Abstract

The problem central to sparse recovery and compressive sensing is that of stable sparse recovery: we want a distribution \( \mathcal{A} \) of matrices \( A \in \mathbb{R}^{m \times n} \) such that, for any \( x \in \mathbb{R}^n \) and with probability \( 1 - \delta > 2/3 \) over \( A \in \mathcal{A} \), there is an algorithm to recover \( \hat{x} \) from \( Ax \) with

\[
\|\hat{x} - x\|_p \leq C \min_{k\text{-sparse } x'} \|x - x'\|_p
\]

for some constant \( C > 1 \) and norm \( p \).

The measurement complexity of this problem is well understood for constant \( C > 1 \). However, in a variety of applications it is important to obtain \( C = 1 + \epsilon \) for a small \( \epsilon > 0 \), and this complexity is not well understood. We resolve the dependence on \( \epsilon \) in the number of measurements required of a \( k \)-sparse recovery algorithm, up to polylogarithmic factors for the central cases of \( p = 1 \) and \( p = 2 \).

Namely, we give new algorithms and lower bounds that show the number of measurements required is \( k/\epsilon^p \text{polylog}(n) \). For \( p = 2 \), our bound of \( 1/\epsilon \log(n/k) \) is tight up to constant factors. We also give matching bounds when the output is required to be \( k \)-sparse, in which case we achieve \( k/\epsilon \text{polylog}(n) \).

This shows the distinction between the complexity of sparse and non-sparse outputs is fundamental.

1 Introduction

Over the last several years, substantial interest has been generated in the problem of solving underdetermined linear systems subject to a sparsity constraint. The field, known as compressed sensing or sparse recovery, has applications to a wide variety of fields that includes data stream algorithms [Mut05], medical or geological imaging [CRT06, Don06], and genetics testing [SAZ10]. The approach uses the power of a sparsity constraint: a vector \( x' \) is \( k \)-sparse if at most \( k \) coefficients are non-zero. A standard formulation for the problem is that of stable sparse recovery: we want a distribution \( \mathcal{A} \) of matrices \( A \in \mathbb{R}^{m \times n} \) such that, for any \( x \in \mathbb{R}^n \) and with probability \( 1 - \delta > 2/3 \) over \( A \in \mathcal{A} \), there is an algorithm to recover \( \hat{x} \) from \( Ax \) with

\[
\|\hat{x} - x\|_p \leq C \min_{k\text{-sparse } x'} \|x - x'\|_p
\]

for some constant \( C > 1 \) and norm \( p \). We call this a \( C \)-approximate \( \ell_p/\ell_p \) recovery scheme with failure probability \( \delta \). We refer to the elements of \( Ax \) as measurements.

It is known [CRT06, GLPS10] that such recovery schemes exist for \( p \in \{1, 2\} \) with \( C = O(1) \) and \( m = O(k \log \frac{n}{k}) \). Furthermore, it is known [DIPW10, FPRU10] that any such recovery scheme requires \( \Omega(k \log(n/k)) \) measurements. This means the measurement complexity is well understood for \( C = 1 + \Omega(1) \), but not for \( C = 1 + o(1) \).

\footnote{Some formulations allow the two norms to be different, in which case \( C \) is not constant. We only consider equal norms in this paper.}
A number of applications would like to have \( C = 1 + \epsilon \) for small \( \epsilon \). For example, a radio wave signal can be modeled as \( x = x^* + w \) where \( x^* \) is \( k \)-sparse (corresponding to a signal over a narrow band) and the noise \( w \) is i.i.d. Gaussian with \( \|w\|_p \approx D \|x^*\|_p \) [TDB09]. Then sparse recovery with \( C = 1 + \alpha/D \) allows the recovery of a \((1 - \alpha)\) fraction of the true signal \( x^* \). Since \( x^* \) is concentrated in a small band while \( w \) is located over a large region, it is often the case that \( \alpha/D \ll 1 \).

The difficulty of \((1 + \epsilon)\)-approximate recovery has seemed to depend on whether the output \( x' \) is required to be \( k \)-sparse or can have more than \( k \) elements in its support. Having \( k \)-sparse output is important for some applications (e.g. the aforementioned radio waves) but not for others (e.g. imaging). Algorithms that output a \( k \)-sparse \( x' \) have used \( \Theta(\ell k/\epsilon) \) measurements [CCF02, CM06, Wai09]. In contrast, [GLPS10] uses only \( \Theta(\ell k \log(n/k)) \) measurements for \( p = 2 \) and outputs a non-\( k \)-sparse \( x' \).

**Our results** We show that the apparent distinction between complexity of sparse and non-sparse outputs is fundamental, for both \( p = 1 \) and \( p = 2 \). We show that for sparse output, \( \Omega(k/\epsilon^p) \) measurements are necessary, matching the upper bounds up to a \( \log n \) factor. For general output and \( p = 2 \), we show \( \Omega(\ell k \log(n/k)) \) measurements are necessary, matching the upper bound up to a constant factor. In the remaining case of general output and \( p = 1 \), we show \( \tilde{\Omega}(k/\sqrt{\epsilon}) \) measurements are necessary. We then give a novel algorithm that uses \( \tilde{O}(\log^3(1/\epsilon)k / \sqrt{\epsilon}) \) measurements, beating the \( 1/\epsilon \) dependence given by all previous algorithms. As a result, all our bounds are tight up to factors logarithmic in \( n \). The full results are shown in Figure 1.

In addition, for \( p = 2 \) and general output, we show that thresholding the top \( 2k \) elements of a Count-Sketch [CCF02] estimate gives \((1 + \epsilon)\)-approximate recovery with \( \Theta(\ell k \log n) \) measurements. This is interesting because it highlights the distinction between sparse output and non-sparse output: [CM06] showed that thresholding the top \( k \) elements of a Count-Sketch estimate requires \( m = \Theta(\ell k \log n) \). While [GLPS10] achieves \( m = \Theta(\ell k \log(n/k)) \) for the same regime, it only succeeds with constant probability while ours succeeds with probability \( 1 - n^{-\Omega(1)} \); hence ours is the most efficient known algorithm when \( \delta = o(1), \epsilon = o(1) \), and \( k < n^{0.9} \).

**Related work** Much of the work on sparse recovery has relied on the Restricted Isometry Property [CRT06]. None of this work has been able to get better than \( 2\)-approximate recovery, so there are relatively few papers achieving \((1 + \epsilon)\)-approximate recovery. The existing ones with \( O(k \log n) \) measurements are surveyed above (except for [IR08], which has worse dependence on \( \epsilon \) than [CM04] for the same regime).

A couple of previous works have studied the \( \ell_\infty/\ell_p \) problem, where every coordinate must be estimated with small error. This problem is harder than \( \ell_p/\ell_p \) sparse recovery with sparse output. For \( p = 2 \), [Wai09] showed that schemes using Gaussian matrices \( A \) require \( m = \Omega(\ell k \log(n/k)) \). For \( p = 1 \), [CM05] showed that any sketch requires \( \Omega(k/\epsilon) \) bits (rather than measurements).
Independently of this work and of each other, multiple authors [CD11, IT10, ASZ10] have matched our $\Omega(n \log(n/k))$ bound for $\ell_2/\ell_2$ in related settings. The details vary, but all proofs are broadly similar in structure to ours: they consider observing a large set of "well-separated" vectors under Gaussian noise. Fano’s inequality gives a lower bound on the mutual information between the observation and the signal; then, an upper bound on the mutual information is given by either the Shannon-Hartley theorem or a KL-divergence argument. This technique does not seem useful for the other problems we consider in this paper, such as lower bounds for $\ell_1/\ell_1$ or the sparse output setting.

**Our techniques** For the upper bounds for non-sparse output, we observe that the hard case for sparse output is when the noise is fairly concentrated, in which the estimation of the top $k$ elements can have $\sqrt{\epsilon}$ error. Our goal is to recover enough mass from outside the top $k$ elements to cancel this error. The upper bound for $p = 2$ is a fairly straightforward analysis of the top $2k$ elements of a Count-Sketch data structure.

The upper bound for $p = 1$ proceeds by subsampling the vector at rate $2^{-i}$ and performing a Count-Sketch with size proportional to $\frac{1}{\sqrt{\epsilon}}$, for $i \in \{0, 1, \ldots, O(\log(1/\epsilon))\}$. The intuition is that if the noise is well spread over many (more than $k/\epsilon^{3/2}$) coordinates, then the $\ell_2$ bound from the first Count-Sketch gives a very good $\ell_1$ bound, so the approximation is $(1 + \epsilon)$-approximate. However, if the noise is concentrated over a small number $k/\epsilon^{c}$ of coordinates, then the error from the first Count-Sketch is proportional to $1 + \epsilon^{c/2+1/4}$. But in this case, one of the subsamples will only have $O(k/\epsilon^{c/2-1/4}) < k/\sqrt{\epsilon}$ of the coordinates with large noise. We can then recover those coordinates with the Count-Sketch for that subsample. Those coordinates contain an $\epsilon^{c/2+1/4}$ fraction of the total noise, so recovering them decreases the approximation error by exactly the error induced from the first Count-Sketch.

