Neuromyelitis optica MOG-IgG causes reversible lesions in mouse brain

Abstract

Introduction: Antibodies against myelin oligodendrocyte glycoprotein (MOG-IgG) are present in some neuromyelitis optica patients who lack antibodies against aquaporin-4 (AQP4-IgG). The effects of neuromyelitis optica MOG-IgG in the central nervous system have not been investigated in vivo. We microinjected MOG-IgG, obtained from patients with neuromyelitis optica, into mouse brains and compared the results with AQP4-IgG.

Results: MOG-IgG caused myelin changes and altered the expression of axonal proteins that are essential for action potential firing, but did not produce inflammation, axonal loss, neuronal or astrocyte death. These changes were independent of complement and recovered within two weeks. By contrast, AQP4-IgG produced complement-mediated myelin loss, neuronal and astrocyte death with limited recovery at two weeks.

Conclusions: These differences mirror the better outcomes for MOG-IgG compared with AQP4-IgG patients and raise the possibility that MOG-IgG contributes to pathology in some neuromyelitis optica patients.

Keywords: Antibody, Demyelination, Myelin oligodendrocyte glycoprotein, Neuromyelitis optica

Introduction

Most neuromyelitis optica (NMO) patients have IgG against aquaporin-4 (AQP4), here termed AQP4-IgG [1,2]. AQP4 is a water channel protein found in astrocytes throughout the central nervous system (CNS), especially in perivascular astrocyte foot processes [3]. In cultured cells, AQP4-IgG binds extracellular conformational domains of AQP4 and activates complement, causing cell lysis [4]. In mice, intracerebral injection of AQP4-IgG activates co-injected human complement (C_hu) and damages the astrocytes [5,6]. Inflammatory cells then enter the lesion causing further tissue injury including demyelination and axonal damage. In AQP4-IgG NMO patients, recovery after an attack is usually limited [7-9].

A few NMO patients without AQP4-IgG have IgG against myelin oligodendrocyte glycoprotein (MOG-IgG), which recognize extracellular conformational domains of MOG [10-13]. MOG is expressed on the outer surface of CNS myelin sheaths and comprises about 0.05% of total myelin protein [14]. There is mounting evidence that MOG-IgG NMO has more favorable clinical outcome than AQP4-IgG NMO, with resolution of imaging abnormalities [10,11,15,16]. It is currently unclear whether MOG-IgG plays any role in NMO by causing lesions in the CNS in vivo. Here we compared the effects of MOG-IgG with those of AQP4-IgG in the intracerebral injection mouse model. We used total IgG from a normal subject (IgGCON) and from NMO patients with AQP4-IgG (IgGAQP4) or MOG-IgG (IgGMOG).

Materials and methods

IgG and complement

NMO patients with MOG-IgG or AQP4-IgG were identified using live cell-based assays. Briefly, AQP4-IgG and MOG-IgG positivity was determined by visualization of binding to human embryonic kidney cells, transfected with the extracellular and trans-membrane domains of MOG [10-13]. MOG is expressed on the outer surface of CNS myelin sheaths and comprises about 0.05% of total myelin protein [14]. There is mounting evidence that MOG-IgG NMO has more favorable clinical outcome than AQP4-IgG NMO, with resolution of imaging abnormalities [10,11,15,16]. It is currently unclear whether MOG-IgG plays any role in NMO by causing lesions in the CNS in vivo. Here we compared the effects of MOG-IgG with those of AQP4-IgG in the intracerebral injection mouse model. We used total IgG from a normal subject (IgGCON) and from NMO patients with AQP4-IgG (IgGAQP4) or MOG-IgG (IgGMOG).

the right hemisphere was inserted 3 mm deep to micro-infuse (1:50 ml gas-tight glass syringe (Hamilton, Reno, NV, USA) unaware of the aim of the study. A 30 g needle attached to the different experimental groups by a person (lateral, anterior): (1, 0), (1, 35), (2, 35) g, 8 – 12w old. Protocols were approved by the British Home Office (Project Licence, PPL 70/7081). After administering 2,2,2-tribromoethanol i.p., mice were mounted onto a stereotactic frame (Benchmark, Neurolab, St Louis, MO, USA). Four burrholes were made on the right side using a high speed drill (0.7 mm burr, Foredom, Bethel, CT, USA) at the following coordinates in millimetres from the bregma (lateral, anterior): (1, 0), (1, −1), (1, −2), (2, −1). Mice were unmasked in citrate, incubated with primary antibody (1:500, one hour, 25°C) and visualized using the Vectastain ABC reagent (1:200, 12 hours, 25°C) followed by Alexafluor-linked anti-rabbit antibody (1:200, one hour, 25°C, Invitrogen, Paisley, UK).

