Effects of nitrogen loading under low and high phosphorus conditions on above- and below-ground growth of hybrid larch F₁ seedlings

Saki Fujita (1), Xiaona Wang (2), Kazuhito Kita (3), Takayoshi Koike (4)

Under present environmental conditions, hybrid larch F₁ (Larix gmelinii var. japonica × Larix kaempferi) is a promising afforestation species as it has a high growth rate and tolerance against grazing damage, disease and cold. However, the input of nitrogen (N) to forests due to the increase of anthropogenic N is causing imbalances of N compared to other nutrients, especially phosphorus (P), thus affecting the root growth of healthy seedlings. However, knowledge on how different N and P conditions affect F₁ root growth is still limited. In this study, various N (3 levels) and P (no addition and addition) conditions were imposed to investigate the effect of N loading on larch F₁ seedlings under different P conditions. Needle N: P ratio, aboveground growth, belowground growth as well as fine root production were measured. The results showed that needle N: P ratio was higher under low P loading, and aboveground growth of seedlings increased with N loading at both low and high P conditions. Relative fine root production was decreased by N loading. On the other hand, fine root to total dry proportion was increased by N loading at no P addition, suggesting that limited P availability could increase fine root production. Total root proportion to total dry mass was decreased by N loading at both P conditions. We concluded that N loading has different effects on above- and below-ground growth of larch F₁ and its effects may also differ according to P conditions, indicating that both N and P conditions should be carefully considered when planting hybrid larch F₁.

Keywords: Nitrogen Deposition, Phosphorus, Fine Root Production, N: P Ratio, Hybrid Larch F₁.

Introduction

The genus Larix is largely distributed over cool temperate regions in the northern hemisphere (Gower & Richards 1990, Abaimov et al. 2002). Among the Larix species, Japanese larch (Larix kaempferi) is especially known for its high growth rate (Matyssek & Schulze 1987) and is an important afforestation species across the northern hemisphere, especially in the east Eurasian regions (Ryu et al. 2009). However, problems such as low tolerance to vole feeding and shoot blight disease have raised concerns (Koike et al. 2000, 2004). To address these concerns, hybrid larch F₁ was developed by intercrossing Dahurian larch (Larix gmelinii var. japonica) and Japanese larch. As a result, F₁ not only shows high tolerance to vole feeding and shoot blight disease but also has a higher initial growth rate and high capacity for carbon absorption under present environmental conditions such as CO₂ concentration, temperature, rainfall etc. (Miyako 1990, Kita et al. 2009, Ryu et al. 2009). As the Larix species is broadly distributed across east Eurasian regions (Abaimov et al. 2002), F₁ is one of the promising new afforestation species for CO₂ fixation, storage and timber production. Therefore, it is important to investigate the F₁’s growth under changing environmental conditions, as the increase of nitrogen (N) deposition which alters soil nutrient conditions.

Anthropogenic N has been drastically increasing at a global level since the industrial and agricultural revolution, and various studies have focused on its effects on forest ecosystems (Aber et al. 2003, Galloway et al. 2004, 2008, Matyssek et al. 2012). Since the growth of boreal forest ecosystems are reported to be limited by soil N (Vitousek et al. 2002), N input may increase plant growth to some extent. However, N saturation and negative effects have also been reported (Aber et al. 1989, Magill et al. 2004). Plant growth can also be limited by other elements such as phosphorus (P). P limitation has been observed in immature volcanic ash soil (Vitric Andisols), which show strong P retention (Takahashi & Shoji 2002). Therefore, increase of N deposition under Vitric Andisols may cause imbalances in soil N and P, and simultaneously induce P limitation (Vitousek et al. 2010) which may potentially have negative effects on plant growth. The literature review by Peñuelas et al. (2015) reported that N deposition (or N loading) has indirect effects on plants by causing alteration to the N: P ratio. Several other studies have observed that N: P ratio of foliage correlates negatively with net photosynthetic rate (Reich & Oleksyn 2004), plant growth (Elser et al. 2010) and biomass production (Güsewell 2004). As N loading may be one approach to address N deposition effects, Qu et al. (2003)
reported detrimental effects of N loading on root growth and biomass of larch F. seedlings by conventional and exponential fertilization methods. Indeed, high N loading decreased root length and surface, which resulted in decreased shoot development. Moreover, they noted that when enough N is available for seedlings, aboveground growth was prioritized over belowground growth. Mao et al. (2014) investigated the effect of N loading on 2-year-old F. seedlings at low soil P conditions to evaluate P limitation induced by N increase. However, when their hypotheses were tested, N loading had the same increasing effect on growth at both low and high P conditions in forest brown soil (Dystric Cambisols). Mao (2013) found that both N and P loading increased the surface area of fine roots in Vitric Andisols (low nutrient condition soil). As fine roots play the role of absorbing nutrients and water, fine root growth is vital for seedling survival and drought tolerance. Furthermore, fine roots are also strongly influenced by nutrient availability (Burton et al. 2000), and can be easily altered by changes in N and P conditions.