The lower bounds use substantially different techniques for sparse output and for non-sparse output. For sparse output, we use reductions from communication complexity to show a lower bound in terms of bits. Then, as in [DIPW10], we embed $\Theta(\log n)$ copies of this communication problem into a single vector. This multiplies the bit complexity by $\log n$; we also show we can round $Ax$ to $\log n$ bits per measurement without affecting recovery, giving a lower bound in terms of measurements.

We illustrate the lower bound on bit complexity for sparse output using $k = 1$. Consider a vector $x$ containing $1/e^p$ ones and zeros elsewhere, such that $x_{2i} + x_{2i+1} = 1$ for all $i$. For any $i$, set $z_{2i} = z_{2i+1} = 1$ and $z_j = 0$ elsewhere. Then successful $(1 + \epsilon/3)$-approximate sparse recovery from $A(x + z)$ returns $\hat{z}$ with $\text{supp}(\hat{z}) = \text{supp}(x) \cap \{2i, 2i+1\}$. Hence we can recover each bit of $x$ with probability $1 - \delta$, requiring $\Omega(1/e^p)$ bit. We can generalize this to $k$-sparse output for $\Omega(k/e^p)$ bits, and to $\delta$ failure probability with $\Omega(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$. However, the two generalizations do not seem to combine.

For non-sparse output, we split between $\ell_2$ and $\ell_1$. In $\ell_2$, we consider $A(x + w)$ where $x$ is sparse and $w$ has uniform Gaussian noise with $\|w\|_2 \approx \|x\|_2^2 / \epsilon$. Then each coordinate of $y = A(x + w) = Ax + Aw$ is a Gaussian channel with signal to noise ratio $\epsilon$. This channel has channel capacity $\epsilon$, showing $I(y; x) \leq \epsilon m$. Correct sparse recovery must either get most of $x$ or an $\epsilon$ fraction of $w$; the latter requires $m = \Omega(\epsilon n)$ and the former requires $I(y; x) = \Omega(k \log(n/k))$. This gives a tight $\Theta(\frac{1}{\epsilon}k \log(n/k))$ result. Unfortunately, this does not easily extend to $\ell_1$, because it relies on the Gaussian distribution being both stable and maximum entropy under $\ell_2$; the corresponding distributions in $\ell_1$ are not the same.

Therefore for $\ell_1$ non-sparse output, we have yet another argument. The hard instances for $k = 1$ must have one large value (or else 0 is a valid output) but small other values (or else the 2-sparse approximation is significantly better than the 1-sparse approximation). Suppose $x$ has one value of size $\epsilon$ and $d$ values of size $1/d$ spread through a vector of size $d^2$. Then a $(1 + \epsilon/2)$-approximate recovery scheme must either locate the large element or guess the locations of the $d$ values with $\Omega(\epsilon d)$ more correct than incorrect. The former requires $1/(d\epsilon^2)$ bits by the difficulty of a novel version of the Gap-$\ell_\infty$ problem. The latter requires $\epsilon d$ bits because it allows recovering an error correcting code. Setting $d = \epsilon^{-3/2}$ balances the terms at $\epsilon^{-1/2}$

\[\text{For } p = 1, \text{ we can actually set } |\text{supp}(z)| \approx 1/\epsilon \text{ and search among a set of } 1/\epsilon \text{ candidates. This gives } \Omega(\frac{1}{\epsilon} \log(1/\epsilon)) \text{ bits.}\]
bits. Because some of these reductions are very intricate, this extended abstract does not manage to embed log \( n \) copies of the problem into a single vector. As a result, we lose a \( \log n \) factor in a universe of size \( n = \text{poly}(k/\epsilon) \) when converting to measurement complexity from bit complexity.

2 Preliminaries

Notation We use \([n]\) to denote the set \(\{1 \ldots n\}\). For any set \(S \subset [n]\), we use \(\overline{S}\) to denote the complement of \(S\), i.e., the set \([n] \setminus S\). For any \(x \in \mathbb{R}^n\), \(x_i\) denotes the \(i\)th coordinate of \(x\), and \(x_S\) denotes the vector \(x' \in \mathbb{R}^n\) given by \(x'_i = x_i\) if \(i \in S\), and \(x'_i = 0\) otherwise. We use \(\text{supp}(x)\) to denote the support of \(x\).

3 Upper bounds

The algorithms in this section are indifferent to permutation of the coordinates. Therefore, for simplicity of notation in the analysis, we assume the coefficients of \(x\) are sorted such that \(|x_1| \geq |x_2| \geq \ldots \geq |x_n| \geq 0\).

Count-Sketch Both our upper bounds use the Count-Sketch [CCF02] data structure. The structure consists of \(c \log n\) hash tables of size \(O(q)\), for \(O(cq \log n)\) total space; it can be represented as \(Ax\) for a matrix \(A\) with \(O(cq \log n)\) rows. Given \(Ax\), one can construct \(x^*\) with

\[
\|x^* - x\|_\infty^2 \leq \frac{1}{q} \|x_E\|_2^2
\]

with failure probability \(n^{1-\epsilon}\).

3.1 Non-sparse \(\ell_2\)

It was shown in [CM06] that, if \(x^*\) is the result of a Count-Sketch with hash table size \(O(k/\epsilon^2)\), then outputting the top \(k\) elements of \(x^*\) gives a \((1+\epsilon)\)-approximate \(\ell_2/\ell_2\) recovery scheme. Here we show that a seemingly minor change—selecting \(2k\) elements rather than \(k\) elements—turns this into a \((1+\epsilon^2)\)-approximate \(\ell_2/\ell_2\) recovery scheme.

Theorem 3.1. Let \(\hat{x}\) be the top \(2k\) estimates from a Count-Sketch structure with hash table size \(O(k/\epsilon)\). Then with failure probability \(n^{-\Omega(1)}\),

\[
\|\hat{x} - x\|_2 \leq (1 + \epsilon) \|x_E\|_2.
\]

Therefore, there is a \(1 + \epsilon\)-approximate \(\ell_2/\ell_2\) recovery scheme with \(O(\frac{1}{\epsilon}k \log n)\) rows.

Proof. Let the hash table size be \(O(ck/\epsilon)\) for constant \(c\), and let \(x^*\) be the vector of estimates for each coordinate. Define \(S\) to be the indices of the largest \(2k\) values in \(x^*\), and \(E = \|x_E\|_2\).

By (3), the standard analysis of Count-Sketch:

\[
\|x^* - x\|_\infty^2 \leq \frac{\epsilon}{ck} E^2.
\]

so

\[
\|x^* - x\|_2^2 - E^2 = \|x^* - x\|_2^2 - \|x_E\|_2^2 \leq \|x^* - x\|_2^2 + \|x_{[n] \setminus S}\|_2^2 - \|x_{[k]}\|_2^2 \leq |S| \|x^* - x\|_\infty^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2 \leq \frac{2\epsilon}{c} E^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2 \leq \frac{2\epsilon}{c} E^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2 \leq \frac{2\epsilon}{c} E^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2 \leq \frac{2\epsilon}{c} E^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2 \leq \frac{2\epsilon}{c} E^2 + \|x_{[k]}\|_2^2 - \|x_{[k]}\|_2^2
\]
Let \( a = \max_{i \in [k] \setminus S} x_i \) and \( b = \min_{i \in S \setminus [k]} x_i \), and let \( d = |k \setminus S| \). The algorithm passes over an element of value \( a \) to choose one of value \( b \), so

\[
a \leq b + 2 \|x^* - x\|_\infty \leq b + 2 \sqrt{\frac{\epsilon}{ck}} E.
\]

Then

\[
\|x[k] \setminus S\|_2^2 - \|x[S] \setminus [k]\|_2^2 \leq d a^2 - (k + d)b^2 \\
\leq d(b + 2 \sqrt{\frac{\epsilon}{ck}} E)^2 - (k + d)b^2 \\
\leq - k b^2 + 4 \frac{\epsilon}{ck} d b E + \frac{4 \epsilon}{ck} d E^2 \\
\leq - k(b - 2 \sqrt{\frac{\epsilon}{ck}} d E)^2 + \frac{4 \epsilon}{ck^2} d E^2 (k - d) \\
\leq \frac{4d(k - d)\epsilon}{ck^2} E^2 \leq \frac{\epsilon}{c} E^2
\]

and combining this with (4) gives

\[
\|x^*_S - x\|_2^2 - E^2 \leq 3\epsilon E^2
\]
or

\[
\|x^*_S - x\|_2 \leq (1 + 3\epsilon) E
\]

which proves the theorem for \( c \geq 3/2 \).