To determine MOG-IgG binding to mouse brain sections, brains were removed, immersed in 30% sucrose overnight, embedded in OCT and cut into 7 μm sections. These were fixed in acetone and exposed to IgGMOG(AdsHEK), IgG MOG(AdsMOG-HEK), IgGCON (1:100) or MOG-IgG2b7 (1 mg/mL) ± rabbit anti-MOG (1:100, InsightBio) for one hour at 25°C followed by Alexafluor-linked anti-human ± anti-rabbit antibody (1:200, one hour, 25°C, Invitrogen) and DAPI.

Photomicrographs were taken using an Olympus BX-51 microscope.

Data analysis
Coded photomicrographs were analysed with ImageJ (v1.45S, NIH). Neurifilament immunoreactivity in the injected hemisphere was quantified as mean staining intensity minus background. AnkG and Caspr expression was the number of fluorescent spots/mm² in four photomicrographs, 90 μm×67 μm, taken from the injected hemisphere 0.5 mm from the needle tract. After subtracting background, formatting images to 8-bit, adjusting threshold, the ‘analyse particles’ function of Image J was used. Spots < 0.01 μm² were excluded as noise.

The purified, dialysed and pooled total IgG preparations (6 – 38 mg/ml) are termed IgG\textsubscript{AQP4}, IgG\textsubscript{MOG} and IgG\textsubscript{CON}. Clinical details of the 5 AQP4-IgG + [5] and 5 MOG-IgG + [11,15] patients are given elsewhere. To deplete MOG-IgG, the IgG\textsubscript{MOG} was adsorbed by incubation with MOG-HEK cells until MOG-IgG became undetectable (IgG\textsubscript{MOG(AdsMOG-HEK)}). IgG\textsubscript{MOG} adsorbed against untransfected HEK cells (IgG\textsubscript{MOG(AdsHEK)}) was used as control. A chimeric mouse-human recombinant monoclonal anti-mouse MOG antibody, MOG-IgG\textsubscript{2B7}, was produced as described [19]. Human recombinant monoclonal anti-AQP4 IgG\textsubscript{i}, termed AQP4-IgG\textsubscript{53}, was also generated [20]. A measles virus–antibody termed CON-IgG\textsubscript{2B4} was used as isotype control [20]. The source of C\textsubscript{hu} was fresh serum from healthy volunteers [5].

Mice
Experiments were performed at St. George’s, University of London using CD1 mice 8 – 12 30 – 35 g, 8 – 12w old. Mice were anaesthetized and perfused-fixed by injecting 4% formaldehyde through the left cardiac ventricle. Brains were removed, post-fixed in 4% formaldehyde for 6 hours and processed into paraffin. Coronal tissue sections (7 μm thick) through the injection tract were stained with H + E, Luxol Fast Blue [5] or immunostained.

For immunofluorescence staining, we used rabbit anti-Ankynir G (AnkG, InsightBio, Wembley, UK) or rabbit anti-Contactin associated protein (Caspr) from Abcam (1:200, 12 hours, 25°C) followed by Alexafluor-linked anti-rabbit antibody (1:200, one hour, 25°C, Invitrogen, Paisley, UK).

Photomicrographs were taken using an Olympus BX-51 microscope.

Mouse brain histology and immunohistology
Mice were anaesthetized and perfused-fixed by injecting 4% formaldehyde through the left cardiac ventricle. Brains were removed, post-fixed in 4% formaldehyde overnight and processed into paraffin. Coronal tissue sections (7 μm thick) through the injection tract were stained with H + E, Luxol Fast Blue (LFB) [5] or immunostained.

For dianminobenzidine immunostaining, the sections were unmasked in citrate, incubated with primary antibody (one hour, 25°C), biotinylated secondary antibody (1:500, one hour, 25°C) and visualized using the Vectorstain HRP kit (Vector Labs, Peterborough, UK). We counterstained nuclei with haematoxylin. Primary antibodies were rabbit anti-AQP4 (1:100), rabbit anti-glial fibrillary acidic protein (GFAP, 1:200), mouse anti-NeuN (1:200), (Millipore, Livingstone, UK), mouse anti-myelin basic protein (MBP, 1:400, Leica, Newcastle, UK), mouse antineurofilament-70 (1:600, DAKO, Ely, UK), rabbit anti-C5b-9 (1:100, Abcam, Cambridge, UK) and rat anti-CD45 (1:200, BD Bioscience, Oxford, UK). Samples were then incubated with the appropriate species biotinylated secondary antibody (1:500, Vector Laboratories). Immunostaining was visualized brown using the Vectastain horseradish peroxidase kit (Vector Laboratories) followed by dianminobenzidine/H2O2. Nuclei were counterstained blue with haematoxylin.