Materials and methods

Plant material and soil conditions

Thirty-six hybrid larch F, (Larix gmelinii var. japonica × Larix kaempferi) seedlings produced at the Hokkaido Forestry Research Institute (Bibai, Japan) were used. In 2012, the 2-year-old seedlings were taken out of a stock room and planted in 30 L pots filled with Akadama soil and Kanuma pumice soil at a volume ratio of 1:1. This soil mix was then transferred to 44 L pots with the same soil mix to prevent their roots from becoming pot-bound (pot effect). Seedlings were grown at the experimental nursery of Hokkaido University (43° 07′ N, 141° 38′ E, elevation 15 m a.s.l.) under natural (open air) conditions. Annual average precipitation was 1274.5 mm and 1360.0 mm in 2015 and 2016, respectively, while annual average temperature was approximately 10 °C and 3 °C, respectively, as measured at the Sapporo Regional Headquarters (JMA: 43° 03′-6′ N, 141° 38′ E, elevation 19.7 m a.s.l.). When there was no rainfall for a week, seedlings were irrigated until the pots were fully watered. The snow free period is from mid-November to late April. The accumulated snow depth is approximately 1.2 m during mid-January to early March.

Loading treatments

To investigate the effects of N deposition at low and high P conditions, 3 levels of N and 2 levels of P were imposed (Mao et al., 2014). The loading treatment begun in 2012 and continued until 2016 (4 years). The 3 N levels were: 0, 50 and 100 kg N ha⁻¹ yr⁻¹ and were labeled as N₀, N₅₀, N₁₀₀, respectively. N₀ treatment simulates the typical estimation of N deposition at Asian regions (Nakaji et al. 2001, Galoway et al. 2003) and the N₁₀₀ treatment reflected an excessive N loading. Regarding P loading, the high treatment was set at 50 kg P ha⁻¹ yr⁻¹ (hereafter: P₅₀) with reference to common agricultural practices, while 0 kg P ha⁻¹ yr⁻¹ was set as low P treatment (hereafter: P₀). Six different treatments were obtained by combining the three N with the two P levels, which were labeled as following: N₀P₀, N₅₀P₀, N₁₀₀P₀, N₀P₅₀, N₅₀P₅₀, and N₁₀₀P₅₀ (control). There were 6 seedlings in each treatment for a total of 36 seedlings. Kanuma soil and Akadama soils have almost no nutrients, thus Hyponex® fertilizer (N: P: K = 6:1:0.5; Mg: 0.05%, Mn: 0.01%, B: 0.05% - HYPOXet® NEX, Japan, Japan) was added in 2015 as top dressing in mid-May and at the end of June with 1000× dilution by deionized water. By Hyponex addition, 12.5 kg N ha⁻¹ and 21.1 kg P ha⁻¹ yr⁻¹ was added. The amount added by Hyponex was subtracted from the N and P loading in 2015. However, when Hyponex was given to all seedlings, treatments N₀ received 12.5 kg N ha⁻¹ yr⁻¹ and treatments P₀ received 21.1 kg P ha⁻¹ yr⁻¹ in 2015.