3.2 Non-sparse \( \ell_1 \)

**Theorem 3.2.** There exists a \( (1 + \epsilon) \)-approximate \( \ell_1/\ell_1 \) recovery scheme with \( O\left(\frac{\log^{3/2} 1/k \log n}{\sqrt{\epsilon}}\right) \) measurements and failure probability \( e^{-\Omega(k/\sqrt{c})} + n^{-\Omega(1)} \).

Set \( f = \sqrt{\epsilon} \), so our goal is to get \( (1 + f^2) \)-approximate \( \ell_1/\ell_1 \) recovery with \( O\left(\frac{\log^{3/2} 1/f}{k \log n}\right) \) measurements.

For intuition, consider 1-sparse recovery of the following vector \( x \): let \( c \in [0, 2] \) and set \( x_1 = 1/f^9 \) and \( x_2, \ldots, x_{1 + 1/f^{1+c}} \in \{\pm 1\} \). Then we have

\[
\left\|x_{[T]}\right\|_1 = 1/f^{1+c}
\]

and by (3), a Count-Sketch with \( O(1/f) \)-sized hash tables returns \( x^* \) with

\[
\|x^* - x\|_\infty \leq \sqrt{f} \left\|x_{[T]}\right\|_2 \approx 1/f^{c/2} = f^{1+c/2} \left\|x_{[T]}\right\|_1.
\]

The reconstruction algorithm therefore cannot reliably find any of the \( x_i \) for \( i > 1 \), and its error on \( x_1 \) is at least \( f^{1+c/2} \left\|x_{[T]}\right\|_1 \). Hence the algorithm will not do better than a \( f^{1+c/2} \)-approximation.

However, consider what happens if we subsample an \( f^c \) fraction of the vector. The result probably has about \( 1/f \) non-zero values, so a \( O(1/f) \)-width Count-Sketch can reconstruct it exactly. Putting this in our output improves the overall \( \ell_1 \) error by about \( 1/f = f^c \left\|x_{[T]}\right\|_1 \). Since \( c < 2 \), this more than cancels the \( f^{1+c/2} \left\|x_{[T]}\right\|_1 \) error the initial Count-Sketch makes on \( x_1 \), giving an approximation factor better than 1.
This tells us that subsampling can help. We don’t need to subsample at a scale below \( k/f \) (where we can reconstruct well already) or above \( k/f^3 \) (where the \( \ell_2 \) bound is small enough already), but in the intermediate range we need to subsample. Our algorithm subsamples at all \( \log 1/f^2 \) rates in between these two endpoints, and combines the heavy hitters from each.

First we analyze how subsampled Count-Sketch works.

**Lemma 3.3.** Suppose we subsample with probability \( p \) and then apply Count-Sketch with \( \Theta(\log n) \) rows and \( \Theta(q) \)-sized hash tables. Let \( y \) be the subsample of \( x \). Then with failure probability \( e^{-\Omega(q)} + n^{-\Omega(1)} \) we recover a \( y^* \) with

\[
\|y^* - y\|_{\infty} \leq \sqrt{p/q} \|x_{[q/p]}\|_2.
\]

**Proof.** Recall the following form of the Chernoff bound: if \( X_1, \ldots, X_m \) are independent with \( 0 \leq X_i \leq M \), and \( \mu \geq E[\sum X_i] \), then

\[
\Pr[\sum X_i \geq 4\frac{\mu}{3}] \leq e^{-\Omega(\mu/M)}.
\]

Let \( T \) be the set of coordinates in the sample. Then

\[
E[T \cap \left\lfloor \frac{3q}{2p} \right\rfloor] = \frac{3q}{2},
\]

so

\[
\Pr[T \cap \left\lfloor \frac{3q}{2p} \right\rfloor \geq 2q] \leq e^{-\Omega(q)}.
\]

Suppose this event does not happen, so \( T \cap \left\lfloor \frac{3q}{2p} \right\rfloor < 2q \). We also have

\[
\|x_{[q/p]}\|_2 \geq \sqrt{\frac{q}{2p}} \|x_{\left\lfloor \frac{3q}{2p} \right\rfloor}\|.
\]

Let \( Y_i = 0 \) if \( i \notin T \) and \( Y_i = x_i^2 \) if \( i \in T \). Then

\[
E[\sum Y_i] = p \|x_{\left\lfloor \frac{3q}{2p} \right\rfloor}\|_2^2 \leq p \|x_{[q/p]}\|_2^2.
\]

For \( i > \frac{3q}{2p} \) we have

\[
Y_i \leq \left|x_{\left\lfloor \frac{3q}{2p} \right\rfloor}\right|^2 \leq \frac{2p}{q} \|x_{[q/p]}\|_2^2
\]

giving by Chernoff that

\[
\Pr[\sum Y_i \geq \frac{4}{3} p \|x_{[q/p]}\|_2^2] \leq e^{-\Omega(q/2)}
\]

But if this event does not happen, then

\[
\|y_{[2q]}\|_2^2 \leq \sum_{i \in T, i \geq \frac{3q}{2p}} x_i^2 = \sum_{i \geq \frac{3q}{2p}} Y_i \leq \frac{4}{3} p \|x_{[q/p]}\|_2^2
\]

By (3), using \( O(2q) \)-size hash tables gives a \( y^* \) with

\[
\|y^* - y\|_{\infty} \leq \frac{1}{\sqrt{2q}} \|y_{[2q]}\|_2 \leq \sqrt{p/q} \|x_{[q/p]}\|_2
\]

with failure probability \( n^{-\Omega(1)} \), as desired. \( \square \)
Let \( r = 2 \log 1 / f \). Our algorithm is as follows: for \( j \in \{0, \ldots, r\} \), we find and estimate the \( 2^{j/2} k \) largest elements not found in previous \( j \) in a subsampled Count-Sketch with probability \( p = 2^{-j} \) and hash size \( q = ck / f \) for some parameter \( c = \Theta(r^2) \). We output \( \hat{x} \), the union of all these estimates. Our goal is to show

\[
\|\hat{x} - x\|_1 - \|x_{[k]}\|_1 \leq O(f^2) \|x_{[k]}\|_1.
\]

For each level \( j \), let \( S_j \) be the \( 2^{j/2} k \) largest coordinates in our estimate not found in \( S_1 \cup \cdots \cup S_{j-1} \). Let \( S = \bigcup S_j \). By Lemma 3.3 for each \( j \) we have (with failure probability \( e^{-\Omega(k/f)} + n^{-\Omega(1)} \)) that

\[
\| (\hat{x} - x)_{S_j} \|_1 \leq |S_j| \sqrt{\frac{2^{-j} f}{ck}} \|x_{[2^j ck/f]}\|_2 \\
\leq 2^{-j/2} \sqrt{\frac{fk}{c}} \|x_{[2^j ck/f]}\|_2
\]

and so

\[
\| (\hat{x} - x)_{S} \|_1 = \sum_{j=0}^{r} \| (\hat{x} - x)_{S_j} \|_1 \leq \frac{1}{(1 - 1/\sqrt{2}) \sqrt{c}} \sqrt{fk} \|x_{[2^j ck/f]}\|_2
\]

By standard arguments, the \( \ell_\infty \) bound for \( S_0 \) gives

\[
\|x_{[k]}\|_1 \leq \|x_{S_0}\|_1 + k \|x_{S_0} - x_{S_0}\|_\infty \leq \sqrt{fk/c} \|x_{[2^j ck/f]}\|_2
\]

Combining Equations (5) and (6) gives

\[
\|\hat{x} - x\|_1 - \|x_{[k]}\|_1 = \| (\hat{x} - x)_{S} \|_1 + \|x_{[k]}\|_1 - \|x_{S}\|_1 \\
= \| (\hat{x} - x)_{S} \|_1 + \|x_{[k]}\|_1 - \|x_{S}\|_1 \\
= \| (\hat{x} - x)_{S} \|_1 + \|x_{[k]}\|_1 - \sum_{j=1}^{r} \|x_{S_j}\|_1 \\
\leq \left( \frac{1}{(1 - 1/\sqrt{2}) \sqrt{c}} + \frac{1}{\sqrt{c}} \right) \sqrt{fk} \|x_{[2^j ck/f]}\|_2 - \sum_{j=1}^{r} \|x_{S_j}\|_1 \\
= O \left( \frac{1}{\sqrt{c}} \right) \sqrt{fk} \|x_{[2^j ck/f]}\|_2 - \sum_{j=1}^{r} \|x_{S_j}\|_1
\]

We would like to convert the first term to depend on the \( \ell_1 \) norm. For any \( u \) and \( s \) we have, by splitting into chunks of size \( s \), that

\[
\|u_{[2s]}\|_2 \leq \sqrt{\frac{1}{s}} \|u_{[s]}\|_1 \\
\|u_{[s] \cap [2s]}\|_2 \leq \sqrt{s} |u_s|.
\]

Along with the triangle inequality, this gives us that

\[
\sqrt{fk} \|x_{[2^j ck/f]}\|_2 \leq \sqrt{fk} \|x_{[2^j ck/f]}\|_2 + \sqrt{fk} \sum_{j=1}^{r} \|x_{[2^j ck/f] \cap [2^{j+1} k/f]}\|_2 \\
\leq f^2 \|x_{[k/f]}\|_1 + \sum_{j=1}^{r} k2^{j/2} |x_{2^j k/f}|
\]

7
so
\[
\|\hat{x} - x\|_1 - \|x_{[k]}\|_1 \leq O(\frac{1}{\sqrt{e}}) f^2 \|x_{[k/f]}\|_1 + \sum_{j=1}^{r} O(\frac{1}{\sqrt{e}}) k^{2j/2} |x_{2j/k/f}| - \sum_{j=1}^{r} \|x_{S_j}\|_1 \tag{8}
\]

Define \(a_j = k^{2j/2} |x_{2j/k/f}|\). The first term grows as \(f^2\) so it is fine, but \(a_j\) can grow as \(f^{2j/2} > f^2\). We need to show that they are canceled by the corresponding \(\|x_{S_j}\|_1\). In particular, we will show that \(\|x_{S_j}\|_1 \geq \Omega(a_j) - O(2^{-j/2} f^2 \|x_{[k/f]}\|_1)\) with high probability—at least wherever \(a_j \geq \|a\|_1/(2r)\).

Let \(U \subseteq [r]\) be the set of \(j\) with \(a_j \geq \|a\|_1/(2r)\), so that \(\|a_U\|_1 \geq \|a\|_1/2\). We have
\[
\|x_{[2j/k/f]}\|_2^2 = \|x_{[2k/f]}\|_2^2 + \sum_{i=1}^{r} \|x_{[2k/f]} \cap [2j+1/k/f]\|_2^2 \\
\leq \|x_{[2k/f]}\|_2^2 + \frac{1}{kf} \sum_{i=j}^{r} a_j^2
\tag{9}
\]

For \(j \in U\), we have
\[
\sum_{i=j}^{r} a_i^2 \leq a_j \|a\|_1 \leq 2ra_j^2
\]
so, along with \((y^2 + z^2)^{1/2} \leq y + z\), we turn Equation (9) into
\[
\|x_{[2j/k/f]}\|_2 \leq \|x_{[2k/f]}\|_2 + \sqrt{\frac{1}{kf} \sum_{i=j}^{r} a_j^2} \\
\leq \sqrt{\frac{f^3}{k}} \|x_{[k/f]}\|_1 + \sqrt{\frac{2r}{kf} a_j}
\]

When choosing \(S_j\), let \(T \subseteq [n]\) be the set of indices chosen in the sample. Applying Lemma 3.3 the estimate \(x^*\) of \(x_T\) has
\[
\|x^* - x_T\|_\infty \leq \sqrt{\frac{f}{2^{j}ck}} \|x_{[2j/k/f]}\|_2 \\
\leq \sqrt{\frac{1}{2^{j}c k}} \|x_{[k/f]}\|_1 + \sqrt{\frac{2r}{2^{j}c k}} a_j \\
= \sqrt{\frac{1}{2^{j}c k}} \|x_{[k/f]}\|_1 + \sqrt{\frac{2r}{c}} |x_{2j/k/f}|
\]

for \(j \in U\).

Let \(Q = [2j/k/f] \setminus (S_0 \cup \cdots \cup S_{j-1})\). We have \(|Q| \geq 2^{j-1}k/f\) so \(E[|Q \cap T|] \geq k/2f\) and \(|Q \cap T| \geq k/4f\) with failure probability \(e^{-\Omega((k/f))}\). Conditioned on \(|Q \cap T| \geq k/4f\), since \(x_T\) has at least \(|Q \cap T| \geq k/(4f) = 2^{j/2}k/4 \geq 2^{j/2}k/4\) possible choices of value at least \(x_{2j/k/f}\), \(x_{S_j}\) must have at least \(k^{2j/2}/4\) elements at least \(x_{2j/k/f}\). \(x_S\) must have at least \(k^{2j/2}/4\) elements at least \(x_{2j/k/f}\). Therefore, for \(j \in U\),
\[
\|x_{S_j}\|_1 \geq - \frac{1}{4} \sqrt{e} f^2 \|x_{[k/f]}\|_1 + \frac{k^{2j/2}}{4} (1 - \sqrt{\frac{2r}{c}}) |x_{2j/k/f}|
\]

8
and therefore

\[ \sum_{j=1}^r \|x_{S_j}\|_1 \geq \sum_{j \in U} \|x_{S_j}\|_1 \geq \sum_{j \in U} -\frac{1}{4 \sqrt{c}} f^2 \|x_{[k/f]}\|_1 + \frac{k2^{j/2}}{4} (1 - \sqrt{\frac{2r}{c}}) |x_{2/k/f}| \]

\[ \geq -\frac{r}{4 \sqrt{c}} f^2 \|x_{[k/f]}\|_1 + \frac{1}{4} (1 - \sqrt{\frac{2r}{c}}) \|a_U\|_1 \]

\[ \geq -\frac{r}{4 \sqrt{c}} f^2 \|x_{[k/f]}\|_1 + \frac{1}{8} (1 - \sqrt{\frac{2r}{c}}) \sum_{j=1}^r k2^{j/2} |x_{2/k/f}| \]  \hspace{1cm} (10)

Using (8) and (10) we get

\[ \|\hat{x} - x\|_1 - \|x_{[k]}\|_1 \leq \left( \frac{r}{4 \sqrt{c}} + O\left(\frac{1}{\sqrt{c}}\right) \right) f^2 \|x_{[k/f]}\|_1 + \sum_{j=1}^r \left( O\left(\frac{1}{\sqrt{c}}\right) + \frac{1}{8} \sqrt{\frac{2r}{c}} - \frac{1}{8} \right) k2^{j/2} |x_{2/k/f}| \]

\[ \leq f^2 \|x_{[k/f]}\|_1 \leq f^2 \|x_{[k]}\|_1 \]

for some \( c = O(r^2) \). Hence we use a total of \( \frac{rf}{c} \log n = \frac{\log^3 1/f}{f} k \log n \) measurements for \( 1 + f^2 \)-approximate \( \ell_1/\ell_1 \) recovery.

For each \( j \in \{0, \ldots, r\} \) we had failure probability \( e^{-\Omega(k/f)} + n^{-\Omega(1)} \) (from Lemma 3.3 and \( |Q \cap T| \geq \kappa/2f \)). By the union bound, our overall failure probability is at most

\[ (\log \frac{1}{f}) (e^{-\Omega(k/f)} + n^{-\Omega(1)}) \leq e^{-\Omega(k/f)} + n^{-\Omega(1)}, \]

proving Theorem 3.2.

### 4 Lower bounds for non-sparse output and \( p = 2 \)

In this case, the lower bound follows fairly straightforwardly from the Shannon-Hartley information capacity of a Gaussian channel.

We will set up a communication game. Let \( \mathcal{F} \subset \{S \subset [n] \mid |S| = k\} \) be a family of \( k \)-sparse supports such that:

- \( |S \Delta S'| \geq k \) for \( S \neq S' \in \mathcal{F}, \)
- \( \Pr_{S \in \mathcal{F}}[i \in S] = k/n \) for all \( i \in [n], \)
- \( \log |\mathcal{F}| = \Omega(k \log (n/k)). \)

This is possible; for example, a random linear code on \([n/k]^k\) with relative distance \( 1/2 \) has these properties [Gur10].

Let \( X = \{ x \in \{0, \pm 1\}^n \mid \text{supp}(x) \in \mathcal{F}\} \). Let \( w \sim N(0, \alpha \frac{k}{n} I_n) \) be i.i.d. normal with variance \( \alpha k/n \) in each coordinate. Consider the following process:

\[^3\text{This assumes } n/k \text{ is a prime power larger than } 2. \text{ If } n/k \text{ is not prime, we can choose } n' \in [n/2, n] \text{ to be a prime multiple of } k, \text{ and restrict to the first } n' \text{ coordinates. This works unless } n/k < 3, \text{ in which case a bound of } \Theta(\min(n, \frac{1}{2} \alpha k \log(n/k))) = \Theta(k) \text{ is trivial.}\]
Procedure First, Alice chooses $S \in \mathcal{F}$ uniformly at random, then $x \in X$ uniformly at random subject to $\text{supp}(x) = S$, then $w \sim N(0, \alpha \frac{\sigma}{n} A^T)$. She sets $y = A(x + w)$ and sends $y$ to Bob. Bob performs sparse recovery on $y$ to recover $x' \approx x$, rounds to $X$ by $\hat{x} = \arg \min_{\hat{x} \in X} \|\hat{x} - x'\|_2$, and sets $S' = \text{supp}(\hat{x})$. This gives a Markov chain $S \rightarrow x \rightarrow y \rightarrow x' \rightarrow S'$.

If sparse recovery works for any $x + w$ with probability $1 - \delta$ as a distribution over $A$, then there is some specific $A$ and random seed such that sparse recovery works with probability $1 - \delta$ over $x + w$; let us choose this $A$ and the random seed, so that Alice and Bob run deterministic algorithms on their inputs.

**Lemma 4.1.** $I(S; S') = O(m \log(1 + \frac{1}{\alpha}))$.

**Proof.** Let the columns of $A^T$ be $v^1, \ldots, v^m$. We may assume that the $v^i$ are orthonormal, because this can be accomplished via a unitary transformation on $Ax$. Then we have that $y_i = \langle v^i, x + w \rangle = \langle v^i, x \rangle + w_i'$, where $w_i' \sim N(0, \alpha k \|v^i\|_2^2/n) = N(0, \alpha k/n)$ and

$$E_x[(v^i, x)^2] = E_S[\sum_{j \in S} (v^j)^2] = \frac{k}{n}$$

Hence $y_i = z_i + w_i'$ is a Gaussian channel with power constraint $E[z_i^2] \leq \frac{k}{n} \|v^i\|_2^2$ and noise variance $E[(w_i')^2] = \alpha \frac{k}{n} \|v^i\|_2^2$. Hence by the Shannon-Hartley theorem this channel has information capacity

$$\max_{v_i} I(z_i; y_i) = C \leq \frac{1}{2} \log(1 + \frac{1}{\alpha}).$$

By the data processing inequality for Markov chains and the chain rule for entropy, this means

$$I(S; S') \leq I(z; y) = H(y) - H(y \mid z) = H(y) - H(y - z \mid z)$$

$$= H(y) - \sum H(w_i' \mid z, w_i', \ldots, w_{i-1}')$$

$$= H(y) - \sum H(w_i') \leq \sum H(y_i) - H(w_i')$$

$$= \sum H(y_i) - H(y_i \mid z_i) = \sum I(y_i; z_i)$$

$$\leq \frac{m}{2} \log(1 + \frac{1}{\alpha}).$$

(11)

We will show that successful recovery either recovers most of $x$, in which case $I(S; S') = \Omega(k \log(n/k))$, or recovers an $\epsilon$ fraction of $w$. First we show that recovering $w$ requires $m = \Omega(\epsilon n)$.

**Lemma 4.2.** Suppose $w \in \mathbb{R}^n$ with $w_i \sim N(0, \sigma^2)$ for all $i$ and $n = \Omega(\frac{1}{\epsilon^2} \log(1/\delta))$, and $A \in \mathbb{R}^{m \times n}$ for $m < \delta n$. Then any algorithm that finds $w'$ from $Aw$ must have $\|w' - w\|_2^2 > (1 - \epsilon) \|w\|_2^2$ with probability at least $1 - O(\delta)$.

**Proof.** Note that $Aw$ merely gives the projection of $w$ onto $m$ dimensions, giving no information about the other $n - m$ dimensions. Since $w$ and the $\ell_2$ norm are rotation invariant, we may assume WLOG that $A$ gives the projection of $w$ onto the first $m$ dimensions, namely $T = [m]$. By the norm concentration of Gaussians, with probability $1 - \delta$ we have $\|w\|_2^2 < (1 + \epsilon) \sigma^2$, and by Markov with probability $1 - \delta$ we have $\|w_T\|_2^2 < \epsilon n \sigma^2$.

For any fixed value $d$, since $w$ is uniform Gaussian and $w'_T$ is independent of $w_T$,

$$\Pr[\|w' - w\|_2^2 < d] \leq \Pr[\|w'_T - w_T\|_2^2 < d] \leq \Pr[\|w_T\|_2^2 < d].$$

10
Because recovery is successful,
\[
\Pr[\|w' - w\|_2^2 < (1 - 3\epsilon) \|w\|_2^2] \leq \Pr[\|w' - w\|_2^2 < (1 - 2\epsilon)n\sigma^2] \\
\leq \Pr[\|w_T\|_2^2 < (1 - 2\epsilon)n\sigma^2] \\
\leq \Pr[\|w_T\|_2^2 < (1 - \epsilon)(n - m)\sigma^2] \leq \delta
\]
as desired. Rescaling \(\epsilon\) gives the result.

**Lemma 4.3.** Suppose \(n = \Omega(1/\epsilon^2 + (k/\epsilon) \log(k/\epsilon))\) and \(m = O(\epsilon n)\). Then \(I(S; S') = \Omega(k \log(n/k))\) for some \(\alpha = \Omega(1/\epsilon)\).

**Proof.** Consider the \(x'\) recovered from \(A(x + w)\), and let \(T = S \cup S'\). Suppose that \(\|w\|_2^2 \leq O(\frac{m}{n} \log n)\) and \(\|w\|_2^2/(\alpha k) \in [1 \pm \epsilon]\), as happens with probability at least (say) 3/4. Then we claim that if recovery is successful, one of the following must be true:

\[
\|x'_T - x\|_2^2 \leq 9\epsilon \|w\|_2^2 \\
\|x'_T - w\|_2^2 \leq (1 - 2\epsilon) \|w\|_2^2
\]

(12)

(13)

To show this, suppose \(\|x'_T - x\|_2^2 > 9\epsilon \|w\|_2^2 \geq 9 \|w_T\|_2^2\) (the last by \(|T| = 2k = O(\epsilon n/\log n)\)). Then

\[
\|x' - (x + w)\|_2^2 > (\|x' - x\|_2^2 - \|w_T\|_2^2)^2 \\
\geq (2\|x' - x\|_2^2/3)^2 \geq 4\epsilon \|w\|_2^2.
\]

Because recovery is successful,
\[
\|x' - (x + w)\|_2^2 \leq (1 + \epsilon) \|w\|_2^2.
\]

Therefore
\[
\|x'_T - w_T\|_2^2 + \|x'_T - (x + w)_T\|_2^2 = \|x' - (x + w)\|_2^2 \\
\|x'_T - w_T\|_2^2 + 4\epsilon \|w\|_2^2 < (1 + \epsilon) \|w\|_2^2 \\
\|x'_T - w\|_2^2 - \|w_T\|_2^2 < (1 - 3\epsilon) \|w\|_2^2 \leq (1 - 2\epsilon) \|w\|_2^2
\]
as desired. Thus with 3/4 probability, at least one of (12) and (13) is true.

Suppose Equation (13) holds with at least 1/4 probability. There must be some \(x\) and \(S\) such that the same equation holds with 1/4 probability. For this \(S\), given \(x'\) we can find \(T\) and thus \(x'_T\). Hence for a uniform Gaussian \(w_T\), given \(Aw_T\) we can compute \(A(x + w_T)\) and recover \(x'_T\) with \(\|x'_T - w_T\|_2^2 \leq (1 - \epsilon) \|w_T\|_2^2\). By Lemma [4.2] this is impossible, since \(n - |T| = \Omega(\frac{1}{\epsilon^2})\) and \(m = \Omega(\epsilon n)\) by assumption.

Therefore Equation (12) holds with at least 1/2 probability, namely \(\|x'_T - x\|_2^2 \leq 9\epsilon \|w\|_2^2 \leq 9\epsilon(1 - \epsilon)\alpha k < k/2\) for appropriate \(\alpha\). But if the nearest \(\hat{x} \in X\) to \(x\) is not equal to \(x\),

\[
\|x' - \hat{x}\|_2^2 = \|x'_T - \hat{x}\|_2^2 + \|x'_T - \hat{x}\|_2^2 \geq \|x'_T\|_2^2 + (\|x - \hat{x}\|_2^2 - \|x'_T - x\|_2^2)^2 \\
> \|x'_T\|_2^2 + (k - k/2)^2 > \|x'_T\|_2^2 + \|x'_T - x\|_2^2 = \|x' - x\|_2^2,
\]
a contradiction. Hence \(S' = S\). But Fano’s inequality states \(H(S|S') \leq 1 + \Pr[S' \neq S] \log |F|\) and hence

\[
I(S; S') = H(S) - H(S|S') \geq -1 + \frac{1}{4} \log |F| = \Omega(k \log(n/k))
\]
as desired. □
Theorem 4.4. Any \((1 + \epsilon)\)-approximate \(\ell_2/\ell_2\) recovery scheme with \(\epsilon > \sqrt{\frac{k \log n}{n}}\) and failure probability \(\delta < 1/2\) requires \(m = \Omega(\frac{1}{\epsilon} k \log(n/k))\).

Proof. Combine Lemmas 4.3 and 4.1 with \(\alpha = 1/\epsilon\) to get \(m = \Omega(\frac{k \log(n/k)}{\log(1 + \epsilon)}) = \Omega(\frac{1}{\epsilon} k \log(n/k))\), \(m = \Omega(\epsilon n)\), or \(n = O(\frac{1}{\epsilon} k \log(k/\epsilon))\). For \(\epsilon\) as in the theorem statement, the first bound is controlling.

