Abstract

We present the first results from an XMM-Newton observation of RX J1347.5−1145 (z=0.451), the most luminous X-ray cluster of galaxies currently known, with a luminosity $L_X = 6.0 \pm 0.1 \times 10^{45}$ erg s$^{-1}$ in the [2-10] keV energy band. The cluster has an overall temperature of $kT = 10.0 \pm 0.3$ keV and is not isothermal: the temperature profile shows a decline in the outer regions and a drop in the centre, indicating the presence of a cooling core. The spectral analysis identifies a hot region at radii 50-200 kpc to south-east of the main X-ray peak, at a position consistent with the subclump seen in the X-ray image. Excluding the data of the south-east quadrant, the cluster appears relatively relaxed and we estimate a total mass within 1 Mpc of $1.0 \pm 0.2 \times 10^{15} M_\odot$.

Key words: Galaxies:clusters:particular:RX J1347.5−1145 ; X–ray:galaxies:clusters

1 Introduction

The cluster RX J1347.5−1145 detected in the ROSAT All-Sky Survey and further studied with ROSAT HRI and ASCA (Schindler et al. 1995, 1997) is exceptional in many aspects. It is the most X-ray-luminous galaxy cluster known (Schindler et al. 1995), it shows a very peaked X-ray emission profile and presents a strong cooling flow in its central region. Submm observations in its direction showed a very deep SZ decrement (Komatsu et al. 1999, 2001; Pointecouteau et al. 1999, 2001). Due to the presence of gravitational arcs, this cluster is also well suited for a comparison of lensing mass and X-ray mass. Optical studies of weak lensing have been performed by Fischer & Tyson (1997) and Sahu et al. (1998). Recent Chandra observations (Allen et al. 2002) discovered a region of relatively hot, bright X-ray emission, located approximately
20 arcsec to the south-east of the main X-ray peak at a position consistent with the region of enhanced SZ effect.

We present the first results from an XMM-Newton observation of RX J1347.5−1145, which was performed in July 2002 during rev. 484. Standard processing is applied to prepare data and reject the soft proton flares. The exposure times after cleaning are 32.2 ks for MOS1, 32.5 ks for MOS2 and 27.9 ks for pn. The background estimates are obtained using a blank-sky observation consisting of several high-latitude pointings with sources removed (Lumb et al. 2002). The background subtraction (for spectra and surface brightness profiles) is performed as described in full detail in Arnaud et al. (2002). The source and background events are corrected for vignetting using the weighted method described in Arnaud et al. (2001). RX J1347.5−1145 is at a redshift $z = 0.451$. With a Hubble constant of $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, and $\Omega_M = 1 - \Omega_\Lambda = 0.3$, the luminosity distance is 2506 Mpc and the angular scale is 5.77 kpc per arcsec.

2 Spectral analysis

![Fig. 1. Total (MOS+pn) XMM–Newton EPIC mosaic image of RX J1347.5−1145 in the [0.9-10] keV energy band. The image is corrected for vignetting and exposure and is adaptively smoothed.](image)

Since a morphological analysis indicates the presence of a substructure $\sim 20$ arcsec to the south-east (SE) of the X-ray peak (already revealed in previous observations with Chandra, Allen et al. 2002), we perform the spectral analysis for the data excluding the SE quadrant (hereafter undisturbed cluster) and for the full 360° data, separately. In both cases, the data are divided into the
annular regions shown in Fig. 1 and detailed in Table 1. A single spectrum is extracted for each region and then the data from the three cameras are modelled simultaneously using the XSPEC code, version 11.3.0. Spectral fitting is performed in the [0.5-8] keV band. The spectra are modelled using a simple, single-temperature model (MEKAL plasma emission code in XSPEC) with the absorbing column density fixed to the Galactic value \( N_\text{H} = 4.85 \times 10^{20} \, \text{cm}^{-2} \), Dickey & Lockman 1990). The free parameters in this model are the temperature \( kT \), metallicity \( Z \) (measured relative to the solar values) and normalization (emission measure). A typical simultaneous fit to the spectra extracted in each region is shown in Fig. 2. The best-fitting parameter values and 90% confidence levels derived from the fits to the annular spectra are summarized.
Table 1

The results from the spectral fitting in concentric annular regions for the undisturbed cluster and the full 360° data. Temperatures ($kT$) are in keV and metallicities ($Z$) in solar units. The total $\chi^2$ values and numbers of degrees of freedom (DOF) in the fits are listed in columns 4 and 7. Errors are 90% confidence levels.

| Radius (kpc) | SE sector excluded | full 360° |
|--------------|-------------------|----------|
|              | $kT$ | $Z$ | $\chi^2$/DOF | $kT$ | $Z$ | $\chi^2$/DOF |
| 0-115        | 8.9$^{+0.3}_{-0.3}$ | 0.34$^{+0.05}_{-0.05}$ | 982/880 | 9.2$^{+0.3}_{-0.3}$ | 0.31$^{+0.04}_{-0.04}$ | 1183/1026 |
| 115-230      | 10.7$^{+0.7}_{-0.6}$ | 0.26$^{+0.08}_{-0.08}$ | 696/664 | 11.4$^{+0.6}_{-0.5}$ | 0.25$^{+0.07}_{-0.07}$ | 970/855 |
| 230-345      | 11.9$^{+1.6}_{-1.3}$ | 0.16$^{+0.14}_{-0.15}$ | 433/384 | 11.8$^{+1.0}_{-0.8}$ | 0.24$^{+0.10}_{-0.10}$ | 610/564 |
| 345-520      | 10.7$^{+1.1}_{-1.0}$ | 0.24$^{+0.13}_{-0.13}$ | 350/341 | 11.4$^{+1.1}_{-0.9}$ | 0.27$^{+0.11}_{-0.11}$ | 471/493 |
| 520-690      | 9.0$^{+1.4}_{-1.1}$ | 0.16$^{+0.18}_{-0.16}$ | 239/210 | 9.4$^{+1.3}_{-1.0}$ | 0.21$^{+0.16}_{-0.16}$ | 372/300 |
| 690-1040     | 9.4$^{+2.1}_{-1.4}$ | 0.19$^{+0.26}_{-0.19}$ | 293/264 | 9.0$^{+1.5}_{-1.2}$ | 0.27$^{+0.20}_{-0.23}$ | 436/346 |
| 1040-1730    | 6.0$^{+2.6}_{-1.7}$ | 0.40$^{+0.50}_{-0.37}$ | 593/421 | 7.4$^{+3.6}_{-1.6}$ | 0.30$^{+0.42}_{-0.30}$ | 977/542 |
| 0-1730       | 9.4$^{+0.3}_{-0.3}$ | 0.26$^{+0.04}_{-0.04}$ | 1957/1452 | 10.0$^{+0.3}_{-0.2}$ | 0.26$^{+0.03}_{-0.03}$ | 2586/1679 |