Results
Lesions induced by IgG\textsubscript{MOG} compared to IgG\textsubscript{AQP4}
IgG\textsubscript{MOG} + C\textsubscript{hu} caused brain edema at 24 hours, but by seven days and two weeks the brain appeared normal
Although IgGAQP4 +C hu also caused edema at 24 hours, at seven days there was marked leukocyte infiltration and by two weeks reactive gliosis (Figure 1A). IgGMOG +C hu caused loss of Luxol Fast Blue (LFB) staining at 24 hours, but this had reversed by two weeks, while the IgGAQP4 +C hu – injected tissue showed increased loss of LFB staining at seven days and only partially recovered at two weeks (Figure 1B). The recruitment of inflammatory cells also differed markedly between the two preparations. IgGMOG +C hu did not produce inflammation while IgGAQP4 +C hu caused inflammation at 24 hours (perivascular neutrophils) and seven days (mostly macrophages) (Figure 1C).

We immunostained for two astrocyte markers, AQP4 and GFAP. Loss of AQP4 and GFAP was seen in IgGAQP4 +C hu – injected brains (at 24 hours and seven days) but IgGMOG +C hu did not reduce AQP4 and GFAP (Figure 2). At two weeks there was marked gliosis (increased AQP4 and GFAP) in brains injected with IgGAQP4 +C hu compared to little gliosis in brains that received IgGMOG +C hu (Figure 2).

**MOG-IgG binds mouse MOG and causes loss of LFB staining**

To confirm that IgGMOG binds mouse myelin, it was applied to brain sections. IgGMOG bound the corpus callosum; binding co-localized with a commercial anti-MOG antibody (Figure 3A). IgGMOG adsorbed by incubation with MOG-expressing human embryonic kidney (MOG-HEK) cells until MOG-IgG became undetectable.
(IgG\textsubscript{MOG(Ads\textsubscript{MOG-HEK})}) did not bind the corpus callosum, unlike IgG\textsubscript{MOG} adsorbed against untransfected HEK cells (IgG\textsubscript{MOG(Ads\textsubscript{HEK})}) (Figure 3B). To confirm that the MOG-IgG was responsible for the loss of LFB staining, the two adsorbed preparations were injected with \( C\textsubscript{hu} \) and mice were killed at seven days. Loss of LFB staining in the injected hemisphere was only found when IgG\textsubscript{MOG(Ads\textsubscript{HEK})} + \( C\textsubscript{hu} \) was used (Figure 3C).

MOG-IgG\textsubscript{2B7} causes loss of LFB staining largely independent of immune cells or complement activation

In case the amount of MOG-IgG in the patient preparations was insufficient to cause inflammatory cell infiltration, a large amount (20 \( \mu \text{g} \)) of the humanized anti-mouse MOG-IgG\textsubscript{2B7} was co-injected with \( C\textsubscript{hu} \). At seven days, MOG-IgG\textsubscript{2B7} + \( C\textsubscript{hu} \) caused loss of LFB staining, but without inflammatory cell infiltration (Figure 4A). At 24 hours after injecting MOG-IgG\textsubscript{2B7} + \( C\textsubscript{hu} \), there was faint C5b-9 immunoreactivity in white matter tracts suggesting slight complement activation, whereas injection of a monoclonal recombinant anti-AQP4 (AQP4-IgG\textsubscript{53}) + \( C\textsubscript{hu} \) caused strong perivascular C5b-9 immunoreactivity (Figure 4B). Moreover, intracerebral injection of MOG-IgG\textsubscript{2B7} without \( C\textsubscript{hu} \) produced loss of LFB staining at 24 hours similar to MOG-IgG\textsubscript{2B7} + \( C\textsubscript{hu} \) (Figure 4C).

