi\Delta} v_{\Delta}) \\
\frac{v}{2} (M_{H\Delta} - 2\lambda_{H\Delta} v_{\Delta}) & \frac{v_{\phi}}{2} (M_{\phi\Delta} - 2\lambda_{\phi\Delta} v_{\Delta}) & \frac{1}{4 v_{\Delta}} (8\lambda_{\Delta} v_{\Delta}^2 + M_{H\Delta} v_{\Delta}^2 + M_{\phi\Delta} v_{\phi}^2)
\end{pmatrix}.
\]

(18)

The physical fields with definite mass can be obtained by doing the similarity transformation to this mixing matrix via orthogonal rotation matrix, \( \mathcal{O} \), in such a way that

\[
\mathcal{O}^T \cdot \mathcal{M}^2_0 \cdot \mathcal{O} = \text{Diag}(m_{h_1}^2, m_{h_2}^2, m_{h_3}^2),
\]

(19)

where the masses of the fields are arranged in ascending manner \( m_{h_1} \leq m_{h_2} \leq m_{h_3} \).

The interaction basis \( S \) and mass eigenstates are related through the \( \mathcal{O} \) mixing matrix via \( S = \mathcal{O} \cdot \{ h_1, h_2, h_3 \}^T \). In this setup, the 125 GeV Higgs boson observed at the LHC is identified by the lightest mass eigenstate \( h_1 \).

Other \( \mathbb{Z}_2 \)-even scalars are the massless would be Goldstone bosons \( G^\pm, 0 \) and \( G^0_H \) which do not mix with other scalar fields. However they mix with the longitudinal components of the gauge fields and will be absorbed away.

**Dark (\( \mathbb{Z}_2 \)-odd) Scalars**

The charged Higgs is sitting at the upper component of \( H_2 \) which acquires mass from all three VEVs but it does not mix with other fields. Since \( H_2 \) couples to all three multiplets \( H_1, \Phi_H \) and \( \Delta_H \), after SSB it acquires tree mass terms one with each VEV given by

\[
m_{H^\pm}^2 = M_{H\Delta} v_{\Delta} - \frac{1}{2} \lambda_H v^2 + \frac{1}{2} \lambda_{H\phi} v_{\phi}^2.
\]

(20)
The complex fields $G^p_m$, $H^0_2$ and $\Delta_{p,m}$ also acquire mass terms and mix. In the basis of $\mathcal{G} = \{G^p_m, H^0_2, \Delta_{p,m}\}$, the squared mass matrix is given by

$$
\mathcal{M}_0^2 = \begin{pmatrix}
M_{\Delta v_{\Delta}} + \frac{1}{2} \lambda'_{H\Phi} v^2 & \frac{1}{2} \lambda'_{H\Phi} v v_{\Phi} & -\frac{1}{2} M_{\Phi v_{\Phi}} \\
\frac{1}{2} \lambda'_{H\Phi} v v_{\Phi} & M_{H\Delta v_{\Delta}} + \frac{1}{2} \lambda'_{H\Phi} v^2 & \frac{1}{2} M_{H\Delta v} \\
-\frac{1}{2} M_{\Phi v_{\Phi}} & \frac{1}{2} M_{H\Delta v} & \frac{1}{4 v_{\Delta}} (M_{H\Delta v^2} + M_{\Phi v_{\Phi}^2})
\end{pmatrix}.
$$

(21)

This matrix has zero determinant, which means that at least one of the mass eigenstates is massless. Despite complex fields, the mass matrix in Eq. (21) is real and symmetric, we can rotate this matrix into its diagonal form through a similarity transformation with the orthogonal matrix $\mathcal{O}^D$,

$$(\mathcal{O}^D)^T \cdot \mathcal{M}_0^2 \cdot \mathcal{O}^D = \text{Diag}(0, m^2_{D,\Delta}) .
$$

(22)

The relation between interaction and mass states is given by $\mathcal{G} = \mathcal{O}^D \cdot \{\tilde{G}^p, D, \tilde{\Delta}\}$

The first zero eigenvalue in Eq. (22) corresponds to $\tilde{G}^p_m$, the would-be Goldstone boson to be absorbed by $W^{(p,m)}$, the complex gauge bosons of $SU(2)_H$. Here we assume the hierarchy $m^2_D < m^2_{\Delta}$. Note that we strictly avoid degenerate masses to simplify the analysis when $D$ is the dark matter candidate. However, from the mass expressions given below, one can see that very specific parameter choices are necessary to make the two massive states degenerate. The masses of the two physical massive eigenstates are given by

$$
M^2_{D,\Delta} = \frac{-B \mp \sqrt{B^2 - 4AC}}{2A},
$$

where

$$
A = 8v_{\Delta},
$$

$$
B = -2 \left[ M_{H\Delta} \left( v^2 + 4v^2_{\Delta} \right) + M_{\Phi v_{\Phi}} \left( 4v^2_{\Delta} + v^2_{\Phi} \right) + 2\lambda'_{H\Phi} v_{\Delta} \left( v^2 + v^2_{\Phi} \right) \right],
$$

$$
C = \left( v^2 + v^2_{\Phi} + 4v^2_{\Delta} \right) \left[ M_{H\Delta} \left( \lambda'_{H\Phi} v^2 + 2M_{\Phi v_{\Phi}} v_{\Delta} \right) + \lambda'_{H\Phi} M_{\Phi v_{\Phi}^2} \right].
$$

(24)

See previous footnote for the definitions of these complex scalars.
The lightest state between $H^\pm$ and $D$, if lighter than every other $\mathbb{Z}_2$-odd states, has the possibility to become the DM candidate. However, an electrically charged DM candidate such as $H^\pm$ is undesirable. For this reason, we will concentrate on parameter space where $m_{H^\pm} > m_D$.

Gauge Bosons

After SSB, the gauge bosons that acquire mass terms are the $B$, $X$, and all the components of $W$ and $W'$. The charged $W^\pm$ gauge bosons remains completely SM-like with its mass given by $M_W = g v / 2$. The $W'^{\prime p} = (W'^{\prime m})^*$ does not mix with the SM $W^\pm$ and acquires a mass given by

$$m_{W^{\prime p,m}}^2 = \frac{1}{4} g_H^2 \left( v^2 + v^2_\phi + 4v^2_\Delta \right).$$

(25)

The remaining gauge bosons, $B$, $W^3$, $W'^3$ and $X$ have mixing terms. We can write their mass terms as a $4 \times 4$ matrix using the basis $\mathcal{V}' = \{B, W^3, W'^3, X\}^T$,

$$M^2_1 = \begin{pmatrix}
\frac{g'^2 v^2}{4} + M^2_Y & -\frac{g' g v^2}{4} & \frac{g' g_H v^2}{4} & \frac{g' g_X v^2}{2} + M_X M_Y \\
-\frac{g' g v^2}{4} & \frac{g'^2 v^2}{4} - \frac{g' g_H v^2}{4} & -\frac{g g_H v^2}{4} & \frac{g g_X v^2}{2} \\
\frac{g' g_H v^2}{4} & -\frac{g g_H v^2}{4} & \frac{g'^2 (v^2 + v^2_\phi)}{4} & \frac{g g_H (v^2 - v^2_\phi)}{2} \\
\frac{g' g_X v^2}{2} + M_X M_Y & -\frac{g g_X v^2}{2} & \frac{g g_H (v^2 - v^2_\phi)}{2} & \frac{g^2 X (v^2 + v^2_\phi)}{2} + M^2_X
\end{pmatrix},$$

(26)

where $M_X$ and $M_Y$ are the two Stueckelberg mass parameters [52–60] introduced for $U(1)_X$ and $U(1)_Y$ respectively. This mass matrix has zero-determinant, meaning that there is at least one massless state that can be identified with the photon. The remaining three states are massive in general. One of them, the $Z$, is related to the SM gauge boson $Z^{\text{SM}}$, and the other two are the extra gauge bosons $Z'$ and $Z''$. As in the neutral scalars case, we can diagonalize this mass matrix by an orthogonal rotation matrix $O^G_{4 \times 4}$ such that $\mathcal{V}' = O^G_{4 \times 4} \cdot \{A, Z, Z', Z''\}^T$. We will also use $Z_i$. 

15
with $i = 1, 2, 3$ for $Z, Z', Z''$ respectively in the following. As noted in Ref. [35], one can justify the parameter choice $M_Y = 0$ by considering the electric charges of the fermions. Otherwise, the neutrinos would not be neutral and all the SM electric charges would receive a correction that grows with $M_Y$. Therefore, hereafter we will consider $M_Y = 0$. This choice makes possible to rotate the first and second rows and columns of Eq. (26) (with $M_Y$ set to 0) using the Weinberg angle in a SM-like manner. Applying the $4 \times 4$ rotation

$$
O^W = \begin{pmatrix}
c_W & -s_W & 0 & 0 \\
s_W & c_W & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}
$$

as $(O^W)^T \cdot M^2_Z(M_Y = 0) \cdot O^W$, we find the mass matrix

$$
M^2_Z = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & M^2_{Z^{SM}} & -g_H v M^2_{Z^{SM}} & -g_X v M^2_{Z^{SM}} \\
0 & -g_H v M^2_{Z^{SM}} & g_H^2 (v^2 + v_3^2) & \frac{g_X g_H (v^2 - v_3^2)}{2} \\
0 & -g_X v M^2_{Z^{SM}} & \frac{g_X g_H (v^2 - v_3^2)}{2} & g_X^2 (v^2 + v_3^2) + M^2_X
\end{pmatrix},
$$

(28)

where $M^2_{Z^{SM}} = \sqrt{g^2 + g'^2} v / 2$ is the SM gauge boson $Z^{SM}$ mass. Given the form of the rotation matrix $O^W$ we can identify the first component of the basis of this matrix with the photon, which is immediately massless, and the second with the $Z^{SM}$. The new intermediate basis in this case is $\mathcal{V}'_Z = \{ A, Z^{SM}, W'^3, X \}^T$. We can rewrite the original rotation matrix as the product of two matrices $O^G_{4 \times 4}(M_Y = 0) = O^W \cdot O^Z$, where the matrix $O^Z$ diagonalizes $M^2_Z$ in Eq. (28). In that case we can relate the mass eigenstates with the intermediate states as $\mathcal{V}'_Z = O^Z, \{ A, Z, Z', Z'' \}^T$. Hereafter, we will call $O^G$ to the non-diagonal $3 \times 3$ part of $O^Z$, such that $O^Z_{j+1,k+1} = O^G_{j,k}$ with $j$ and $k = 1, 2, 3$, as explicitly shown in Eq. (6) of Ref. [35]. Note that the photon
A remains the same between the intermediate states \( V_Z' \) and the mass eigenstates. This necessarily means that the only non-zero element in the first column and row of \( O_Z \) is \( O_{1,1}^Z = 1 \).