\section{Bit complexity to measurement complexity}

The remaining lower bounds proceed by reductions from communication complexity. The following lemma (implicit in [DIPW10]) shows that lower bounding the number of bits for approximate recovery is sufficient to lower bound the number of measurements. Let \(B_p^n(R) \subset \mathbb{R}^n\) denote the \(\ell_p\) ball of radius \(R\).

Definition 5.1. Let \(X \subset \mathbb{R}^n\) be a distribution with \(x_i \in \{-n^d, \ldots, n^d\}\) for all \(i \in [n]\) and \(x \in X\). We define a \(1 + \epsilon\)-approximate \(\ell_p/\ell_p\) sparse recovery bit scheme on \(X\) with \(b\) bits, precision \(n^{-c}\), and failure probability \(\delta\) to be a deterministic pair of functions \(f : X \rightarrow \{0, 1\}^b\) and \(g : \{0, 1\}^b \rightarrow \mathbb{R}^n\) where \(f\) is linear so that \(f(a + b)\) can be computed from \(f(a)\) and \(f(b)\). We require that, for \(u \in B_p^n(n^{-c})\) uniformly and \(x\) drawn from \(X\), \(g(f(x))\) is a valid result of \(1 + \epsilon\)-approximate recovery on \(x + u\) with probability \(1 - \delta\).

Lemma 5.2. A lower bound of \(\Omega(b)\) bits for such a sparse recovery bit scheme with \(p \leq 2\) implies a lower bound of \(\Omega(b/(1 + c + d) \log n))\) bits for regular \((1 + \epsilon)\)-approximate sparse recovery with failure probability \(\delta - 1/n\).

Proof. Suppose we have a standard \((1 + \epsilon)\)-approximate sparse recovery algorithm \(A\) with failure probability \(\delta\) using \(m\) measurements \(Ax\). We will use this to construct a (randomized) sparse recovery bit scheme using \(O(m(1 + c + d) \log n)\) bits and failure probability \(\delta + 1/n\). Then by averaging some deterministic sparse recovery bit scheme performs better than average over the input distribution.

We may assume that \(A \in \mathbb{R}^{m \times n}\) has orthonormal rows (otherwise, if \(A = US\Sigma VT\) is its singular value decomposition, \(\Sigma^+UT\) has this property and can be inverted before applying the algorithm). When applied to the distribution \(X + u\) for \(u\) uniform over \(B_p^n(n^{-c})\), we may assume that \(A\) and \(A\) are deterministic and fail with probability \(\delta\) over their input.

Let \(A'\) be \(A\) rounded to \(t \log n\) bits per entry for some parameter \(t\). Let \(x\) be chosen from \(X\). By Lemma 5.1 of [DIPW10], for any \(x\) we have \(A' = Ax = A(x - s)\) for some \(s\) with \(\|s\|_1 \leq n^{2 - t \log n} \|x\|_1\), so \(\|s\|_p \leq n^{1.5 - t} \|x\|_p \leq n^{3.5 - d - t}\). Let \(u \in B_p^n(n^{5.5 + d - t})\) uniformly at random. With probability at least \(1 - 1/n\), \(u \in B_p^n((1 - 1/n^2)n^{5.5 + d - t})\) because the balls are similar so the ratio of volumes is \((1 - 1/n^2)^n > 1 - 1/n\). In this case \(x + s \in B_p^n(n^{5.5 + d - t})\); hence the random variable \(u\) and \(x + s\) overlap in at least a \(1 - 1/n\) fraction of their volumes, so \(x + s + u\) and \(x + u\) have statistical distance at most \(1/n\). Therefore \(A(A(x + u)) = A(A'x + Au)\) with probability at least \(1 - 1/n\).

Now, \(A'\) uses only \((t + d + 1) \log n\) bits per entry, so we can set \(f(x) = A'x\) for \(b = m(t + d + 1) \log n\). Then we set \(g(y) = A(y + Au)\) for uniformly random \(u \in B_p^n(n^{5.5 + d - t})\). Setting \(t = 5.5 + d + c\), this gives a sparse recovery bit scheme using \(b = \frac{1}{\epsilon} m(6.5 + 2d + c) \log n\).

\section{Non-sparse output Lower Bound for \(p = 1\)}

First, we show that recovering the locations of an \(\epsilon\) fraction of \(d\) ones in a vector of size \(n > d/\epsilon\) requires \(\Omega(ed)\) bits. Then, we show high bit complexity of a distributional product version of the Gap-\(\ell_\infty\) problem. Finally, we create a distribution for which successful sparse recovery must solve one of the previous problems, giving a lower bound in bit complexity. Lemma 5.2 converts the bit complexity to measurement complexity.
6.1 \(\ell_1\) Lower bound for recovering noise bits

**Definition 6.1.** We say a set \(C \subset [q]^d\) is a \((d, q, \epsilon)\) code if any two distinct \(c, c' \in C\) agree in at most \(\epsilon d\) positions. We say a set \(X \subset \{0, 1\}^{dq}\) represents \(C\) if \(X\) is \(C\) concatenated with the trivial code \([q] \to \{0, 1\}^q\) given by \(i \mapsto e_i\).

**Claim 6.2.** For \(\epsilon \geq 2/q\), there exist \((d, q, \epsilon)\) codes \(C\) of size \(q^{\Omega(d)}\) by the Gilbert-Varshamov bound (details in [DIPW10]).

**Lemma 6.3.** Let \(X \subset \{0, 1\}^{dq}\) represent a \((d, q, \epsilon)\) code. Suppose \(y \in \mathbb{R}^{dq}\) satisfies \(\|y - x\|_1 \leq (1 - \epsilon)\|x\|_1\). Then we can recover \(x\) uniquely from \(y\).

**Proof.** We assume \(y_i \in [0, 1]\) for all \(i\); thresholding otherwise decreases \(\|y - x\|_1\). We will show that there exists no other \(x' \in X\) with \(\|y - x\|_1 \leq (1 - \epsilon)\|x\|_1\); thus choosing the nearest element of \(X\) is a unique decoder. Suppose otherwise, and let \(S = \text{supp}(x), T = \text{supp}(x')\). Then

\[
(1 - \epsilon)\|x\|_1 \geq \|y - x\|_1 = \|x\|_1 - \|ys\|_1 + \|ys\|_1 \\
\|ys\|_1 \geq \|ys\|_1 + \epsilon d
\]

Since the same is true relative to \(x'\) and \(T\), we have

\[
\|ys\|_1 + \|yt\|_1 \geq \|ys\|_1 + \|ys\|_1 + 2\epsilon d \\
2\|ys \cap T\|_1 \geq 2\|ys \cap T\|_1 + 2\epsilon d \\
\|ys \cap T\|_1 \geq \epsilon d \\
|S \cap T| \geq \epsilon d
\]

This violates the distance of the code represented by \(X\).

**Lemma 6.4.** Let \(R = [s, cs]\) for some constant \(c\) and parameter \(s\). Let \(X\) be a permutation independent distribution over \(\{0, 1\}^n\) with \(\|x\|_1 \in R\) with probability \(p\). If \(y\) satisfies \(\|y - x\|_1 \leq (1 - \epsilon)\|x\|_1\) with probability \(p'\) with \(p' - (1 - p) = \Omega(1)\), then \(I(x; y) = \Omega(\epsilon s \log(n/s))\).

**Proof.** For each integer \(i \in R\), let \(X_i \subset \{0, 1\}^n\) represent an \((i, n/i, \epsilon)\) code. Let \(p_i = \mathbb{P}_{x \in X}[\|x\|_1 = i]\). Let \(S_n\) be the set of permutations of \([n]\). Then the distribution \(X'\) given by (a) choosing \(i \in R\) proportional to \(p_i\), (b) choosing \(\sigma \in S_n\) uniformly, (c) choosing \(x_i \in X_i\) uniformly, and (d) outputting \(x' = \sigma(x_i)\) is equal to the distribution \((x \in X \mid \|x\|_1 \in R)\).

Now, because \(p' \geq \mathbb{P}[\|x\|_1 \notin R] + \Omega(1)\), \(x'\) chosen from \(X'\) satisfies \(\|x' - y\|_1 \leq (1 - \epsilon)\|x'\|_1\) with \(\delta \geq p' - (1 - p)\) probability. Therefore, with at least \(\delta/2\) probability, \(i\) and \(\sigma\) are such that \(\|\sigma(x_i) - y\|_1 \leq (1 - \epsilon)\|\sigma(x_i)\|_1\) with \(\delta/2\) probability over uniform \(x_i \in X_i\). But given \(y\) with \(\|y - \sigma(x_i)\|_1\) small, we can compute \(y' = \sigma^{-1}(y)\) with \(\|y' - x_i\|_1\) equally small. Then by Lemma 6.3, we can recover \(x_i\) from \(y\) with probability \(\delta/2\) over \(x_i \in X_i\). Thus for this \(i\) and \(\sigma\), \(I(x; y \mid i, \sigma) \geq \Omega(\log |X_i|) = \Omega(\delta s \log(n/s))\) by Fano’s inequality. But then \(I(x; y) = \mathbb{E}_{i, \sigma}[I(x; y \mid i, \sigma)] = \Omega(\delta^2 s \log(n/s)) = \Omega(\epsilon \log(n/s))\).