MOG-IgG causes reversible damage to myelinated axons

At two weeks there was marked neuronal loss in IgG\textsubscript{AQP4} + \( C\textsubscript{hu} \) lesions compared to little neuronal loss in brains injected with IgG\textsubscript{MOG} + \( C\textsubscript{hu} \) (Figure 5A). We investigated the effect of IgG\textsubscript{MOG} + \( C\textsubscript{hu} \) on myelin and axonal proteins including myelin basic protein (MBP), neurofilament, ankyrin G (AnkG) and contactin associated protein (Caspr) (Figure 5B). MBP adheres adjacent cytoplasmic faces of myelin together, neurofilament provides structural support for axons, AnkG clusters voltage-gated Na\(^+\) channels at nodes of Ranvier [21] and Caspr attaches paranodal myelin loops to the axons [22]. At 24 hours after IgG\textsubscript{MOG} + \( C\textsubscript{hu} \) injection, MBP expression appeared abnormal (Figure 5C) and there was significant reduction in AnkG (Figure 5D) and Caspr (Figure 5E) immunoreactivities. At two weeks, the MOG-IgG + \( C\textsubscript{hu} \) induced changes in MBP, AnkG and Caspr had recovered and neurofilament expression was normal (Figure 5F), indicating intact axons.

Discussion

Although there is growing interest in the potential pathogenicity of MOG antibodies in NMO, the effects of NMO MOG-IgG have not been explored in vivo. Our results indicate that MOG-IgG directly damages myelin. The detrimental effects of MOG-IgG markedly differ from those of AQP4-IgG and are reversible (see Table 1).
AQP4-IgG lesions are characterized by astrocyte damage followed by leukocyte infiltration that entirely depend on complement activation [5]. We showed that recovery of myelin loss in AQP4-IgG lesions is limited, with gliosis and neuronal death. This finding may explain why clinical recovery after AQP4-IgG NMO attacks is often limited [7-9]. By contrast, MOG-IgG, as examined here, damages myelin and axons temporarily, with little complement activation, and no leukocyte infiltration. The myelin and axonal recovery and lack of neuronal death mirror the reported good outcomes of MOG-IgG NMO patients [10,11,15,16].

One study suggested that IgGMOG obtained from children with demyelination does not bind mouse MOG [23], but another study showed that human MOG-IgG binds mouse MOG [24]. Our IgGMOG samples obtained from adult NMO patients, and the anti-mouse MOG-specific monoclonal antibody, both recognized mouse MOG in frozen brain sections, and produced comparable LFB loss without inflammation. This discrepancy may be due to differences in MOG-IgG levels and specificity or differences in MOG glycosylation state, which plays a key role in MOG-IgG binding [24], between children and adults.

The effects of MOG-IgG on cultured oligodendrocytes have already been studied. MOG-IgG binds extracellular epitopes on MOG [23] and can cause crosslinking [25] and internalization [12] of MOG molecules and reversible retraction of oligodendrocyte processes [25]. At high concentration, MOG-IgG causes complement-mediated lysis of MOG-expressing cells [12]. Passive transfer of MOG-IgG antibodies exacerbates CNS damage in experimental autoimmune encephalomyelitis rodent models in which cellular immunity is the predominant pathogenic mechanism [26,27]. Using the intracerebral injection mouse model, we have shown unequivocally that NMO MOG-IgG directly damages myelin in vivo independent of pre-existing cellular immunity and complement.

MOG-IgG changed MBP architecture and reduced expression of axonal proteins. Caspr and AnkG are required for the integrity of the nodes of Ranvier and normal action potential firing [21,22]. Mice that lack MBP have a
characteristic motor dysfunction including tremor and seizures [28], mice that lack Caspr have severe motor paresis [22] whereas mice lacking cerebellar ankG develop progressive ataxia [21]. Therefore, the altered MBP expression and reduced Caspr and AnkG expression produced by MOG-IgG are predicted to produce a neurological deficit if the NMO lesion is in an eloquent region of the CNS. Unlike AQP4-IgG, MOG-IgG did not produce axonal disintegration or neuronal death. Given the 96% homology between mouse and human MOG [14], our findings raise the possibility that MOG-IgG may also cause similar reversible lesions in the human CNS.

MOG-IgG has been reported in other non-NMO diseases including multiple sclerosis, acute disseminated encephalomyelitis and even some normal subjects [29].

Does MOG-IgG from these non-NMO subjects also cause the same reversible CNS changes, as described here for NMO MOG-IgG? This question is difficult to answer at present because of the variety of assays used to detect MOG-IgG. For example, the assay used here, which employs C-terminal truncated rather than full-length MOG, did not detect MOG-IgG in adult multiple sclerosis patients and normal individuals [11], which suggests that different assays detect different subpopulations of MOG-IgG. It is important to first standardize the assays before determining which subpopulations of MOG-IgG can cause CNS damage and in which diseases.