Interestingly, the only gauge boson that acquires mass contributions from the three non-zero VEVs is the \( W^{\prime(p,m)} \) with its mass given in Eq. (25).

### III. ACCIDENTAL DISCRETE SYMMETRY (\( h \)-PARITY) AND DARK MATTER CANDIDATE

As mentioned in the previous session, the stability of the scalar dark matter candidate in this model is protected by the accidental discrete \( Z_2 \) symmetry in the scalar potential which is automatically implied by the \( SU(2)_L \times U(1)_Y \times SU(2)_H \times U(1)_X \) gauge symmetry. Due to its special vacuum alignment where the \( H_2 \) field does not acquire a VEV, the accidental \( Z_2 \) symmetry remains intact after SSB. It was argued in [28] that there is no gauge invariant higher dimensional operator that one can write down which can lead to the decay of DM candidate in G2HDM. The presence of the accidental discrete \( Z_2 \) symmetry after SSB reinforces such argument.

This discrete \( Z_2 \) symmetry in G2HDM that we observe here is kind of peculiar in the sense that different components of the \( SU(2)_H \) doublets \( H \) and \( \Phi_H \), and triplet \( \Delta_H \) have opposite parity. Thus for dark matter physics it is mandatory to give VEVs to those scalars with even parity. Otherwise the \( Z_2 \) symmetry will be broken spontaneously which will lead to no stable DM as well as the domain wall problem in the early universe. Another peculiar feature of this \( Z_2 \) symmetry is that it acts on the complex fields. We will refer this accidental discrete \( Z_2 \) symmetry as the hidden parity (\( h \)-parity) in G2HDM in what follows.

This \( h \)-parity can actually be extended to the whole renormalizable Lagrangian of G2HDM, including the gauge, scalar and Yukawa interactions. For example, while
the SM $W^\pm$ and all the neutral gauge bosons $\gamma, Z_i$ are always coupled to a pair of SM fermions $\bar{f} f^{(i)}$ or a pair of new heavy fermions $\bar{f}^H f^{(i)H}$, the $W^{(p,m)}$ always couples to one SM fermion and one new heavy fermion $\bar{f}^H f'$ or $\bar{f} f^{iH}$. Similar features can be observed in the gauge-Higgs sector and the Yukawa couplings in G2HDM. For instance, while $\gamma, Z_i$ and $W^\pm$ are always coupled to a pair of $\mathcal{Z}_2$-even scalars or a pair of $\mathcal{Z}_2$-odd scalars, the $W^{(p,m)}$ always couples to one $\mathcal{Z}_2$-even and one $\mathcal{Z}_2$-odd scalars. Also, $h_i$ always couple to either $\bar{f} f$ or $\bar{f}^H f^H$, while for the new Yukawa couplings, the dark matter $D (D^*)$ always couples with $\bar{u} u^H$ and $\bar{d} d^H (\bar{u}^H u$ and $\bar{d}^H d$) and the charged Higgs $H^+ (H^-)$ always couples with $\bar{u} d^H$ and $\bar{u}^H u$ and $\bar{d} u^H$, etc. Therefore, besides the $\mathcal{Z}_2$-even/odd scalars discussed in the previous section, one is naturally lead to assign $W^{(p,m)}$ and all new heavy fermions $f^H$ to have odd $h$-parity, and all SM gauge particles including the additional neutral gauge bosons to have even $h$-parity. A summary of the $h$-parity for all the fields in G2HDM is collected in Table II.

| Fields                                | $h$-parity |
|---------------------------------------|------------|
| $h, G^{\pm,0}, \phi_2, G_H^0, \delta_3, f, W_{1,2,3}^\mu, B_\mu, X^\mu, W_{3}^{\mu H}, G^{\mu a}$ | 1          |
| $G_H^{p,m}, H_2^0, H_2^{0*}, H^\pm, \Delta_{p,m}, f^H, W_{1,2}^\mu$           | -1         |

TABLE II. Classification of all the fields in G2HDM under $h$-parity.

Thus besides the two well-known accidental global symmetries of baryon number and lepton number inherited from the SM, there is also an accidental discrete $\mathcal{Z}_2$ symmetry in G2HDM. Other than protecting the stability of the lightest electrically neutral $\mathcal{Z}_2$-odd particle to give rise a DM candidate, this accidental $\mathcal{Z}_2$ symmetry also provides natural flavor conservation laws for neutral currents [61, 62] at the tree level for the SM sector in G2HDM [28], as described in previous paragraph. While it is important to unravel if the $h$-parity in G2HDM has a deeper origin from a
larger theoretical structure, for example like grand unification or supersymmetry or braneworld, we will not pursue further here.

In principle, any electrically neutral $\mathbb{Z}_2$-odd neutral particle can be a DM candidate (e.g. the heavy neutrinos $\nu^H$, the complex scalar mass eigenstate $D$ and the gauge boson $W^{\prime(p,m)}$). In this work, we focus on the lightest $\mathbb{Z}_2$-odd complex scalar field $D$. From Eq. (21) we know that $D$ is a linear combination of the interaction states $G_H^p$, $H_2^{0*}$, and $\Delta_p$. Using $\mathcal{G} = \mathcal{O}^D \cdot \{\tilde{G}^p, D, \tilde{\Delta}\}^T$ we can write this linear combination as

$$D = \mathcal{O}_{12}^D G_H^p + \mathcal{O}_{22}^D H_2^{0*} + \mathcal{O}_{32}^D \Delta_p,$$

(29)

where $\mathcal{O}_{ij}^D$ represents the $(i,j)$ element of the orthogonal matrix $\mathcal{O}^D$. The actual values of the elements of this matrix depend on the actual numerical values of the parameters in Eq. (21).

Since a particular dominant component cannot be inferred from Eq. (21) together with the constraints presented in Sec. II B, we take the approach of considering three different main compositions. Using the rotation matrix elements we can define the $G_H^p$, $H_2^{0*}$ and $\Delta_p$ compositions as $f_{G^p} = (\mathcal{O}_{12}^D)^2$, $f_{H_2} = (\mathcal{O}_{22}^D)^2$ and $f_{\Delta_p} = (\mathcal{O}_{32}^D)^2$ respectively, satisfying $f_{G^p} + f_{H_2} + f_{\Delta_p} = 1$. Our results will be classified in three different cases:

1. Inert doublet-like DM for $f_{H_2} > 2/3$,

2. $SU(2)_H$ triplet-like DM for $f_{\Delta_p} > 2/3$,

3. $SU(2)_H$ Goldstone boson-like DM for $f_{G^p} > 2/3$.

To avoid cluttering in the following, we will use the more concise terms doublet-like, triplet-like and Goldstone-like DM to refer to the above cases of 1, 2 and 3 respectively.
FIG. 1. Correlation between the ratio $v_\Delta/v_\Phi$ and the composition mixing parameter $f_{GP}$ for all the DM types after applying constraints from the scalar and gauge sectors.

In order to realize any one of the three cases of the DM discussed above, one needs to have its diagonal element in the mass matrix given by Eq. (21) to be the lightest, while its mixings with the other two off-diagonal elements are small. However, the mixing among the other two can be arbitrary. Take the Goldstone-like DM as an example. It is easy to note that the $(1,1)$ and $(3,3)$ elements of the mass matrix in Eq. (21) have a see-saw behaviour controlled by the value of $v_\Delta$. The $(2,2)$ element remains almost unaffected thanks to the term proportional to large $v_\Phi^2$. Goldstone-like DM is characterized by a large value in the $(1,1)$ element of Eq. (21) when compared to the $(1,2)$ and $(1,3)$ elements, given by $\lambda'_{H\Phi} vv_\Phi/2$ and $-M_{\Phi\Delta} v_\Phi/2$ respectively, so as to suppress the mixing effects. The size of the $(1,2)$ element is not relevant since it is proportional to the smaller term $vv_\Phi$ as compared with both the $(1,1)$ and $(2,2)$ elements which are always much larger. The difference in size between the $(1,1)$ and $(1,3)$ elements is best measured by taking the ratio between...
them which is roughly about \(2v_\Delta/v_\Phi\). In other words, the \(v_\Delta/v_\Phi\) ratio controls the Goldstone boson composition of the DM mass eigenstate. This is illustrated in Fig. 1 where the correlation between the ratio \(v_\Delta/v_\Phi\) and the composition mixing parameter \(f_{G^p}\) is shown for all DM types. The small arc in the correlation curve with \(f_{G^p} > 2/3\) is highlighted by red color indicating only a small parameter space is allowed for Goldstone-like DM. Note that when the ratio \(v_\Delta/v_\Phi\) grows close to 1, EWPT disfavors the presence of relatively light \(Z'\) state with larger mixing with the SM \(Z\). Values of \(f_{G^p}\) larger than \(\sim 0.8\) are accessible only through negative \(M_{\Phi,\Delta}\) resulting in tachyonic DM mass. Therefore to realize a Goldstone-like DM with \(f_{G^p} > 2/3\) in the following numerical analysis, one needs to do some fine-tunings in the parameter space. For the inert doublet-like and triplet-like DM, no fine-tunings are required.