Ammonium nitrate (NH₄NO₃) was used as nitrogen source to simulate N deposition from acid rain and aerosols in Japan (Kaneyasu et al. 2014), while monopotassium phosphate (KH₂PO₄) was used as P source. Both were dissolved and given with 500 mL of deionized water. In Hokkaido, a considerable amount of N is released from snowmelt, therefore N was applied 3 times at a ratio of 2:1:1 (100 kg N ha⁻¹ yr⁻¹: 50, 25, 25 kg N ha⁻¹ yr⁻¹; 50 kg N ha⁻¹ yr⁻¹: 25, 12.5, 12.5 kg N ha⁻¹ yr⁻¹) in mid-June, mid-July and mid-August. As for P, it was applied 3 times at a ratio of 1:1:1 (16.7, 16.7, and 16.7 kg P ha⁻¹ yr⁻¹) at the same time as N. In 2016, N and P were applied in 4 times at a ratio of 2:1:1:1 for N (100 kg N ha⁻¹ yr⁻¹: 40, 20, 20, 20 kg N ha⁻¹ yr⁻¹; 50 kg N ha⁻¹ yr⁻¹: 20, 10, 10, 10 kg N ha⁻¹ yr⁻¹) and a ratio of 1:1:1:1 for P (12.5, 12.5, 12.5, 12.5 kg P ha⁻¹ yr⁻¹). This was to shorten the time between N and P applications and to prevent N and P from being washed away with rain as much as possible. Large plates were also placed under the pots to prevent leaching.

Sampling and analysis

Aboveground

To examine needle N and P concentrations, a small proportion of needles located at the top part (i.e., elongation shoot and its branches) of all 36 seedlings were randomly collected before and after N and P loading treatments (2015: May 25 and September 3; 2016: June 12 and August 15). The sampled needles were dried at 70°C for 72 hours. Leaf litter was also collected on December 15, 2015 and November 12, 2016 by covering each whole seedling with a litter trap made with 1 mm mesh net, as described in Miyaura & Hozumi (1988). Traps were placed in mid-October of each year, right after the needles began to change color. The litter collected in 2015 was also used as total needle biomass. Collected leaves were dried at 70°C for 72 hours, and then weighed.

Needle N concentration was measured with a NC analyzer (ELAN 6000, PerkinElmer, Waltham, MA, USA) and the inductively coupled plasma-mass emission spectrometer ICPAES® (IRIS/IRIS Advantage ICAP, Thermo Fisher Scientific Inc., MA, USA) was used to measure needle P concentration. Needle P ratio was calculated by dividing needle N concentration by needle P concentration (eqn.1):
Effects of nitrogen and phosphorus on larch seedlings growth

where $M_i$ and $M_n$ are the values measured at time $t$ and $t-1$, respectively.

The aboveground biomass was measured in September 2016 by harvesting the 4 tallest seedlings in each treatment. The selection of the four more robust seedlings from each treatment was done to avoid any bias related to possible mechanical injuries suffered by seedlings due to the heavy snowfall occurring in the experimental area (see above).

The aboveground biomass was separated into stem, branch and needle components. Each component was dried at 70 °C for 72 hours, and then weighed. The other 12 seedlings were not harvested until mid-November after collecting leaf fall.

**Belowground**

Fine roots were measured in 2015 by soil core samples (Mao 2013). Two soil cores from each pot were taken, and the fine roots inside the soil core were measured. Soil cores were approximately 30 cm deep and 3 cm in diameter (Daiki Co. Ltd, Tokyo, Japan), taken in symmetrical directions, approximately 10 cm away from the stem. The fine root sampling was done 5 times in 2015 (June 26, July 30, September 3, October 3 and November 4). Each soil sample was approximately 1% of the total pot volume. Circular plastic tubes were placed at the sampling locations in the pots, so that samplings could be carried out at the same place every time. The holes made after the sampling were refilled with similar conditioned soil. Using this procedure, the fine root biomass obtained from the soil cores reflected the fine root production between the sampling dates except the first sampling (June 26, 2016). The soil cores were carefully washed with water and a brush. They were scanned with a scanner (CanonScan LIDE 200®, Canon, Japan), dried at 70 °C for 72 hours, and then weighed. The root analysis software WinRHIZO TRON® 2012a (Regent Instruments Canada Inc., Canada) was used to measure root length (cm). Specific root length (SRL) was calculated for the total sampling core according to Ostonen et al. (2007).

Roots were harvested after the aboveground harvest in September 2016 (4 seedlings per treatment). Roots were divided into coarse (> 5 mm) and fine roots (< 5 mm), dried at 70 °C for 72 hours, and then weighed.

We calculated the relative fine root production (FRP, g g⁻¹) from the total fine root production and the estimated total root biomass of 2015, as follows (eqn. 3):

$$FRP = \frac{T(\text{frp})}{E(\text{trb})} \quad (3)$$

where $T(\text{frp})$ is total fine root production of 2015 (initial sampling excluded), and $E(\text{trb})$ is the estimated total root biomass of 2015. $E(\text{trb})$ was calculated from the relationships between stem basal diameter, aboveground biomass and belowground biomass (Fig. 1a, Fig. 1b) obtained from harvest measurement data of 2015 and 2016. Data of 2015 was obtained in spring 2015 from 19 additional seedlings ($n = 24$ for each treatment) which were subjected to the same N and P treatment, but were not included in the main experiment. The data of 2016 were obtained from the sampling material harvested in September (4 tallest seedlings in each treatment). To estimate total root biomass of NoP0 (control), data from 2015 was used. This was because the height for NoP0 was significantly small and did not fit the regression line made with the data used in 2016. For the rest of the treatments, harvest data from 2016 were used.

**Statistics**

A fully randomized scheme with 3 levels of N (0, 50, 100 kg N ha⁻¹) and 2 levels of P was adopted in this study. Two-way ANOVA ($n=36$, except litter: $n=12$) was used to evaluate the effect of N, P, and their interaction on aboveground growth, fine root production and nutrient condition. Biomass was evaluated using data from the 24 robust seedlings harvested in autumn 2016. All measurements were done once, except the measurement of stem basal diameter which was the average of 2 measurements. Regarding the litter, since there were only 12 seedlings in total (2 seedlings per treatment), we measured 2 samples per seedling for measurement robustness. All analysis was done using R ver. 3.2.2, except the regression analysis, which was carried out using the software package Microsoft EXCEL 2013®.

**Results**

**Aboveground**

Needle N, P concentration and needle N:P ratio were measured to evaluate nutrient conditions of larch seedlings (Tab. 1). Both in 2015 and 2016, N loading increased the N concentration in needles for both P50 and P0 treatments. In 2016, needle N concentration was higher at P0 treatment. In both 2015 and 2016, needle P concentration was higher in seedlings subjected to P50 treatment than under the P0 treatment. In 2015, significant effects of N and P loading on needle N: P ratio were detected ($p < 0.10$), with values generally lower for seedlings grown under the P50 treatment. In 2016, only P had a significant effect and the needle N: P ratio was significantly higher for the P0 seedlings. Litter N concentration was significantly lower than needle N concentration of growing season needles. However, in N0P0, the litter N concentration was significantly higher compared to other treatments in both years (2015 and 2016).

N and P had similar effects on aboveground growth of seedlings (Fig. 2a, Fig. 2b, Tab. 2). Final height was increased by both N and P loading. Total height growth rate of 2015 was affected by both N and P loading, and N and P showed a significant interaction effect. Total growth rate of 2016 was overall smaller than that of 2015, and was significantly affected by N addition. Final stem basal diameter (SBD) was increased by both N and P. Concerning SBD growth rate of 2015, N had an increasing effect. In 2016, N loading had a significant decreasing effect on all seedlings, except those of the NoP0 treatment.

---

**Tab. 1** - Mean value (±SE) of each treatment on needle N concentration, needle P concentration, needle N:P ratio and litter N concentration (n=6 for each treatment, litter N concentration; n=2, 2 measurements per seedling) of 2015 and 2016. N0, N50 and N100 represent the different N loading treatments (No: 0 kg N ha⁻¹ yr⁻¹, N50: 50 kg N ha⁻¹ yr⁻¹, N100: 100 kg N ha⁻¹ yr⁻¹). P0 indicates treatments without P loading (0 kg P ha⁻¹ yr⁻¹), while P50 represents treatments with P loading (50 kg P ha⁻¹ yr⁻¹). p values (F values in brackets) of two-way ANOVA are also shown. (***): p < 0.001; (**): p < 0.01; (*): p < 0.05; (ns): not significant.

Total biomass, stem biomass, branch biomass and needle biomass of seedlings showed a significant increase after N and P loading (Tab. 3). Also, a significant interaction between P and N addition was detected on leaf and stem biomass.

N and P had different effects on proportion of stem, branch and needle biomass to total dry biomass (Tab. 4). Stem proportion was increased by N loading. An interaction effect was also observed. The proportion of branch and needle biomass over the total seedling biomass was increased only by N loading.

Belowground

Treatments with N and P loading showed larger fine root biomass values from core samples compared to treatments with no N or P (Fig. 3). This is because seedling size differed according to the different N and P conditions, and so the initial sampling results from core sampling also differed. Similar results were observed throughout the season. There was a severe decrease of fine root in between the first and the second core sampling, likely due to the fact that all fine roots at sampling points in the pots were removed with the first sampling. However, at the next sampling dates fine root production showed a slight trend with two peaks, one in later summer and another in late autumn (Fig. 3), though large differences existed among different treatments.

As shown in Fig. 4a and Tab. 5, N loading decreased relative fine root production and this was especially observed at P0. SRL was not affected by neither N nor P loading (Fig. 4b, Tab. 5). Seedlings subjected to N loading showed an increased needle: fine root biomass ratio in the P50 treatments, however, N loading did not show any significant effect on the above ratio at P0 SRL.

Both fine and coarse root biomass of seedlings were increased by both N and P loading (Tab. 3). Furthermore, there were no significant effects of N and P loading on coarse root biomass.

![Fig. 3 - Seasonal change of fine root production, including the initial value (sampled on 6-25.2015). N0 (dotted lines), N50 (dashed lines) and N100 (solid line) represent the different N loading treatments (N0: 0 kg N ha−1 yr−1, N50: 50 kg N ha−1 yr−1, N100: 100 kg N ha−1 yr−1). Po (gray) represents treatments without P loading (0 kg P ha−1 yr−1) and P50 (black) represents treatments with P loading (50 kg P ha−1 yr−1). Measurement dates are reported on the horizontal axis. Effects of nitrogen and phosphorus on larch seedlings growth

N100P0 and N50P0, since negative effects of N loading on height and stem basal diameter growth rates were observed in 2016 (Fig. 2a, Fig. 2b). Nitrogen limitations may have also simultaneously occurred where the nutrient content in 2016 was not enough to support seedling growth after transplantation in 2015. Furthermore, as loading treatment was applied for as much as four years, continuous loading may have altered plants nutrient demand in N and P (Braun et al. 2010). Needle P concentration was also lower in 2016 and so N loading may have caused P deficiency, and consequently, shortage of P may have decreased aboveground growth in 2016 compared to 2015. Our results showed that N loading tends to increase the aboveground proportion of the total seedling biomass, especially at P50. It can be assumed that when N availability is high, seedlings have enough nutrients to support aboveground plant activities such as photosynthesis and so investments to the aboveground is prioritized instead of belowground. If this is so, N loading may induce imbalances between above- and below-ground growth.

Belowground

Regarding the seasonal changes of fine root production obtained from soil core samplings, a slight trend of two growing peaks was observed. This result was also observed by Satoh (1995), although the latter growing peak was relatively later in the autumn. This was especially seen in high N loading treatments. Therefore, the favorable nutrient condition of N and P may have prolonged the growing season of fine roots. N loading decreased relative fine root production of seedlings under the P0 treatments. Our starting hypothesis was that at P50 fine root production would decrease more than in the P0 treatments. In our experiment, treatments other than NoP0 had relatively low relative fine root production values. Therefore, P may have not been the limiting factor for fine root production and N was the determining factor in 2015. Fine root production may have been enhanced by seedlings grown at NoP0 (low nutrient conditions) to absorb more nutrients. Both N and P loading did not affect SRL in our experiment. On the other hand, N loading increased total root biomass, including both coarse roots and fine roots at both P conditions. This biomass increasing effect of N loading is consistent with other research results (Nadelhoffer 2000, Tingeey et al. 2000). It can be hypothesized that seedlings were not experiencing P deficiency and root growth was promoted to support aboveground growth.

We found that seedlings with high needle N: P ratio allocated less biomass to roots compared to seedlings with low needle N: P ratio (Tab. 4). This trend has also been reported by previous research (Güsewell 2004). Similarly, total root proportion was significantly higher at NoP0 than at N100P0 treatment, and NoP50 was higher than N100P0. High root proportion under low P conditions has also been reported in previous studies and has shown that P deficiency enhances fine root growth for efficient P absorption (Lynch 1995, Lynch & Brown 1998, Gilroy & Jones 2000). In our study, seedlings subjected to the P0 treatments may have been experienced a P deficiency. Under high P conditions, fine root proportion was decreased by N loading. On the other hand, under low P conditions, the fine root proportion increased at N50, although decreased at N100. Therefore, under high N and P conditions fine root proportion was decreased. At low P conditions, N loading may only have increasing effects up to a certain extent, while an excess of N loading may have decreased fine root proportion in fine seedlings. Needle: fine root biomass ratio was significantly higher under N loading at P50 treatments, indicating that more investments were made to the aboveground growth. This result was in agreement with previous studies where sufficient availability of water and nutrients result in smaller amounts of fine roots and a smaller percentage of assimilates is transported to roots (Erisman et al. 1998). This phenomenon could also decrease the seedling’s tolerance to other stress such as drought, since roots have the vital role of absorbing not only nutrients but also water (Hodge et al. 2009). At Po treatments, N did not increase needle: fine root biomass ratio, so it can be speculated that investments were made to fine roots as well as needle production. The core sampling method may not be fully suitable to accurately evaluate fine roots, as the amount of soil sampled was relatively small compared to the total root biomass (% of the total pot volume). To accurately evaluate fine root growth using soil core samples, more samplings are needed and more soil volume should be explored, though this could damage the root system and cause a decline in overall seedling growth. Using the in-growth method in parallel to core samples, may have increased the accuracy of fine root evaluation without harming the seedling. Evaluation of fine roots is strongly altered by the methodology (Nadelhoffer 2000), therefore more improvements of fine root measurement methodologies and techniques, such as a non-destructive Mini-rhizotron (MR-fine root observation tubes) method (Wang et al. 2016) could increase the accuracy of estimations.

Conclusion

N loading had different effects on above- and below-ground growth of hybrid larch F. seedlings. Although, aboveground growth was increased by N loading under both low and high P conditions, belowground growth was suppressed. This could affect seedlings’ tolerance or susceptibility to other stress, such as drought, since roots have the vital role of water absorption. Root growth of F. could be altered by increasing N deposition under low P soil conditions. Furthermore, high N loading at low P conditions altered litter quality. This could indirectly accelerate the input of N to soils. To efficiently use larch F, as an afforestation species, considerations should be taken on the location of plantation site, related to imbalances in N and P conditions, especially high N loading at P deficient soils.

Acknowledgements

We thank Dr. Ivano Brunner of WSL of Switzerland for helpful discussion and comments on the manuscript. We are grateful to Dr. Cong Shi, Mr. Testuto Sugai and Dr. Eugenios Agathokleous of Hokkaido University for constructive discussion. Gratitude is also given to Dr. Toshiyuki Hirata and Dr. Yoshitaka Uchida of Hokkaido University for the use of the NC Analyzer. We thank Dr. Toshihiro Watanabe of Hokkaido University for the use the ICP Analyzer and Dr. Tatsuo Nakaji of Hokkaido University for use of WinRHIZO TRON software. This research was in part by Grant-in-aid of basic research, type B (to TK: No.26292075) of Japan Society of Promotion of Science.