The mechanism of MOG-IgG-induced myelin damage in vivo is unknown. Our data show that MOG-IgG – mediated myelin damage is a direct effect of MOG-IgG and that complement activation is not necessary. MOG-IgG binding may cause MOG conformational changes or internalization that disrupts the myelin structure and secondarily alters axonal protein expression. To explain the lack of complement involvement, we hypothesize that, after MOG-IgG binding, MOG might not aggregate (because of its low abundance) or MOG might become internalized (thus prohibiting C1q activation). The full recovery within two weeks of the MOG-IgG-induced LFB, MBP, ankG and Caspr changes suggests that MOG-IgG does not kill the oligodendrocytes, but causes a reversible damage.

Our findings raise the possibility that MOG-IgG contributes to pathology in some NMO patients. If MOG-IgG is pathogenic, antibody depletion (plasmapheresis) or suppression with steroids should be effective, as indeed appears to be the case [10,11,15,16]. Conversely, some of the newly proposed therapies for AQP4-IgG NMO, such as sivelestat for inhibiting neutrophils [17], or eculizumab for inhibiting complement [30], are less likely to be needed in MOG-IgG NMO. Examining lesions from MOG-IgG NMO patients may help elucidate the pathogenicity of MOG-IgG in the human CNS.

Figure 4 MOG-IgG2B7 causes loss of LFB staining largely independent of immune cells or complement activation. A. Adherent sections stained with H + E and LFB at seven days after injecting MOG-IgG2B7 + Chu. Green line shows loss of LFB staining. Rectangles show sites of Sections. B. Mouse brain immunostained for C5b-9 at 24 hours after injection of IgGCON + Chu, IgGMOG + Chu, or IgGAQP4 + Chu. Lu, lumen; wm, white matter. Weak (gray arrows) and strong (black arrows) immunoreactivity. C. Loss of LFB staining at 24 hours after injection of MOG-IgG2B7, MOG-IgG2B7 + Chu, or isotype control (CON-IgG2B4). 5 mice per group. Mean ± SEM. P < 0.05*, < 0.01**. Bar 50 μm (A bottom right, B), 200 μm (A bottom left), 1 mm (A top).
Conclusions

MOG-IgG obtained from neuromyelitis optica patients causes myelin changes and alters the expression of axonal proteins when injected in mouse brain. These effects are not associated with inflammatory cell infiltration, are largely independent of complement and recover within two weeks. AQP4-IgG obtained from neuromyelitis optica patients causes complement-mediated myelin loss, inflammatory cell infiltration, neuronal and astrocyte death with limited recovery at two weeks. These findings raise the possibility that MOG-IgG contributes to pathology in some neuromyelitis optica patients.

Table 1 Comparison of MOG-IgG with AQP4-IgG lesions in mouse brain

| Characteristic                     | MOG-IgG                  | AQP4-IgG                  |
|-----------------------------------|--------------------------|--------------------------|
| Target cell                       | Oligodendrocyte (myelin)| Astrocyte (foot process) |
| Lesion onset                      | Within hours of exposure to MOG-IgG | Within hours of exposure to AQP4-IgG |
| Effect on astrocytes              | No major effect (normal AQP4 and GFAP) | Astrocyte death (loss of AQP4 and GFAP) |
| Effect on neurons                 | No major effect          | Neuronal death (loss of NeuN, FJ-C staining [5]) |
| Effect on oligodendrocytes        | Change in myelin (loss of LFB) | Loss of myelin (loss of LFB) |
| Effect on axons                   | Myelin (transient change in MBP) | Permanent loss of myelin |
|                                  | Intact axons (normal nfil) | Axonal degeneration (β-APP expression [5]) |
|                                  | Node of Ranvier (transient change in casp and ankG) |  |
| Inflammatory cell infiltration    | No                       | Yes                      |
| Complement activation             | Slight (in white matter tracts) | Marked (perivascular) |
| Recovery                          | Yes, within 2 weeks      | No, pan-necrosis followed by glial scarring |

β-APP, beta amyloid precursor protein; FJ-C, fluorojade C; GFAP, glial fibrillary acidic protein; LFB, Luxol fast blue; MBP, myelin basic protein; NeuN, neuronal nuclear marker; nfil, neurofilament.

Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution
