Abstract. The marl's minerals are abundant untreated material in several areas worldwide. They are often under-valued for human use. However, due to demands of the society in terms of sustainability and energy saving, the valuation of these resources to develop new materials, most environmentally friendly has become a concern both scientific and industrial aims. Ceramics are the growing research to obtain materials with good chemical stability and good hot properties [1]. The balance between these properties and industrial requirements allowed clay materials uses at craft departure (pottery, tile), to progress towards high-tech applications such as electrical and thermal insulation, electric candle, sound insulation [2]. The behavior of the doping (Al₂O₃), which has more scientific research interest, has been a renewed interest since 1980 [3] with the emergence of alumina very high purity. Miocene marl is one of the widespread geological substrates in Fez-Taza vicinity (Central Morocco). In this study we proceed by a physicochemical characterization of the marl after doping with metal oxides, by various analytical techniques, namely the X-ray fluorescence, the mineralogical analysis and geotechnical test. The doping of these marl was conducted by solid oxides of Al₂O₃ at different percentages (5%, 10% and 15%). The results of chemical analysis showed the Al₂O₃ increase during doping. So, the mineralogical analysis of doped clays shows peaks’ increases for kaolin. The marl doped acquired the property of their good plasticity and good mechanical resistance compared to crass marl.

Index Terms. Clay, Pozzolan, Doping, Chemical, Geochemical, Mechanical characteristic.

1. Introduction
In Morocco, a well-developed mining activity since the beginning of this century has allowed Moroccan citizens to acquire know-how in the areas of operations and mineral exploration. This was accompanied by the necessary infrastructure development in the implementation and development of this activity [1]. In particular, The Miocene clay substrates are abundant in the region of Taza, yet they remain insufficiently valued. However, considering the new demands of the society in terms of sustainable
development and energy conservation, recovery of the clay and its use in building materials may be more environmentally sustained and become a scientific and industrial concern.

Ceramics are the growing research to obtain materials with good chemical stability and good hot properties [3]. The balance between these properties and industrial requirements allowed clay materials uses at craft departure (pottery, tile), to progress towards high-tech applications such as electrical and thermal insulation, electric candle, sound insulation, etc [4]. The behavior of the doping (Al₂O₃), which has more scientific research interest, has been renewed interest since 1980 [5] with the emergence of alumina very high purity. The present study focuses on the influence of doping on the microstructure of marl, based on the results obtained by X-ray fluorescence and X-Ray.

In this perspective, the doping of the marl clays with alumina oxide could increase the added value of the clay used in the technology and building industry [6].

One of the major problems encountered by users of these materials is the fragility and high shrinkage induced by cookery causing defects in the briquette [7], and can go until it bursts. To improve performance, efficiency and the quality in the manufacture of this marl, we opted doping dry voice of these materials by the alumina oxide it has considering percentages of 5, 10 and 15%.

The findings allow us to conceive and suggest new improvements of the physicochemical and mechanical parameters for marl, to rise the value and use of this low cost material.

2. Materials and Methods

2.1. Materials

The basic raw material is a clay marl Miocene the region of Taza (Figure 1) which outcrop in the eastern area of Taza (Figure 2).

The importance of clay-based materials in the ceramic industry is due to their plastic properties [8] allowing final ceramic products to retain their shapes after firing. The process is complex because usually the shaped product depends on the mineralogical composition of the raw material and the nature and quantity of impurities in clay.
Figure 1. The location and geological map of Fez-Taza area (Morocco).

Figure 2. Geological cross section of South Rif (DRH et ONI, 1971-1977).
2.1. Preparation of composite clay / Alumina oxide

The Al$_2$O$_3$/clay system was achieved by solid route at room temperature. The doping ranged from 5%, 10%, to 15%. The implementation of composite clay / Alumina oxide, consisted of, first, a 20-minute grinding our base material, then a direct mixture in the solid state of the clay with the oxide of alumina, different percentages of 5, 10 and 15%, and grinding in a ball mill for 20 minutes agate. It allows obtaining homogeneous powders relatively fine-grained and narrow particle size distribution and that at room temperature.

2.3. Methods

In the aim to study the homogeneity and the concentration of Al$_2$O$_3$ incorporated in the clay sheets, several analysis techniques were used:

- Chemical analysis: the quantitative chemical analysis of clays was performed by X-ray fluorescence spectrometry (WD-XRF) spectrometer type Axios sequential brand Panalytical. This analysis was made after grinding the material and taking 10 g of each sample. Then we took 10g of each powder sample and pressed it in a hydraulic press, in order to make the pellets.
- X-ray diffraction DRX study was done with the Philips diffractometer XPERT-PRO” PW 3064, with the Kα1,2 radiation of copper. X-ray diffraction (XRD) data were obtained using oriented samples prepared on glass slides in the 2θ range of 2–40° at a scanning speed of 2° min⁻¹.
- The geotechnical property was performed in the laboratory of geosciences and environment at the FST (Sidi Mohamed Ben Abdellah University). The evaluation of plasticity was performed by the Casagrande method. The Atterberg limits are conventional physical constants indicating the clay transition from plastic to liquid state (WL) and from the plastic to solid state (WP). The plasticity index, which represents the difference between the liquid limit and plastic limit, defines the extent of the plastic field of clay.
- Bricks production is carried out using a metal mold, provided for the operation. It has a length of 50 mm and a width of 10mm. Bricks are previously dried in the open air until the stabilization of the withdrawal. They are fired in electric oven programmable to the temperatures of 900°C, with a bake cycle of 30 minutes and a bearing of one hour and a half to the maximum firing temperature. The rate temperature of firing rise 10°C/min.

The parameters resulting from the bricks firing are observed as the materials withdrawal along drying and firing, the ignition loss, and the mechanical resistance to flexural strength.

3. Results and Discussion

3.1. Chemical analysis

We note that the predominant components in all samples are silica and alumina, respectively, for the raw clay and doped (Table 1).

The easiest way to determine the influence of a doping is to make measurements of essay material doped before and after doping. Thus, analysis of the chemical composition by XRF clays doped with Al$_2$O$_3$, reveals a significant enrichment in alumina. Its concentration increases as the doping level is increasing.

Table 1. Percentage major elements of our crude marl (T1) and doping with Al$_2$O$_3$.

| Sample           | SiO$_2$ | Al$_2$O$_3$ | CaO   | Fe$_2$O$_3$ | MgO  | K$_2$O | Na$_2$O | TiO$_2$ |
|-----------------|---------|-------------|-------|-------------|------|-------|---------|---------|
| T3 Brut         | 47      | 13.3        | 7.63  | 6.13        | 2.71 | 0.92  | 0.92    | 0.31    |
| T3 doped with 5%| 45.3    | 16.5        | 7.06  | 5.93        | 2.13 | 0.86  | 0.92    | 0.31    |
However, doping causes a slight decrease in some major element remains. It is varying quantitatively. There is also an increase in the content of alumina oxide in combination with increasing doping content (5.10 and 15%). Its exceeds twenty percent (20%).

2.2. Mineralogical analysis

The mineralogical analysis of crude and doped samples by Alumina at different percentages (5, 10 and 15%), shows that kaolin, illite, quartz, dolomite and calcite are the main crystalline phases (Fig. 3). The increase of the peak intensity of the kaolin doped marl can be explained by the incorporation of alumina in the silica tetrahedral site (Fig. 4). So, the intensity of the highest peak is manifested by a 15% Al₂O₃ doped marl. Furthermore, there is thus a continuous and positive correlation between increasing the Al₂O₃ content of the doping and the elevation of the peak intensity (Fig. 4). This result is conform with the results of chemical analysis.

Figure 3. X-Ray of crude marl T3 before and after doping with oxide alumina at different percentages 5, 10 and 15%. With: K = kaolin, Q = quartz, I = illite, C = calcite, D = dolomite.
3.2. Technological testing (Atterberg limits)

Based on the results of Table 2, we note the raw material T3 has an average plasticity later increase with the level of doping. However the greater plasticity is observed in the doped marl with 15% alumina.

Table 2. The Results of Plasticity Analysis and Water Content in the Samples.

| Sample             | Liquid Limit (Wl) | Plastic Limit (Wp) |
|--------------------|-------------------|--------------------|
| T3 Brut            | 45.65             | 18.59              |
| T3 doped with 5%   | 50.07             | 23.90              |
| T3 doped with 10%  | 46.74             | 22.30              |
| T3 doped with 15%  | 46.86             | 27.94              |

3.3. Effect of Firing

During the rise of the firing temperature, the physicochemical transformations of the phase’s marls affect the material (Fig.5). Each mineral in the mixture behaves as if it was alone. The decomposition products or new structural varieties, which take place under the influence of heat, react together to form new compounds [9].

Figure 4. X-Ray comparison of peaks intensity of Kaolin between crude and differently doped marls.
However, upon baking, the initial crystalline minerals disappeared and make space in varying proportions to an amorphous phase and new minerals [10]. Shrinkage accompanies this solid reaction, and is associated with changes in porosity and particle size. The proportions of the clay phase and/or associated minerals play an important role in these changes as well as the particle size removing charged in the raw material is very important. This is due to the expansion case by new neoformed minerals.

In this study all doped materials has attended a withdrawal reduction until its cancellation. Therefore be concluded the doping plays a role in limiting internal withdrawal.

### 3.4. Mechanical properties

The marl doped 5% of Al₂O₃ have a relatively high resistance up to 25 KN compared with bricks doped 10% and 15% Al₂O₃ (Fig.6). We find that the effect of doping alumina is obvious. Indeed, the higher content of doping increasing the mechanical strength of bricks decreases.

This resistance is in fact related to the increase of the porosity induced by the increase of the content of the doping. This causal relationship is in full agreement with the results obtained in the study of the porosity of the bricks.

**Figure 5.** Evolution the withdrawal of raw samples and doped according to the firing temperature.
Figure 6. The Firing Impacts on the samples characteristics: loss on ignition and compression strength for the temperature 900°C.

4. Conclusion
The results of chemical analysis showed the higher rate of Al$_2$O$_3$ doping increases, its content increases in the marl.

Mineralogical analysis indicated the presence of illite and kaolin clay minerals such as essential clay. The intensity of kaolin peaks increase with increasing doping level. This can be attributed to the combination of alumina with free silica of kaolin.

Technological tests showed suitable industrial properties of these marls, their doping with aluminum oxide induced an increase in their plasticity. The alumina acts as a degreaser and decrease shrinkage. However, the withdrawal response is correlated with the content of Al$_2$O$_3$ doping. Indeed, the degreaser plays the role of internal framework and limits the withdrawal.

The mechanical resistance of the doped bricks marl is independent of quantity Al$_2$O$_3$ doping. The marl doped with 5% Al$_2$O$_3$ have a relatively high resistance compared with bricks doped with 10% and 15% Al$_2$O$_3$. So, additional content of doping decreases mechanical strength of bricks. This resistance is in fact related to the increase of the porosity induced by the increase of the content of the doping. This causal relationship is in full agreement with the results obtained in the study of the porosity of the bricks. The bricks of marls fired at 900°C and doped with 5% gives better mechanical strength of up to 25 kN. So, suggesting the use of this composite in ceramics, in construction and in pottery.