6.2 Distributional Indexed Gap \(\ell_\infty\)

Consider the following communication game, which we refer to as \(\text{Gap}_{\ell_\infty}^{B}\), studied in [BYJKS04]. The legal instances are pairs \((x, y)\) of \(m\)-dimensional vectors, with \(x_i, y_i \in \{0, 1, 2, \ldots, B\}\) for all \(i\) such that

- NO instance: for all \(i, y_i - x_i \in \{0, 1\}, or \)
The *distributional* communication complexity $D_{\sigma, \delta}(f)$ of a function $f$ is the minimum over all deterministic protocols computing $f$ with error probability at most $\delta$, where the probability is over inputs drawn from $\sigma$.

Consider the distribution $\sigma$ which chooses a random $i \in [m]$. Then for each $j \neq i$, it chooses a random $d \in \{0, \ldots, B\}$ and $(x_i, y_i)$ is uniform in $\{(d, d), (d, d+1)\}$. For coordinate $i$, $(x_i, y_i)$ is uniform in $\{(0, 0), (0, B)\}$. Using similar arguments to those in [BYJKS04], Jayram [Jay02] showed $D_{\sigma, \delta}(\text{Gap}_l^{B}) = \Omega(m/B^2)$ (this is reference [70] on p.182 of [BY02]) for $\delta$ less than a small constant.

We define the one-way distributional communication complexity $D_{\sigma, \delta}^1(f)$ of a function $f$ to be the smallest distributional complexity of a protocol for $f$ in which only a single message is sent from Alice to Bob.

**Definition 6.5** (Indexed $\text{Ind}_{f^r}^{E,B}$ Problem). There are $r$ pairs of inputs $(x^1, y^1), (x^2, y^2), \ldots, (x^r, y^r)$ such that every pair $(x^i, y^i)$ is a legal instance of the $\text{Gap}_{l}^{B}$ problem. Alice is given $x^1, \ldots, x^r$. Bob is given an index $I \in [r]$ and $y^1, \ldots, y^r$. The goal is to decide whether $(x^I, y^I)$ is a NO or a YES instance of $\text{Gap}_{l}^{B}$.

Let $\eta$ be the distribution $\sigma^r \times U_r$, where $U_r$ is the uniform distribution on $[r]$. We bound $D_{\eta, \delta}^1(\text{Ind}_{f^r})^{E,B}$ as follows. For a function $f$, let $f^\sigma$ denote the problem of computing $r$ instances of $f$. For a distribution $\zeta$ on instances of $f$, let $D_{\sigma, \delta}^1(f^\tau)$ denote the minimum communication cost of a deterministic protocol computing a function $f$ with error probability at most $\delta$ in each of the $r$ copies of $f$, where the inputs come from $\zeta^r$.

**Theorem 6.6.** (special case of Corollary 2.5 of [BR11]) Assume $D_{\sigma, \delta}(f)$ is larger than a large enough constant. Then $D_{\sigma^r, \delta/r}^1(f^\tau) = \Omega(rD_{\sigma, \delta}(f))$.

**Theorem 6.7.** For $\delta$ less than a sufficiently small constant, $D_{\eta, \delta}^1(\text{Ind}_{f^r})^{E,B} = \Omega(\delta^2rm/(B^2 \log r))$.

**Proof.** Consider a deterministic 1-way protocol $\Pi$ for $\text{Ind}_{f^r}^{E,B}$ with error probability $\delta$ on inputs drawn from $\eta$. Then for at least $r/2$ values $i \in [r]$, $\Pr[\Pi(x^1, \ldots, x^r, y^1, \ldots, y^r, I) = \text{Gap}_{l}^{B}(x^I, y^I) | I = i] \geq 1 - 2\delta$. Fix a set $S = \{i_1, \ldots, i_{r/2}\}$ of indices with this property. We build a deterministic 1-way protocol $\Pi'$ for $f^r$ with input distribution $\sigma^{r/2}$ and error probability at most $6\delta$ in each of the $r/2$ copies of $f$.

For each $\ell \in [r] \setminus S$, independently choose $(x^\ell, y^\ell) \sim \sigma$. For each $j \in [r/2]$, let $Z^j_s$ be the probability that $\Pi(x^1, \ldots, x^r, y^1, \ldots, y^r, I) = \text{Gap}_{l}^{B}(x^j, y^s)$ given $I = i_j$ and the choice of $(x^\ell, y^\ell)$ for all $\ell \in [r] \setminus S$.

If we repeat this experiment independently $s = O(\delta^{-2} \log r)$ times, obtaining independent $Z^1_s, \ldots, Z^r_s$ and let $Z_j = \sum Z^j_s$, then $\Pr[Z_j \geq s - s \cdot 3\delta] \geq 1 - \frac{1}{2}$. So there exists a set of $s = O(\delta^{-1} \log r)$ repetitions for which for each $j \in [r/2], Z_j \geq s - s \cdot 3\delta$. We hardwire these into $\Pi'$ to make the protocol deterministic.

Given inputs $((X_1^1, \ldots, X^r_1), (Y^1_1, \ldots, Y^r_1)) \sim \sigma^{r/2}$ to $\Pi'$, Alice and Bob run $s$ executions of $\Pi$, each with $X^j_i = X^j$ and $y^j_i = Y^j$ for all $j \in [r/2]$, filling in the remaining values using the hardwired inputs. Bob runs the algorithm specified by $\Pi$ for each $i_j \in S$ and each execution. His output for $(X^j, Y^j)$ is the majority of the outputs of the $s$ executions with index $i_j$.

Fix an index $i_j$. Let $W$ be the number of repetitions for which $\text{Gap}_{l}^{B}(X^j, Y^j)$ does not equal the output of $\Pi$ on input $i_j$, for a random $(X^j, Y^j) \sim \sigma$. Then, $\mathbb{E}[W] \leq 3\delta$. By a Markov bound, $\Pr[W \geq s/2] \leq 6\delta$, and so the coordinate is correct with probability at least $1 - 6\delta$.

The communication of $\Pi'$ is a factor $s = \Theta(\delta^{-2} \log r)$ more than that of $\Pi$. The theorem now follows by Theorem 6.6 using that $D_{\sigma, 12\delta}(\text{Gap}_{l}^{B}) = \Omega(m/B^2)$.

### 6.3 Lower bound for sparse recovery

Fix the parameters $B = \Theta(1/\epsilon^2)$, $r = k$, $m = 1/\epsilon^3$, and $n = k/\epsilon^3$. Given an instance $(x^1, y^1), \ldots, (x^r, y^r), I$ of $\text{Ind}_{f^r}^{E,B}$, we define the input signal $z$ to a sparse recovery problem. We allocate a set $S^i$ of $m$ disjoint
coordinates in a universe of size \( n \) for each pair \((x^i, y^i)\), and on these coordinates place the vector \( y^i - x^i \). The locations are important for arguing the sparse recovery algorithm cannot learn much information about the noise, and will be placed uniformly at random.

Let \( \rho \) denote the induced distribution on \( z \). Fix a \((1 + \epsilon)\)-approximate \( k \)-sparse recovery bit scheme \( Alg \) that takes \( b \) bits as input and succeeds with probability at least \( 1 - \delta/2 \) over \( z \sim \rho \) for some small constant \( \delta \). Let \( S \) be the set of top \( k \) coordinates in \( z \). \( Alg \) has the guarantee that if it succeeds for \( z \sim \rho \), then there exists a small \( u \) with \( \|u\|_1 < n^{-2} \) so that \( v = Alg(z) \) satisfies

\[
\|v - z - u\|_1 \leq (1 + \epsilon) \left\| (z + u)_{[n] \setminus S} \right\|_1 \\
\|v - z\|_1 \leq (1 + \epsilon) \left( \left\| z_{[n] \setminus S} \right\|_1 + (2 + \epsilon)/n^2 \right) \\
\leq (1 + 2\epsilon) \left\| z_{[n] \setminus S} \right\|_1
\]

and thus

\[
\left\| (v - z)_{S} \right\|_1 + \left\| (v - z)_{[n] \setminus S} \right\|_1 \leq (1 + 2\epsilon) \left\| z_{[n] \setminus S} \right\|_1. \tag{14}
\]

**Lemma 6.8.** For \( B = \Theta(1/\epsilon^{1/2}) \) sufficiently large, suppose that \( \Pr_{z \sim \rho} \left[ \left\| (v - z)_{S} \right\|_1 \leq 10\epsilon \cdot \left\| z_{[n] \setminus S} \right\|_1 \right] \geq 1 - \delta \). Then \( Alg \) requires \( b = \Omega(k/(\epsilon^{1/2} \log k)) \).