IV. DARK MATTER EXPERIMENTAL CONSTRAINTS

To determine WIMP DM properties, one can measure the DM-SM interactions via several approaches. Conventionally, DM direct detection, DM indirect detection, and collider search are used for the hunting for DM. Thus far null signals were reported from all these experimental efforts and only allowed regions have been shown in the DM model parameter space. On the other hand, the DM relic density measurement can indeed give a signal region which can constrain the parameter space of DM model in a significant way. Hence, our strategy is to determine the parameter space in G2HDM allowed by the current relic density measurement, and the limits deduced from DM direct detection, DM indirect detection, and collider search (at the LHC). In this section we briefly describe each of these experimental constraints used in this analysis.
A. Relic Density

It is fascinating to wonder about the thermal history of DM based on all our current knowledge of physics. The simplest scenario is that a WIMP maintains its thermal equilibrium with the SM sector before freeze-out and the DM number density can be described by a Boltzmann distribution. Therefore, the DM mass determines its abundance before freeze-out. As in most WIMP theories, owing to the small DM-SM couplings, the relic density comes out too large and the correct abundance can be only achieved by some specific mechanisms. The mechanisms to reduce the thermal DM relic density in the G2HDM can be both from DM annihilation and also from coannihilation with heavier $Z_2$-odd particles. Coannihilation only happens if the next lightest $Z_2$-odd particles are slightly heavier than DM (usually $\lesssim 10\%$) so that its number density at the temperature higher than freeze-out does not suffer a large Boltzmann suppression. In our setup, the heavier $Z_2$-odd scalar $\tilde{\Delta}$, the charged Higgs, new heavy fermions, or gauge boson $W^{\prime (p,m)}$ can coannihilate with the DM candidate $D$. Additionally, the SM Higgs and $Z$ resonance can play an important role for the doublet-like DM while there is no $Z$ resonance in the triplet-like and Goldstone-like DM cases because both $\Delta_H$ and $\Phi_H$ are SM singlets. As we will see later, the couplings between DM and some of the mediators in G2HDM could be suppressed by mixings or cancellations.

The scalar $\tilde{\Delta}$ and the DM candidate $D$ come from the same mass matrix. The splitting between their masses is mostly controlled by the second term in the numerator of Eq. [23]. Hence, coannihilation between DM and $\tilde{\Delta}$ can only happen if $M_{\Phi,\Delta} \gtrsim \mathcal{O}(10 \text{ GeV})$ and $\nu_{\Phi} \gtrsim 70 \text{ TeV}$. However, this condition also makes DM masses at around $\mathcal{O}(1 \text{ TeV})$ or larger.

For the doublet-like DM case, the mass of the DM candidate is close to the mass
of the charged Higgs with the splitting approximately given by

\[ m^2_{H^\pm} - m^2_D \approx -\frac{1}{2} \lambda'_{H} v^2, \]  

(30)

in the approximation where DM mass is dominated by the (2,2) element of the matrix in Eq. (21). For triplet-like DM, the mass differences between \( D \) and the other heavy \( \mathcal{Z}_2 \)-odd scalars are usually large enough so that coannihilation can be avoided. Coannihilation between \( D \) and \( W' \) occurs for DM mass closing to \( W' \) mass which is heavy due to large \( v_\Phi \). As for the resonance, only \( h_1 \) and \( h_2 \) resonances are present. Due to \( \Delta_H \) being an SM singlet, any \( D \) annihilation through \( Z \)-boson like mediator is suppressed by mixings.

To compare against experimental data, we will consider the latest result from the PLANCK collaboration [63] for the relic density, \( \Omega h^2 = 0.120 \pm 0.001 \). In particular, we will require the parameter space of G2HDM to reproduce this well measured value with a 2\( \sigma \) significance.

B. Direct Detection

The most recent constraint for DM direct search is given by the XENON1T collaboration [64]. The null signal result from this search puts the most stringent limit on DM nucleon cross section so far, especially for the DM mass that lies between 10 GeV to 100 GeV. The XENON1T collaboration excluded DM-nucleon elastic cross sections above \( 10^{-46} \text{ cm}^2 \) for a DM particle with mass around 25 GeV.

In models with isospin violation (ISV), DM interactions with proton and neutron can be different and the ratio between the DM-neutron and DM-proton effective couplings, \( f_n/f_p \), can have values that differ from 1 significantly depending on the model parameters. In particular, for a target made of xenon, the ratio \( f_n/f_p \approx -0.7 \) corresponds to maximal cancellation between proton and neutron contributions [65].
For instance, if DM interacts with nucleons mediated by the $Z$ boson, the strength is characterized by the electric charge and the third generator $T_3$ of $SU(2)_L$ group. The vectorial coupling of quark $q$ ($u$ or $d$-type) to the SM $Z$ boson in G2HDM is

$$g_{qqZ}^V = \frac{i}{2} \left[ \frac{g}{c_W} (T_3 - 2Q_q s_W^2) O_{11}^G + g_H T_3' O_{21}^G + g_X X O_{31}^G \right].$$

Due to different $Q_q$, $T_3$, $T_3'$ and $X$ charges, this coupling is expected to vary depending on the quark $q$ being $u$ or $d$-type. Hence, the $Z$ boson interacts with proton and neutron differently and the $f_n/f_p$ can be different from 1. For the case of DM with a non-negligible doublet composition we found that DM can couple to proton or neutron differently via $Z_i$ boson exchange and it leads to ISV.

Generally speaking, exact cancellation between neutrons and protons is expected to be in a tiny region of parameter space. Nevertheless, the G2HDM doublet-like DM can have a much wider distribution of $f_n/f_p$. Furthermore, a more subtle interference between the contributions from neutral gauge and Higgs boson exchange can result in two different scattering cross sections for DM ($D$) and antiDM ($D^*$) with neutrons. Such a difference may compensate for any cancellation caused by ISV. While one can expect a negligible cancellation from ISV effects in most of the G2HDM parameter space, we consider these effects in all the DM scenarios. To include ISV effects, one has to compute the DM-nucleus elastic scattering cross section $\sigma_{DN}$

$$\sigma_{DN} = \frac{4\mu_A^2}{\pi} [f_pZ + f_n(A - Z)]^2,$$

where $N$ stands for a nucleus with mass number $A$ and proton number $Z$. For definiteness, we will ignore all the isotopes of xenon and fix $A$ and $Z$ to 131 and 54 respectively in this work. We obtain the effective couplings $f_p$ and $f_n$ by using micrOMEGAs [66]. The DM-nucleon reduced mass is denoted as $\mu_A = m_D m_A/(m_D + m_A)$. On the other hand, the limit published by XENON1T is for the nucleon with isospin conserving assumption $f_n = f_p$. To reconstruct the XENON1T results at the
nucleus level for general value of the ratio \( f_n / f_p \), we use the following expression

\[
\sigma_{\text{DN}}^\text{X1T} = \sigma_{\text{p}}^\text{X1T} \times \frac{\mu_A^2}{\mu_p^2} \times \left[ Z + \frac{f_n}{f_p} (A - Z) \right]^2,
\]  

(33)

where \( \mu_p^2 \) is the DM-proton reduced mass. In this work, we use Eq. (33) to constrain our direct detection prediction.

\[ \begin{array}{c}
  D, D^* \\
  \text{h}_{\text{i}} \\
  q \\
  \end{array} \quad \begin{array}{c}
  D, D^* \quad D, D^* \quad D, D^* \\
  \text{Z}_{\text{i}} \quad \text{Z}_{\text{i}} \quad \text{Z}_{\text{i}} \\
  q \quad q \quad q \\
  \end{array} \]

FIG. 2. The dominant Feynman diagrams with the \( Z_2 \)-even Higgs bosons (left) and neutral gauge bosons (right) exchange for direct detection of DM.

Since we are dealing with complex scalar DM, we need to consider the antiDM interaction with the nucleon. The DM-nucleon interaction and antiDM-nucleon interaction in general can be quite different. When the mediators are heavy enough, one can integrate them out to obtain effective interactions for the DM and nucleon. The spin independent interaction for complex scalar DM can be written in terms of effective operator as [67]

\[
\mathcal{L}_D = 2\lambda_{N,e} M_D D D^* \bar{\psi}_N \psi_N + i\lambda_{N,o} \left( D^* \left( \partial_\mu D \right) \right) \bar{\psi}_N \gamma^\mu \psi_N
\]  

(34)

where the \( \psi_N \), \( \lambda_{N,e} \), and \( \lambda_{N,o} \) denote the nucleon field operator, the coupling of even operator, and the coupling of odd operator respectively. The effective coupling of DM (antiDM) with the nucleon is given by

\[
\lambda_N = \frac{\lambda_{N,e} \pm \lambda_{N,o}}{2},
\]  

(35)
where the plus (minus) sign stands for DM-nucleon (antiDM-nucleon) interaction. The first term in the right hand side of Eq. \((34)\) represents the \textit{even} operator interaction between DM and the nucleon. It is called \textit{even} operator because when one exchanges \(D\) with \(D^*\), the interaction stays the same. On the other hand, under a similar exchange between \(D\) and \(D^*\) the second term flips sign. Thus, it is called \textit{odd} operator. As a result, the interaction strength between DM-nucleon and antiDM-nucleon will not be the same and it is given by Eq. \((35)\). Hence the numerical value of \(\sigma_{D^*N}\) is in general not equal to \(\sigma_{DN}\) given by Eq. \((32)\) because the effective couplings \(f_p\) and \(f_n\) for \(D\) are not the same as those for \(D^*\).