In Table 1. The projected temperature profiles determined with this model from the data excluding the SE quadrant and for the full 360° data are shown in Fig. 3. The temperature of the undisturbed cluster rises from a mean value of 8.9 ± 0.3 keV within 115 kpc to $kT = 11.1 ± 1.0$ keV over the 0.1-0.5 Mpc region, then declines down to a mean value of 6.0$^{+2.6}_{-1.6}$ keV in the outer regions (1.0-1.7 Mpc). As a general trend, we note that the temperature of the undisturbed cluster is lower than that estimated from the full 360° data, even though consistent within the errors. The derived temperature profile indicates the existence of a cool core: even though the gas temperature in the central 100 kpc is hotter than that usually found in cooling core clusters, there is probably a much cooler gas in the very center, which cannot be resolved due to the relatively high cluster redshift. The metallicity profile is consistent with being constant, with an overall value of $Z = 0.26 ± 0.04 Z_\odot$. Within the radius of 1.7 Mpc, a fit to the full 360° data gives an overall $kT = 10.0 ± 0.3$ keV, $Z = 0.26 ± 0.03 Z_\odot$ and $L_X$ (2-10 keV) = $6.0 ± 0.1 \times 10^{45}$ erg s$^{-1}$.

In order to study in more detail the thermal structure of the cluster, we extract the spectrum in the annular region including the substructure identified by the morphological analysis and compare the results in different directions. A fit to the data for the SE quadrant between radii 50-200 kpc yields a best-fitting temperature $kT = 12.7^{+1.0}_{-0.9}$ keV, while in other directions the mean value is $kT = 10.2 ± 0.5$ keV. Therefore, the spectral analysis confirms that the region corresponding to the subclump seen in the X-ray image is significantly hotter than the surrounding gas.
Fig. 3. *Full circles:* the projected X-ray gas temperature profile measured from data excluding the SE quadrant (undisturbed cluster). *Dotted circles:* same as full circles, but from the full 360° data.

### 3 Spatial analysis and mass determination

We compute a background-subtracted vignetting-corrected radial surface brightness profile for the undisturbed cluster in the [0.3-2] keV energy band. The surface brightness profile is then fitted with a $\beta$-model (Cavaliere & Fusco Femiano 1976). We find that for 350 kpc - 1.7 Mpc the data can be described by a $\beta$-model with a core radius $r_c = 367 \pm 3$ kpc and a slope parameter $\beta = 0.93 \pm 0.01$. However, a single $\beta$-model is not a good description of the entire profile, as the fit to the outer regions shows a strong excess in the centre when compared to the model (see Fig. 4). The peaked emission is a strong indication for a cooling core in this cluster.

The total gravitating mass distribution is calculated under the usual assumptions of hydrostatic equilibrium and spherical symmetry using the deprojected density distribution calculated from the parameters of the $\beta$-model. Only data beyond 30″ (~175 kpc) are considered: in the central bins the temperature as estimated in Sect. 2 is affected by the *XMM* PSF and projection effects, while for the outer regions these effects can be neglected (e.g. Kaastra et al. 2004). Within 1 Mpc we find a total mass of $1.0 \pm 0.2 \times 10^{15} M_\odot$, while within 1.7 Mpc the total mass is $2.0 \pm 0.4 \times 10^{15} M_\odot$. These results are in agreement with *Chandra* (Allen et al. 2002) and weak lensing analysis (Fischer & Tyson 1997) results and slightly higher than that derived by *ROSAT*/ASCA (Schindler et
Fig. 4. Background subtracted, azimuthally averaged radial surface brightness profile for the data excluding the SE quadrant in the [0.3-2] keV range. The line shows the $\beta$-model fit to the outer regions. A clear excess in the center is visible.

4 Conclusions

The XMM-Newton observation of RX J1347.5−1145 confirms that it is, with a luminosity $L_X = 6.0 \pm 0.1 \times 10^{45}$ erg s$^{-1}$ (2-10 keV energy band), the most X-ray-luminous cluster discovered to date. RX J1347.5−1145 is a hot cluster (overall temperature: $kT = 10.0 \pm 0.3$ keV), not isothermal: the temperature profile shows the presence of a cool core and a decline of the temperature in the outer regions. The spectral analysis identifies a relatively hot region at radii 50-200 kpc to the SE of the main X-ray peak. This hot region is found at the same position as the subclump seen in the X-ray image. On the other hand, excluding the data of the SE quadrant the cluster appears relatively relaxed and we estimate a total mass within 1 Mpc of $1.0 \pm 0.2 \times 10^{15} M_\odot$.