The Feynman diagrams of the dominant contribution to describe DM-quark interactions in the G2HDM are shown in Fig. 2. The left panel is the \(t\)-channel with three Higgs bosons exchange while the right panel is the \(t\)-channel with three neutral gauge bosons exchange. Thus G2HDM captures the features from both the Higgs-portal and vector-portal DM models in the literature.

Note that the doublet-like DM in this model has a large scattering cross section because the vertex \(DD^*Z\) is governed by the SM coupling as shown in Eq. \((A2)\), and hence \textit{not} suppressed by any mixing angle. Due to the additional contributions from other heavy gauge bosons (\(Z'\) and \(Z''\)), the DM neutron cross section is three orders of magnitude larger than the DM proton cross section. This ISV effect is also observed in triplet-like DM (\(\Delta_p\)) but the ISV occurs mildly due to the mixing suppression between the DM (\(\Delta_p\)) and \(Z\) coupling. This suppression makes the \(Z\) exchange contribution comparable with \(Z'\) and \(Z''\) as well as the contribution from the SM Higgs \(h_1\) exchange.
C. Indirect Detection: Gamma-ray from dSphs

Excluding the early universe, DM at the present may also annihilate to SM particles significantly at the halo center where DM density is dense enough to produce cosmic rays or photons which can be distinguished from those standard astrophysical background. Such a measurement is known as DM indirect detection. As long as indirect detection constraints are concerned, the continuum gamma-ray observations from dwarf spheroidal galaxies (dSphs) can usually place a robust and severe limit on the DM annihilation cross section for DM masses larger than 10 GeV [68]. This is owing to two advantages of searching DM at the dSphs. First, the dSphs provides an almost background-free system because they are faint but widely believed to be DM dominated systems. Second, their kinematics can be precisely measured, hence the systematical uncertainties from DM halo can be controlled. Therefore, in this work we will only use the dSphs constraints implemented in LikeDM [69] to evaluate the $\chi^2$ statistics of our model based on Fermi Pass 8 data (photon counts), recorded from August 4th 2008 to August 4th 2015. The two-dimensional 2σ criteria is taken to be $\Delta\chi^2 = 5.99$ in our study.

The standard gamma-ray fluxes produced from DM annihilation at the dSphs halo is given by

$$\frac{d\Phi_\gamma}{dE_\gamma} = \frac{\langle \sigma v \rangle}{8\pi m_D^2} \times J \times \sum_{\text{ch}} \text{BR}(\text{ch}) \times \frac{dN_{\gamma \text{ch}}}{dE_\gamma}, \quad (36)$$

where $J = \int dld\Omega \rho(l)^2$ is the so-called $J$-factor, which integrates along the line-of-sight $l$ with the telescope opening angle given by $\Omega$. The DM density distribution is denoted as $\rho(l)$. Here, we take 15 dSphs and their $J$-factors as the default implementation in LikeDM. The index $\text{ch}$ runs over all the DM annihilation channels. The annihilation branching ratio $\text{BR}(\text{ch})$ and energy spectra $dN_{\gamma \text{ch}}/dE_\gamma$ are computed by using micrOMEGAs and PPC4 [70], respectively.
FIG. 3. The representative Feynman diagrams of leading contributions for mono-jet at the LHC in the G2HDM, where $h_i = h_1, h_2, h_3$ and $Z_i = Z, Z', Z''$.

Similar to Higgs portal models, an inert Higgs DM in our setup can only annihilate to the SM fermions via Higgs portal or $Z$-boson. On the other hand, if the DM is heavier than $m_W$ then the four points interaction $DD^*W^+W^-$ can have a higher photon flux to be tested.
D. Collider Search

Mono-jet Search

DM particles could be produced copiously at colliders. Unfortunately, DM can not be detected on its own since it would pass through detectors without leaving any trace. Therefore, one should look for the DM production associated with visible SM particles. At the LHC, the signal of an energetic jet from initial state radiation that balances the momentum of undetected DM, usually referred to mono-jet signal, is one of the sensitive channels to the search for DM. As shown in Fig. 3, the DM pairs are mainly produced in the Feynman diagrams with the exchanges of Z$_2$-even Higgs bosons and neutral gauge bosons in the G2HDM. For numerical study, we take the parameters allowed by EWPT \cite{35} and the XENON1T constraints (to be discussed in Sec. V), and find out that the cross sections are far below the current limits set by ATLAS \cite{71} and CMS \cite{72} collaborations at the LHC. Therefore the mono-jet search would not play any significant role in determining the viable parameter space for DM in G2HDM.

Invisible Higgs Decay

The Higgs boson will decay into a pair of DM when the DM is lighter than half its mass. This decay channel is known as the invisible decay of the Higgs boson. At tree level in G2HDM, the partial decay width of the Higgs boson to pair of dark matter, $h_1 \rightarrow DD^*$, is given by

$$\Gamma(h_1 \rightarrow DD^*) = \frac{(O_{32}^D)^4}{16\pi m_{h_1}^2} \lambda_{DD^* h_1}^2 \sqrt{1 - \frac{4m_D^2}{m_{h_1}^2}}, \quad (37)$$
where the $\lambda_{DD^* h_1}$ coupling depends on the composition of the $h_1$. For example, for the triplet-like DM case, it can be deduced from Eq. (A6), viz.,

$$\lambda_{DD^* h_1} \approx O_{11} \lambda_{H\Delta} v + O_{21} \lambda_{\phi\Delta} v_{\phi} - 2O_{31} \lambda_{\Delta} v_{\Delta}.$$ (38)

Currently the upper limit on the Higgs invisible decay branching ratio is rather loose, about 24% at 95% C.L. [74] at the LHC. Taking $m_D \ll m_{h_1}$ together with SM Higgs total decay width of 13 MeV [74], the LHC limit implies an upper bound,

$$(O_{32}^D)^2 \lambda_{DD^* h_1} < 5.099 \text{ GeV}.$$ (39)

However, we found this limit is not as stringent as DM direct detection unless $m_D \lesssim 10$ GeV where DM recoil energy is below the XENON1T threshold.

V. NUMERICAL ANALYSIS AND RESULTS

A. Methodology

In order to keep consistency with previous G2HDM studies, in particular the scalar sector constraints presented in [34], we will perform random scans to generate a sample of points consistent with all the conditions mentioned there. In our case, we will not keep $v_{\phi}$ fixed. Due to $Z'$ search constraints [35], we start our scan range at $v_{\phi} = 20$ TeV. Considering the energy scale for future colliders, we scan $v_{\phi}$ up to 100 TeV.

We will complete the scan with the free parameters of the gauge sector $g_H$ and $g_X$, while fixing the Stueckelberg mass parameter $M_X = 2$ TeV corresponds to the heavy $M_X$ scenario discussed in [35]. We will keep the $g_H$ coupling below 0.1 to

\footnote{For the Goldstone-like DM scenario, the scan range of $v_{\phi}$ is fine-tuned to a smaller range from 20 to 28 TeV in order to realize this scenario.}
avoid the Drell-Yan constraints. The lower bound of $g_H$ will be decided point by point such that the $W'$ boson is heavier than the DM $D$. From Eq. (25), we can obtain a condition for the minimum value of $g_H$

$$g_{H\text{min}} = \frac{2m_D}{\sqrt{v^2 + v_\Phi^2 + 4v_\Delta^2}}. \quad (40)$$

Additionally, we will require that the gauge bosons $Z'$ and $Z''$ are both heavier than the SM-like $Z$ and that the latter has a mass within its $3\sigma$ measured value of $91.1876 \pm 0.0021$ GeV.

To keep heavy fermions above detection limits, we will consider their masses to be no less than $1.5$ TeV from the searches of SUSY colored particles quoted in the PDG \cite{36} or $1.2 \times m_D$ from coannihilation consideration. In addition, we want to keep the new Yukawa couplings, related to the new heavy fermion masses generically by $m_{fH} = y_{fH}v_\Phi/\sqrt{2}$, to be reasonably small in order to minimize their effects on perturbative unitarity and renormalization group running effects. Therefore, we use the following formula to determine the appropriate Yukawa couplings for each point in our scan

$$y_{fH} = \max \left[ \frac{1.5 \text{ TeV}}{v_\Phi/\sqrt{2}}, \min \left( \frac{1.2 m_D}{v_\Phi/\sqrt{2}}, 1 \right) \right]. \quad (41)$$

Given the size of $v_\Phi$ and the fact that $m_D$ has to be the lightest $Z_2$-odd particle, we expect that Eq. (41) to easily remain below 1 for all our parameter space. Thus, in this set up, one expects most coannihilation contributions are coming from other $Z_2$-odd particles such as $\tilde{\Delta}$, $H^\pm$ and $W'$.

From these two steps we collect $\sim 5$ million points that include numerical values for model parameters, and results from scalar and gauge bosons masses, and

\footnote{We note that while the Yukawa couplings among the SM fermions and the neutral Higgses maintain flavor diagonal in G2HDM, the new Yukawa couplings are in general not. For simplicity, we have set the unitary mixing matrices among different flavors of heavy and SM fermions in the new Yukawa couplings with the $Z_2$-odd scalars to be the identity matrix.}
the elements of three mixing matrices $O$, $O^D$ and $O^G$. We pass these numbers to 
\texttt{MicrOMEGAs} \cite{Belanger:2013oya} to calculate relic density, DM-nucleon cross section and annihilation cross section at present time. Finally, the annihilation cross section and annihilation channels composition are passed to \texttt{LikeDM} \cite{Belanger:2013vya} for the calculation of indirect detection likelihood.

Due to the notably less abundant nature of doublet-like solutions compared to the other two compositions of DM, a scanning dedicated to find doublet-like solutions was made. For a $M_{H\Delta} \ll v_\Delta$ we can make the (2,2) entry in the mass matrix in Eq. (21) smaller than the (3,3) one with the condition

$$\lambda_0' H_0^* \phi < \frac{M_{\phi\Delta}}{2v_\Delta}. \quad (42)$$

Applying this condition increases the abundance of solutions where the lightest complex scalar composition is dominated by $H_0^*$. This explains the far more limited scan range for the parameter $\lambda_0' H_0^* \phi$ for the doublet-like DM case. The complete set of parameters scanned and their ranges can be found in Table \textbf{III}.

Note that in Table \textbf{III} the different ranges for $M_{H\Delta}$, $M_{\phi\Delta}$, $v_\Delta$ and $v_\phi$ are selected for the three cases so that we can easily find the corresponding DM composition. In particular, the very different and smaller fine-tuned ranges of $v_\Delta$ and $v_\phi$ in the Goldstone-like column are due to this composition being present for $v_\Delta/v_\phi \approx 0.8$ but limited by EWPT to be less than $\sim 0.9$, as demonstrated earlier near the end of Sec. \textbf{III}.

Before embarking upon the numerical results, we make some comments on the Sommerfeld enhancement \cite{Sommerfeld:1949ig, Sommerfeld:1949gs} in the DM annihilation cross section for indirect detection which may be important whenever $m_\chi/m_M > 4\pi/g^2$. Here $m_\chi$ and $m_M$ denote the masses of the fermionic DM $\chi$ and vector mediator $M$ respectively and $g$ is the gauge coupling. In G2HDM, the DM is a complex scalar $D$ and the mediators can be either the Higgses $h_i$ or neutral gauge bosons $Z_i$. Since all their masses are
TABLE III. Parameter ranges used in the scans mentioned in the text. $M_X$ is fixed at 2 TeV in this work and $M_Y$ is set to be zero throughout the scan.

| Parameter | Doublet-like | Triplet-like | Goldstone-like |
|-----------|--------------|--------------|----------------|
| $\lambda_H$ | [0.12, 2.75] | [0.12, 2.75] | [0.12, 2.75] |
| $\lambda_\Phi$ | [10^{-4}, 4.25] | [10^{-4}, 4.25] | [10^{-4}, 4.25] |

quite massive and not too distinct from each other, we do not expect significant Sommerfeld enhancement in G2HDM. Certainly a more decent study is necessary in order to provide a definite answer. Furthermore we will see in our analysis below that the direct detection limit from XENON1T will provide more stringent constraints than the current indirect detection results from Fermi-LAT. We will ignore such effects in the present analysis.
B. Results

To ease the discussion of our numerical results, it is useful to divide the DM mass range into several regions:

(i) light DM mass region where annihilation final states of $c\bar{c}$ and $\tau^+\tau^-$ are opened,

(ii) the resonance region where DM mass is close to SM $Z$ or Higgs resonance,

(iii) the intermediate DM mass from Higgs resonance $m_{h_1}/2$ to $\sim 500$ GeV where DM mainly annihilates to $W^+W^-$ and $ZZ$, and

(iv) the heavy DM mass larger than 500 GeV.

_Inert Doublet-like DM_

The doublet-like DM in G2HDM is similar to the IHDM case in the limit where the scalar ($S$) and pseudo-scalar ($P$) components in $H_2^0$ are mass degenerate. We show the scatter plot for the relic density dependence on the DM mass in the left panel of Fig. 4. Similar to Refs. [13, 78], there are several different annihilation mechanisms governing different DM mass regions. However, the observed relic abundance $\Omega_D h^2 \approx 0.1$ only occurs at around $m_D \sim 10$ GeV and $m_D > 500$ GeV.

In the following, we discuss in more detail the DM annihilations for this inert doublet-like DM case in the four DM mass regions (i) to (iv) consecutively.

(i) First, the DM masses that lies between 1 GeV to 10 GeV whose major contributions of the DM annihilation cross section are given by $DD^* \rightarrow c\bar{c}$ and $\tau^+\tau^-$ via $s$-channel SM Higgs exchange. Despite of the small $c$ and $\tau$ Yukawa couplings, the cross section can be slightly enhanced by the relatively big $DD^* h_i$ coupling, as given in Eq. (A4). Thanks to large values for $\lambda_{H\Phi} v_\phi$ and $\lambda_{H\Delta} v_\Delta$. 

34
FIG. 4. Doublet-like DM SGSC allowed regions projected on \((m_D, \Omega D h^2)\) (left) and \((m_D, \sigma_{SI}^n)\) (right) planes. The gray area in the left panel has no coannihilation or resonance. The gray area in the right panel is excluded by PLANCK data at 2\(\sigma\).

However, the total cross section is too small to bring the relic density in this mass range closer to the PLANCK measurement. Due to the opening of the \(DD^* \rightarrow b\bar{b}\) channel and its larger Yukawa coupling, the correct relic density can be obtained for DM masses between 11 GeV and 20 GeV.

(ii) When DM mass is around half the \(Z\) mass, the \(Z\) exchange diagram becomes very efficient and the enhancement in resonant annihilation brings the relic density well below 0.12 of the PLANCK measurement. We note that \(DD^*Z_i\) couplings are unique in G2HDM due to the nature of complex scalar. In IHDM, the DM can be either the real or imaginary parts of \(H_2^0 = S + iP\), in which case neither the \(SSZ\) nor \(PPZ\) coupling is present. Similarly, it also happens for DM mass at around half the SM Higgs mass, where again, enhanced annihilation rate through Higgs exchange brings the relic density
even lower.

(iii) If DM mass is increased above half the SM Higgs mass \((m_{h_1}/2 < m_D < 500 \text{ GeV})\), the Higgs resonance is no longer efficient. However, once the gauge boson final state, especially \(W^+W^-\), opens \((m_D > m_W)\), the total cross section is governed by the process \(DD^* \to W^+W^-\). The relevant diagrams for this process are the 4-point interaction \(DD^*W^+W^-\), \(s\)-channel mediated by each \(h_i\) and each \(Z_i\) gauge bosons, and \(t\)- and \(u\)-channels with charged Higgs mediator. The dominant channel is the \(s\)-channel through lightest Higgs \(h_1\) (not efficient but non-negligible) and second lightest Higgs \(h_2\) exchange. The third Higgs \(h_3\) is too heavy and not relevant. Thus the annihilation cross section is determined by the \(DD^*h_1\) and \(DD^*h_2\) couplings. These two couplings have terms proportional to each of the three VEVs (see Eq. \((A4)\)), which are usually too large in order to have enough relic density at the DM mass region below 500 GeV. As a result, the observed relic density (within 2\(\sigma\) region) can not be satisfied in this regime as one can see in the left panel of Fig. [3]. The other three final states opening in this intermediate mass range are \(ZZ\), \(h_1h_1\) and \(t\bar{t}\), which are all sub-dominant compared with the \(W^+W^-\) final state.

(iv) Finally, in the heavy mass region \((m_D > 500 \text{ GeV})\), the dominant final states are from the the longitudinal components of the gauge bosons, namely \(W_L^+W_L^-\) and \(Z_LZ_L\). For \(Z_LZ_L\) final state, there is an exact cancellation between the 4-point contact interaction diagram and the \(t\) and \(u\)-channels of \(D\) exchange diagrams. The sum of these 3 diagrams is proportional to \((s + t + u - 2m_D^2 - 2m_Z^2)\) and hence vanishes identically due to kinematical constraint. Thus the remaining diagrams for \(DD^* \to Z_LZ_L\) are given by the \(s\)-channel \(h_i\) exchange which lead to \(S\)-wave total cross section in the non-relativistic limit. There is a similar cancellation between the 4-point contact interaction diagram and
the $t$-channel charged Higgs exchange diagram for the $W^+_L W^-_L$ final state. The sum of the amplitudes from these two contributions is given by

$$A_{(4\text{-pt} + \text{Charged Higgs})} \approx \frac{e^2 (\mathcal{O}_{D22}^D)^2}{2 m_W^2 s_W^2} \left[ \frac{(s - 2 m_W^2)}{2} + \frac{(t - m_D^2)^2}{(t - m_{H^\pm}^2)} \right], \quad (43)$$

where $t = m_D^2 + m_W^2 - s/2$. Clearly, when $s$ is sufficiently large such that all masses can be ignored and $t \sim -s/2$, the above amplitude vanishes. However one notes that if $D-\pm H$ coannihilation happens for this heavy DM mass region, \textit{i.e.}, when $m_D \simeq m_{H^\pm}$, the above amplitude is also vanishing. Thus in the heavy DM mass region where the $D-\pm H$ coannihilation occurs, the dominant diagrams that contribute to $DD^* \to W^+_L W^-_L$ are the $h_i$ and $Z_i$ exchanges which give rise to $S$-wave and $P$-wave total cross sections respectively in the non-relativistic limit. We can also conclude that the total cross sections for DM annihilation into both $W^+_L W^-_L$ and $Z_L Z_L$ final states in G2HDM are consistent with unitarity [79].

In the right panel of Fig. [4], we show the scatter plot for the spin independent direct detection cross section versus the DM mass. The interactions between DM and nucleons are mediated by $t$-channel $h_i$ and $Z_i$ boson exchange, with a small contribution from $u$-channel heavy fermion exchange. Due to the $SU(2)_L \times U(1)_Y$ charge of the inert doublet $H_2$, the doublet-like DM-nucleon cross section is dominated by $Z$ exchange. As one can see in the plot, the doublet-like DM in G2HDM predicts a typical value of the cross section of order $10^{-38}$ cm$^2$. It can be excluded by XENON1T [64] and CRESST-III [80] down to DM masses above 2 GeV. For the points below 2 GeV that survive the CRESST-III constraint, the predicted relic abundance is always higher than the measured PLANCK value. Regarding the ISV effects, we check that $|f_n/f_p|$ remains typically 3 orders of magnitude far away from the maximal cancellation value of $f_n/f_p \approx -0.7$. Therefore, there is no noticeable reduction in the nucleon-level DD cross section.
It is clear from the previous discussion that for the doublet-like DM case there is no surviving parameter space that can remain after the constraints from both PLANCK and XENON1T are taken into account. Therefore, doublet-like DM in G2HDM is completely ruled out by current experiments, at least under the somewhat generic conditions set up in this paper. A study of particular mechanisms or very specific sets of parameters (e.g. a very light mediator region) that may bring down the relic density for light doublet-like DM ($\sim 1$ GeV) while keeping the prediction of direct detection intact is out of the scope of the present analysis.

$SU(2)_H$ Triplet-like DM

One fundamental difference between triplet-like and doublet-like DM is that now $D$ is dominated by the term $O_{32}^D \Delta_\nu$ in Eq. (29). Therefore, one should expect all the couplings to behave differently from the previous doublet-like case. In particular, the coupling terms that were relevant for doublet-like DM will now be suppressed by a smaller $O_{22}^D$. In Fig. 5, we show the scatter plots for the relic density and spin independent direct detection cross section versus the DM mass $m_D$ at the left and right panels respectively for the triplet-like case. Similar to the doublet-like case, one can divide the DM mass in different regions for discussions. The opening channels are the same in each region and hence no need to repeat here. However the dominant channels in each region may be changed due to the differences of the couplings in both DM compositions.

For the relic density, the resulting resonances and coannihilation regions are presented in the left panel of Fig. 5. We found that in the DM mass range below $m_{h_1}/2$ (region (i)), the dominant DM annihilation contribution to the relic abundance comes from $s$-channel Higgses exchange with final states of $\tau^+\tau^-$ and $b\bar{b}$. By looking at the $DD^*h_i$ coupling in Eq. (A6), it is easy to see that the large value of $v_\phi$ makes annih-
FIG. 5. Triplet-like DM **SGSC** allowed regions projected on \((m_D, \Omega_D h^2)\) (left) and \((m_D, \sigma_{SI}^n)\) (right) planes. The gray area in the left panel has no coannihilation or resonance. The gray area in the right panel is excluded by PLANCK data at 2\(\sigma\). In the right panel, the lower red solid line is the published XENON1T limit with isospin conservation, while the upper green solid line is the same limit but for ISV with \(f_n/f_p = -0.5\). Some orange filled squares are above the published XENON1T limit due to ISV cancellation at nucleus level.

...through \(h_2\) (\(\delta_3\)-like) comparable with annihilation through \(h_1\) (SM-like) while the heavier \(h_3\) (\(\phi_2\)-like) contribution remains subleading. As expected, the lowest relic density happens at the Higgs resonance region \(m_D \approx m_{h_1}/2\), combining with the large \(DD^* h_1\) coupling from the first term of Eq. (A6). Of course, one can always decrease the values of \(v_\Phi\) or \(v_\Delta\) to reduce the coupling size for larger relic abundance, but this is not particularly interesting for a thermal DM scenario. As DM becomes heavier, other resonance turns on. For \(m_D > 100\,\text{GeV}\), \(D\) is massive enough to have points where \(2m_D \approx m_{h_2}\) and some points resulting in resonant annihilation...
through $s$-channel $h_2$ exchange. In contrast to the doublet-like scenario, it is possible for the triplet-like DM to have a very wide range of relic density values, given the several different possible combinations for the $DD^*h_i$ coupling in Eq. (A6). Unlike the doublet-like case, for the triplet-like DM case in region (ii), the reduction of the relic density due to the $Z$ resonance enhancement in the annihilation cross section is absent because the triplet $\Delta_H$ is a SM singlet, meaning that the interaction between DM and the SM $Z$ is suppressed by product of small mixing elements like $(\mathcal{O}_{32}^D)^2 \mathcal{O}_{21}^G$ according to Eq. (A5).

In region (iii) where $m_{h_1}/2 < m_D < 500$ GeV, the relic density reduction mechanism is similar to the doublet-like DM case discussed above. The annihilation cross section is highly dominated by $W^+W^-$ (more than $\sim 50\%$), $h_1h_1$ ($\sim 25\%$), and $ZZ$ ($\sim 20\%$) final states. The main contribution to the $W^+W^-$ final state comes from $S$-wave given by $h_i$ exchange, while the $P$-wave contribution is suppressed and originated from neutral gauge bosons mediator exchange. The $S$-wave annihilation cross section is controlled by the $DD^*h_1$ and $DD^*h_2$ couplings, as can be seen in Eq. (A6). The contribution from $h_3$ exchange is negligible because of its heavy mass.

In region (iv) where $m_D > 500$ GeV, DM annihilates into $W^+_LW^-_L$ predominantly while other channels are subdominant, similar to the doublet-like DM case. There is no need to elaborate further here.

Generally speaking, the charged Higgs $H^\pm$ contribution here can be omitted since it is more than twice heavier than the DM $D$. Differently from the doublet-like case, there is no coannihilation between $H^\pm$ and $D$ in the triplet-like DM case. Next, the coannihilation between DM and $\tilde{\Delta}$ is absent as well because the $\tilde{\Delta}$ is also much heavier than $D$ due to the choice of larger $v_\Delta$ to make the (3,3) entry of Eq. (21) smaller. Therefore, the only possible efficient coannihilation is between DM and $W'$ for DM mass above 400 GeV (orange boxes at the left panel of Fig. 5). This coannihilation is only important for relic density above 0.12, where some $DD^* \rightarrow$
annihilation channels may be insufficient because their couplings to $h_i$ and $Z_j$ may be suppressed. A small region with heavy fermion coannihilation happens for $m_D > 1$ TeV with relic density above 10 (green shaded points in the left panel of Fig. 5). This is close to the maximal relic density in our scan for that mass range. This indicates that heavy fermion coannihilation is important only when the other annihilation channels are strongly suppressed.

Regarding direct detection, due to the $DD^*Z$ coupling suppression by mixings in this triplet-like case, the elastic DM-nucleon scattering spin independent cross section mediated by the $h_i$ and the extra neutral gauge bosons $Z'$ and $Z''$ bosons may be relevant. We confirm that the dominant contribution to the spin independent cross section is given by $h_1$ and the next dominant contributions are $Z$ and $Z'$, while $h_2$, $h_3$ and $Z''$ are always subdominant. The contributions mediated by heavy fermions are negligible due to suppression by their masses in the propagators.

In the right panel of Fig. 5, we can see that for $m_D \gtrsim 300$ GeV it is possible to find a region that agrees with relic density constraint from PLANCK at 2σ and remains below the published XENON1T limit at the neutron with $f_n/f_p = 1$. Note that some of the allowed points (orange squares) are above this XENON1T limit. This is due to mild ISV cancellation that brings such points below the XENON1T limit at nucleus level, as given by Eq. (33). For comparison, the XENON1T limit at the neutron level with ISV of $f_n/f_p = -0.5$ is also shown.

The constraint of indirect detection from Fermi-LAT’s gamma-ray observation imposed on the triplet-like DM is shown in Fig. 6. The left panel presents the DM annihilation cross section dependence on the DM mass at the present universe with SGSC+RD. Results are only presented for the dominant annihilation channels, $b\bar{b}$ and $W^+W^-$. One can see that DM with $m_D \lesssim 90$ GeV mainly annihilates to $b\bar{b}$.

\footnote{Note that to apply Fermi-LAT constraints we use photon flux as calculated with Eq. (36). The annihilation channels displayed in Fig. 6 are only leading channels that may not be significantly above other channels.}
FIG. 6. The present time total annihilation cross section according to dominant annihilation channel (left) and DM-neutron elastic scattering cross-section (right) for \( f_{\Delta p} > 2/3 \) in the triplet-like DM case versus the DM mass \( m_D \). Two-dimensional 2\( \sigma \) criteria of the ID constraints is \( \Delta \chi^2 = 5.99 \) based on Fermi dSphs gamma-ray flux data. Future CTA measurements may help constrain regions with DM masses above \( \mathcal{O}(10^2) \) GeV as shown in the left panel. In the right panel, the lower red solid line is the published XENON1T limit with isospin conservation, while the upper green solid line is the same limit but for ISV with \( f_n/f_p = -0.5 \). Some blue filled squares are above the published XENON1T limit due to ISV cancellation at nucleus level.

At the region near the \( Z \) or \( h_1 \) resonance, the corresponding cross section at the present universe drops while satisfying the relic density. This is a typical feature of the resonance region because the DM relative velocity at the early universe is much larger than the value at the present one. In order to cancel a large cross section caused by the resonance at the early universe, a small coupling of \( DD^*Z \) or \( DD^*h_1 \) is required to make \( \langle \sigma v \rangle \) at the early universe comes close to the canonical value of
However, when the universe temperature drops, the resonance cannot be maintained by the kinetic energy of DM at the present day. At this time the cross section becomes smaller and is hard to be observed by Fermi-LAT.

Once DM mass is heavier than $W^\pm$ boson mass, the final state $W^+W^-$ starts dominating the annihilation cross section rapidly. Note that the current ID sensitivity can only apply strongly for the DM mass located between 10 GeV and few hundred GeV. However, the future CTA sensitivity [81] might reach the TeV region of $m_D$ and further constrain our parameter space, as show in the left panel of Fig. 6.

In the right panel of Fig. 6 we display the exclusion from ID projected on the plane of DM-neutron spin independent cross section $\sigma_n^{SI}$ versus $m_D$. We can see that all the ID excluded points sit above the limit set by XENON1T. The exclusion limits are given by recent XENON1T data (blue unfilled squares) and Fermi gamma-ray constraints (orange crosses). One can see the XENON1T exclusion power is much stronger than Fermi gamma-ray exclusion.

**SU(2)$_H$ Goldstone boson-like DM**

In this case, as shown at the end of Sec. III (see Fig. 1), the Goldstone-like DM $D$ will be a mixture dominated by $C^0_H$ with an important component coming from $\Delta_p$, while the $H^*_2$ component remains suppressed. In the left panel of Fig. 7, for the DM mass regions (i)-(iii), the dominant channels for DM annihilation in the relic abundance calculation are similar to the triplet-like DM case. In heavy mass region (iv), the cross section is again dominated by the $W^+_LW^-_L$ final state which contributes $\sim$50%, while the transverse component is negligible. The main difference between Goldstone-like and triplet-like DM can be understood by their corresponding dominant couplings. For triplet-like DM, the dominant couplings are given by Eqs. (A5) and (A6) which are proportional to the $(O_{32}^D)^2$ characterizing the
corresponding $\Delta_p$ component. Similarly, one expects that the Goldstone-like DM receives its dominant couplings purely via Eqs. (A7) and (A8). However, this is not the case for Goldstone-like DM. There is also an important contribution coming from the $\Delta_p$ part in the relevant couplings. Thus, one needs to include not only the couplings proportional to $(O^D_{12})^2$ but also the ones proportional to $(O^D_{32})^2$. The effect of $\Delta_p$ component in this case is reducing the $DD^*h_1$ and $DD^*h_2$ couplings while enhancing the $DD^*Z$ and $DD^*Z'$ couplings. As a consequence, the dominant DM annihilation channel $W^+_L W^-_L$ will be dominated by $P$-wave component originated
from the $Z'$ exchange, while the $S$-wave part coming from the $h_1$ and $h_2$ mediators is subdominant. The next important contribution is given by the $Z'Z'$ final state. The $Z'Z'$ final state occurs via four point contact interaction, $t$ and $u$-channels of $D$ exchange and $s$-channel of neutral Higgses exchange. The presence of the $\Delta_p$ component in the Goldstone-like DM further enhance the $DD^*Z'Z'$ coupling resulting the appearance of the new important final state $Z'Z'$ in the heavy mass region (iv).

Coannihilation in this case is very similar to the triplet-like DM case. The most relevant coannihilations happen with $W'$ and heavy fermions for large masses and large relic density. Coannihilation with $W'$ only presents when the DM mass gets close to 300 GeV and its relic density mostly above the PLANCK measurement. As the triplet-like DM case, the usual $DD^*$ annihilation channels become smaller leaving more way for coannihilations that, otherwise, would be negligible. For the case of heavy fermions, coannihilation happens for DM masses above 1 TeV and mostly for the upper bound of relic density, where $DD^*$ coannihilation is even more suppressed than for the $W'$ case.

In the right panel of Fig. 7 we show the scatter plot for the DM-neutron cross section dependence on the DM mass. The dominant contribution comes from $h_1$ exchange with the next dominant ones given by the exchange of $Z$ and $Z'$ bosons. The bottom part of the gray region in Fig. 7 comes mostly from interactions mediated by the $Z$ and $Z'$ gauge bosons and is limited from below by our lower limit for the scan range of $g_H$ determined by Eq. (40). The interference between $h_1$, $Z$, and $Z'$ exchange makes the spin independent cross section varies in a wide range. The orange points located between $200 \text{ GeV} \leq m_D \leq 600 \text{ GeV}$ satisfy the observed relic density while escaping the current bound on direct detection given by XENON1T experiment. The dominant contribution for these points is given by the gauge bosons exchange $Z$ and $Z'$. Due to the fine-tuning parameter space for the Goldstone-like
FIG. 8. The present time total annihilation cross section by dominant annihilation channels (left) and DM-neutron elastic scattering cross-section (right) for $f_{Gp} > 2/3$ in the Goldstone-like DM case versus the DM mass $m_D$. Two-dimensional 2σ criteria of the ID constraints is $\Delta \chi^2 = 5.99$ based on Fermi dSphs gamma-ray flux data. Future CTA measurements may help constrain regions with DM masses above $O(10^2)$ GeV as shown in the left panel. In the right panel, the lower red solid line is the published XENON1T limit with isospin conservation, while the upper green solid line is the same limit but for ISV with $f_n/f_p = -1.5$. Some blue filled squares are above the published XENON1T limit due to ISV cancellation at nucleus level.

DM mentioned earlier, only the ratio of $f_n/f_p = -1.86$ has enough ISV cancellation to satisfy the published XENON1T limit assuming isospin conservation. For comparison, the XENON1T limit with ISV of $f_n/f_p = -1.5$ is also shown.

In the ID side, there is no relevant constraining for this Goldstone boson-like case. Because of $P$-wave suppression of the $Z$ and $Z'$ exchange in the dominant channels of $b\bar{b}$ and $W^+W^-$, most of the points in agreement with the relic density
measurement from PLANCK have a very low annihilation cross section at the present
time and are far beyond the reach of current experiments of indirect detection, as
can be seen clearly in the zoomed in region on the \((\langle \sigma v \rangle, m_D)\) plane at the left
panel in Fig. 8 allowed by the \textbf{SGSC+RD}. For DM masses below 100 GeV, the
annihilation is dominated by \(b \bar{b}\) final state with 90\% of the total cross section in
average. For DM mass above the mass of the \(W^\pm\), the \(W^+W^-\) final state dominates
completely with an average of 50\% of the total cross section. Unlike triplet-like
DM, \textbf{ID} alone does not further constrain the points allowed by PLANCK. The right
panel of Fig. 8 shows the zoomed in region of points on the \((m_D, \sigma_{SI}^n)\) plane allowed
by the \textbf{SGSC+RD+ID} and \textbf{SGSC+RD+ID+DD}. As mentioned before, ISV
effect \((f_n/f_p \approx -1.86)\) reduces the sensitivity of the XENON1T result and some
points pass all the constraints \((\text{SGSC+RD+ID+DD})\) even though they are above
the direct detection limit at nucleon level. Note that there are no points satisfying
\textbf{SGSC+RD+DD+ID} beyond \(m_D \sim 1\) TeV in this Goldstone-like case.

\section*{C. Constraining Parameter Space in G2HDM}

From previous sections, we have learned that the doublet-like DM scenario cannot
fulfill the DM constraints and that the Goldstone-like DM requires some fine-tuning
in the parameter space and to escape the XENON1T limit a particular value of
\(f_n/f_p \approx -1.86\) is required. Therefore, we will be focusing on discussing the allowed
G2HDM parameter space based on the triplet-like DM.

In Fig. 9, we present the allowed regions of the quartic couplings from the \textbf{SGSC}
constraints (green region) and \textbf{SGSC+RD+DD} constraints (red scatter points). Comparing
the green regions with the red scatter points in Fig. 9 one can easily obtain the following results:

- The allowed ranges on \(\lambda_H\) and \(\lambda'_H\) remain more or less the same before and
FIG. 9. A summary plot for the scalar potential parameter space allowed by the SGSC constraints (green region) and SGSC+RD+DD constraints (red scatter points) for the triplet-like DM. The numbers written in the first block of each column are the 1D allowed range of the parameter denoted in horizontal axis after the SGSC+RD+DD cut.

after imposing RD+DD constraints.
• \( \lambda_\Phi, \lambda_{H\Delta}, \) and \( \lambda_{\Phi\Delta} \) are mostly constrained by \textbf{RD+DD} constraints. To understand this effect, one can see from Eq. (A6) that there are three dominant terms that contribute to the \( DD^*h_j \) couplings, \( \lambda_{H\Delta}v\mathcal{O}_{11}, \lambda_{\Phi\Delta}v_\Phi\mathcal{O}_{22}, \) and \( \lambda_{\Delta\Delta}v_\Delta\mathcal{O}_{33} \) for \( j = 1, 2, 3 \) respectively. Clearly, \( \lambda_{H\Delta}, \lambda_{\Phi\Delta} \) are restricted by the allowed Higgs coupling sizes.

• Regarding to lighter mediator, in particular for \( h_2 \), the mixing \( \mathcal{O}_{22} \) is strongly related to \( \lambda_\Phi \), so that \( \lambda_\Phi \) and \( \lambda_{\Phi\Delta} \) are correlated as shown in the third row from bottom to top and second column of Fig. 9. These two parameters are related to \( h_1 \) decay to \( f\bar{f} \) and are constrained by Higgs physics and further by \textbf{DD} constraints.

• However, \( \lambda_{\Delta} \) is not constrained because either the DM annihilation or DM-nucleon elastic scattering cross section via the exchange of \( h_3 \) is suppressed by its heavy mass \( m_{h_3} \).

• On the other hand, the two off-diagonal terms \( \lambda_{H\Phi} \) and \( \lambda'_{H\Phi} \) are constrained mildly. This is due to the loose requirement that we set for the triplet-like DM \( f_\Delta > 2/3 \). In fact, we checked that there can be an important contribution from the \( G_\Phi^\rho \) component with \( f_{G_\Phi^\rho} \) up to 1/3. As a consequence, even though \( \lambda_{H\Phi} \) and \( \lambda'_{H\Phi} \) do not appear explicitly in the coupling of \( DD^*h_i \) given in Eq. (A6), they appear via subdominant component \( G_\Phi^\rho \) as seen in Eq. (A8).

Next, we project the allowed G2HDM parameter space to the two VEVs \( v_\Phi \) and \( v_\Delta \), the two cubic couplings \( M_{H\Delta} \) and \( M_{\Phi\Delta} \), and the two new gauge couplings \( g_H \) and \( g_X \) in Fig. [10]. Again, by comparing the green regions and the red scatter points in Fig. [10], we can arrive at the following results:

• Strikingly, only \( g_H \) and \( v_\Phi \) can be further constrained by \textbf{RD+DD}. Interestingly, we found such an exclusion comes from the lower allowed DM mass. The
FIG. 10. A summary plot for the VEVs, $M_{\Phi\Delta}$, $g_X$ and $g_H$ parameter space allowed by the SGSC constraints (green region) and SGSC+RD+DD constraints (red points) for the triplet-like DM.

allowed DM mass values range from hundreds of GeV to a few TeV. This range is reflected in $g_H$ since the minimal value we choose for $g_H$ is given by Eq. (40)
and depends directly on the DM mass.

- The other 4 parameters $g_X$, $v_\Delta$, $M_{H\Delta}$ and $M_{\Phi\Delta}$ are not sensitive to the dark matter physics constraints from $R D + D D$.

In summary, given the setup of the parameter space in our numerical scanning, a good WIMP candidate in G2HDM is the triplet-like complex scalar with a mass $m_D$ in the electroweak scale, and it requires $g_H \gtrsim 2 \times 10^{-2}$ and $v_\Phi \gtrsim 30$ TeV.

VI. SUMMARY AND CONCLUSION

The G2HDM is a novel two Higgs doublet model with a stable DM candidate protected by an accidental discrete symmetry ($h$-parity) without the need of imposing it by hand as in the IHDM. After $SU(2)_H$ symmetry breaking, the symmetry remains intact and one can find three electrically neutral potential DM candidates with odd $h$-parity: the lightest dark complex scalar $D$, heavy neutrino $\nu^H$, and the $SU(2)_H$ gauge boson $W'(p,m)$. Though these three candidates are all interesting, we focus this paper on the most popular one, the new scalar DM $D$, which is complex and hence differ from the DM in IHDM. Unlike IHDM, the mixing between $Z$-odd scalars adds a touch of complexity since DM in G2HDM not only comes from the inert doublet but may also be $SU(2)_H$ Goldstone-like and triplet-like. We took the dominant composition ($f_j > 2/3$ with $j = H_2, \Delta_\rho, G^\rho$) as a criteria to classify them but the mixture between them can be simply inferred. In this paper, we have discussed these three types individually with two assumptions: that all the new non-SM heavy fermions are heavy enough to have mostly negligible contributions and that DM were thermally produced before the freeze-out temperature. We have comprehensively shown their detectability and exclusions by the current SGSC and DM constraints (mainly $R D + D D$).
Because the DM candidate is chosen to be a complex scalar in G2HDM, the DM phenomenology becomes very rich since it has captured both features of the Higgs-portal and vector-portal DM models discussed in the literature.

For the inert doublet-like DM, we found some interesting features. First, the main difference between the inert doublet DM in IHDM and G2HDM is that in IHDM there is in general a mass splitting between the scalar $S$ and pseudoscalar $P$ components of $H_2^0$, while in G2HDM they are completely degenerate and combined into one single complex field $H_2^0 = S + iP$. Recall that in IHDM there is only $ZSP$ derivative coupling but no $ZSS$ and $ZPP$ derivative couplings. As long as the mass splitting between $S$ and $P$ remains larger than the exchange energy between DM and nucleons in the direct detection experiments, the interactions mediated by the $Z$ gauge boson are suppressed in IHDM. Since this splitting does not exist in G2HDM, such interactions are unsuppressed and they can bring the spin independent cross section up to $\sim 10^{-38}$ cm$^2$, which is significantly above the XENON1T 95% C.L. limit for $m_D \gtrsim 10$ GeV and above CRESST-III result for $m_D \gtrsim 2$ GeV (Fig. 4 right panel). On the other hand, for $m_D \lesssim 10$ GeV, the DM is over abundant because of on-shell annihilation channels in $c\bar{c}$ and $\tau^+\tau^-$ (Fig. 4 left panel). Hence, we conclude that the inert doublet-like DM can be completely excluded by SGSC+RD+DD constraints.

Next, a $SU(2)_H$ triplet scalar like DM was discussed. Since the composition $f_{H_2}$ has to be tiny in order to avoid the tension with DM DD, the triplet-like DM can mostly mix with the Goldstone boson $G^p$. There is no $Z$-resonance region in the triplet-like DM for DM annihilation and the parameter space is more or less consistent with Higgs portal DM. However, DD is still the most stringent constraint comparing with ID and collider constraints. The allowed DM mass by SGSC+RD+DD is required to be heavier than $m_D \gtrsim 300$ GeV (Fig. 5 right panel). Despite weaker constraints coming from ID (Fig. 6 left panel) and collider searches, it might be
possible to detect the heavy DM mass region by the future CTA and 100 TeV colliders even if a DM signal is not found at direct detection experiments before hitting the neutrino floor. As shown by the blue solid boxes in the right panel of Fig. 6, the allowed triplet-like DM mass consistent with $\text{SGSC}+\text{RD}+\text{DD}+\text{ID}$ is $\gtrsim 300$ GeV.

For the last case of the Goldstone-like DM, we found that it is not possible to obtain a pure Goldstone-like DM. The non-tachyonic DM condition and EWPT constraints prohibit the composition $f_{Gp} > 0.75$ (Fig. 1), unless one would like to move to a more fine-tuned region of parameter space. Thus there is a significant component coming from the triplet in the Goldstone-like DM. Because of the $P$-wave suppression of the $Z$ and $Z'$ exchange in the dominated channels of $b\bar{b}$ and $W^+W^-$, the annihilation cross section happens to be smaller than for the triplet-like case and lesser points within the PLANCK relic density measurement (Fig. 7 left panel). Furthermore, XENON1T measurement excludes almost all the points with appropriate relic density, except for those with a particular value of isospin violation ($f_n/f_p \approx -1.86$) where the sensitivity at XENON1T is reduced. Therefore, only a small region of orange boxes in the right panel of Fig. 7 with $m_D$ in the range of 150 ~ 600 GeV can pass all the $\text{SGSC}+\text{DD}$ constraints implemented in this work. For $\text{ID}$, the annihilation cross section at the present time for the Goldstone-like DM is typically smaller than the limit from Fermi gamma-ray constraints (Fig. 8 left panel). With significant ISV, only the Goldstone-like DM with a mass in the window of 150 ~ 600 GeV can be consistent with $\text{SGSC}+\text{RD}+\text{DD}+\text{ID}$, as given by the blue solid boxes in the right panel of Fig. 8.

We also presented the impact of DM constraints on the G2HDM parameter space in Figs. 9 and 10 for the triplet-like DM. In this case, we found that the following parameters $\lambda_\Phi$, $\lambda_{H\Delta}$, $\lambda_{\Phi\Delta}$, $g_H$, and $v_\Phi$ are significantly constrained by DM constraints, mainly $\text{RD}+\text{DD}$, while the four parameters $g_X$, $\lambda_\Delta$, $v_\Delta$, and $M_{H\Delta}$ remains more or less the same as given by the $\text{SGSC}$. It is interesting to note that the $\text{SGSC}$ con-
straints on \( g_H \) and \( v_\Phi \) as studied in \cite{34,35} are now further constrained by \textbf{RD+DD}. We note that the lower limit of \( g_H > 7.09 \times 10^{-3} \) for \( v_\Phi < 100 \) TeV is reachable by the future linear (lepton-antilepton) and 100 TeV hadron colliders.

Before closing, we would like to make a few comments. Originally the \( SU(2)_H \) triplet field \( \Delta_H \) was introduced to give mass to the charged Higgs (Eq. (20)) in \cite{28} where the two parameters \( \lambda'_H \) and \( \lambda'_{H\Phi} \) were missing. With these two extra parameters included, the triplet field \( \Delta_H \) is no longer mandatory. We note however that the triplet field \( \Delta_H \) can give rise to a non-singular ’t Hooft-Polyakov monopole for the hidden \( SU(2)_H \) which can play the role as DM as studied in \cite{82}. Nevertheless, one can have a minimal G2HDM without the triplet field. Then the DM \( D \) in this minimal model would be just mixture of the inert Higgs \( H_2^{0*} \) and the Goldstone field \( G^p_H \). From the analysis in this work, we know that this DM scenario must be highly fine-tuned in the parameter space due to \textbf{SGSC+RD+DD}. A more interesting alternative DM candidate in this minimal G2HDM is the \( W'^{(p,m)} \), which certainly deserves a separate study. Finally, whether the accidental discrete symmetry of \( h \)-parity, identified here in the renormalizable Lagrangian for classification of all particles in G2HDM, has a deeper origin remains to be explored in the future.

Appendix A: Feynman Rules

Here we list the relevant couplings to the DM analysis in various processes discussed in the text. We use the conventional notations $g$ and $g'$ to denote the SM $SU(2)_L$ and $U(1)_Y$ couplings respectively. The $c_W$ and $s_W$ denote the cosine and sine of the Weinberg angle. The gauge couplings for $SU(2)_H$ and $U(1)_X$ are denoted by $g_H$ and $g_X$ respectively. In addition, for the scalar-scalar-gauge derivative vertices, we adopt the convention that all momenta are incoming.