**Proof.** We show how to use \( Alg \) to solve instances of \( \text{Ind}_{\ell_1}^{r,B} \) with probability at least \( 1 - C \) for some small \( C \), where the probability is over input instances to \( \text{Ind}_{\ell_1}^{r,B} \) distributed according to \( \eta \), inducing the distribution \( \rho \). The lower bound will follow by Theorem 6.7 Since \( Alg \) is a deterministic sparse recovery bit scheme, it receives a sketch \( f(z) \) of the input signal \( z \) and runs an arbitrary recovery algorithm \( g \) on \( f(z) \) to determine its output \( v = Alg(z) \).

Given \( x^1, \ldots, x^r \), for each \( i = 1, 2, \ldots, r \), Alice places \(-x^i\) on the appropriate coordinates in the block \( S^i \) used in defining \( z \), obtaining a vector \( z_{\text{Alice}} \), and transmits \( f(z_{\text{Alice}}) \) to Bob. Bob uses his inputs \( y^1, \ldots, y^r \) to place \( y^i \) on the appropriate coordinate in \( S^i \). He thus creates a vector \( z_{Bob} \) for which \( z_{Alice} + z_{Bob} = z \). Given \( f(z_{Alice}) \), Bob computes \( f(z) \) from \( f(z_{Alice}) \) and \( f(z_{Bob}) \), then \( v = Alg(z) \). We assume all coordinates of \( v \) are rounded to the real interval \([0, B]\), as this can only decrease the error.

We say that \( S^i \) is bad if either

- there is no coordinate \( j \) in \( S^i \) for which \( |v_j| \geq \frac{B}{2} \) yet \((x^i, y^i)\) is a YES instance of \( \text{Gap}_{\ell_1}^{r,B} \), or
- there is a coordinate \( j \) in \( S^i \) for which \( |v_j| \geq \frac{B}{2} \) yet either \((x^i, y^i)\) is a NO instance of \( \text{Gap}_{\ell_1}^{r,B} \) or \( j \) is not the unique \( j^* \) for which \( y^i_{j^*} - x^i_{j^*} = B \)

The \( \ell_1 \)-error incurred by a bad block is at least \( B/2 - 1 \). Hence, if there are \( t \) bad blocks, the total error is at least \( t(B/2 - 1) \), which must be smaller than \( 10\epsilon \cdot \left\| z_{[n] \setminus S} \right\|_1 \) with probability \( 1 - \delta \). Suppose this happens.

We bound \( t \). All coordinates in \( z_{[n] \setminus S} \) have value in the set \([0, 1]\). Hence, \( \left\| z_{[n] \setminus S} \right\|_1 < rm \). So \( t \leq 20erm/(B - 2) \). For \( B \geq 6, t \leq 30erm/B \). Plugging in \( r, m \) and \( B \), \( t \leq Ck \), where \( C > 0 \) is a constant that can be made arbitrarily small by increasing \( B = \Theta(1/\epsilon^{1/2}) \).

If a block \( S^i \) is not bad, then it can be used to solve \( \text{Gap}_{\ell_1}^{r,B} \) on \((x^i, y^i)\) with probability \( 1 \). Bob declares that \((x^i, y^i)\) is a YES instance if and only if there is a coordinate \( j \) in \( S^i \) for which \( |v_j| \geq B/2 \).

Since Bob’s index \( I \) is uniform on the \( m \) coordinates in \( \text{Ind}_{\ell_1}^{r,B} \), with probability at least \( 1 - C \) the players solve \( \text{Ind}_{\ell_1}^{r,B} \) given that the \( \ell_1 \) error is small. Therefore they solve \( \text{Ind}_{\ell_1}^{r,B} \) with probability \( 1 - \delta - C \) overall. By Theorem 6.7 for \( C \) and \( \delta \) sufficiently small \( Alg \) requires \( \Omega(mr/(B^2 \log r)) = \Omega(k/(\epsilon^{1/2} \log k)) \) bits.

**Lemma 6.9.** Suppose \( \Pr_{z \sim \rho} \left[ \left\| (v - z)_{[n] \setminus S} \right\|_1 \right] \leq (1 - 8\epsilon) \cdot \left\| z_{[n] \setminus S} \right\|_1 \geq \delta/2 \). Then \( Alg \) requires \( b = \Omega(\frac{1}{\sqrt{\epsilon}} k \log(1/\epsilon)) \).
Proof. The distribution $\rho$ consists of $B(mr, 1/2)$ ones placed uniformly throughout the $n$ coordinates, where $B(mr, 1/2)$ denotes the binomial distribution with $mr$ events of $1/2$ probability each. Therefore with probability at least $1 - \delta/4$, the number of ones lies in $[\delta mr/8, (1 - \delta/8)mr]$. Thus by Lemma 6.4 $I(v; z) \geq \Omega(\epsilon mr \log(n/(mr)))$. Since the mutual information only passes through a $b$-bit string, $b = \Omega(\epsilon mr \log(n/(mr)))$ as well. \qed

Theorem 6.10. Any $(1 + \epsilon)$-approximate $\ell_1/\ell_1$ recovery scheme with sufficiently small constant failure probability $\delta$ must make $\Omega(\frac{1}{\epsilon^2}k/\log^2(k/\epsilon))$ measurements.

Proof. We will lower bound any $\ell_1/\ell_1$ sparse recovery bit scheme $Alg$. If $Alg$ succeeds, then in order to satisfy inequality (14), we must either have $\|(v - z)s\|_1 \leq 10\epsilon \cdot \|z|_\Sigma|s\|_1$ or we must have $\|(v - z)_|\Sigma|s\|_1 \leq (1 - 8\epsilon) \cdot \|z|_\Sigma|s\|_1$. Since $Alg$ succeeds with probability at least $1 - \delta$, it must either satisfy the hypothesis of Lemma 6.8 or the hypothesis of Lemma 6.9. But by these two lemmas, it follows that $b = \Omega(\frac{1}{\epsilon^2}k/\log k)$. Therefore by Lemma 5.2 any $(1 + \epsilon)$-approximate $\ell_1/\ell_1$ sparse recovery algorithm requires $\Omega(\frac{1}{\epsilon^2}k/\log^2(k/\epsilon))$ measurements. \qed

7 Lower bounds for $k$-sparse output

Theorem 7.1. Any $1 + \epsilon$-approximate $\ell_1/\ell_1$ recovery scheme with $k$-sparse output and failure probability $\delta$ requires $m = \Omega(\frac{1}{\epsilon^2}(k \log \frac{1}{\epsilon} + \log \frac{1}{\delta}))$, for $32 \leq \frac{1}{\delta} \leq ne^2/k$.

Theorem 7.2. Any $1 + \epsilon$-approximate $\ell_2/\ell_2$ recovery scheme with $k$-sparse output and failure probability $\delta$ requires $m = \Omega(\frac{1}{\epsilon^2}(k + \log \frac{1}{\delta}))$, for $32 \leq \frac{1}{\delta} \leq ne^2/k$.

These two theorems correspond to four statements: one for large $k$ and one for small $\delta$ for both $\ell_1$ and $\ell_2$.

All the lower bounds proceed by reductions from communication complexity. The following lemma (implicit in [DIPW10]) shows that lower bounding the number of bits for approximate recovery is sufficient to lower bound the number of measurements.

Lemma 7.3. Let $p \in \{1, 2\}$ and $\alpha = \Omega(1) < 1$. Suppose $X \subset \mathbb{R}^n$ has $\|x\|_p \leq D$ and $\|x\|_\infty \leq D'$ for all $x \in X$, and all coefficients of elements of $X$ are expressible in $O(\log n)$ bits. Further suppose that we have a recovery algorithm that, for any $v$ with $\|v\|_p < \alpha D$ and $\|v\|_\infty < \alpha D'$, recovers $x \in X$ from $A(x + v)$ with constant probability. Then $A$ must have $\Omega(\log |X|)$ measurements.

Proof. We use Lemma 5.2. First, we may assume that $A \in \mathbb{R}^{n \times n}$ has orthonormal rows (otherwise, if $A = U\Sigma V^T$ is its singular value decomposition, $\Sigma^+ U^T A$ has this property and can be inverted before applying the algorithm). Let $A'$ be $A$ rounded to $c \log n$ bits per entry. By Lemma 5.1 of [DIPW10], for any $v$ we have $A'v = A(v - s)$ for some $s$ with $\|s\|_1 \leq n^{2.5 - \epsilon} \|v\|_1$ and $\|s\|_p \leq n^{2.5 - \epsilon} \|v\|_p$.

Suppose Alice has a bit string of length $r \log |X|$ for $r = \Theta(\log n)$. By splitting into $r$ blocks, this corresponds to $x_1, \ldots, x_r \in X$. Let $\beta$ be a power of 2 between $\alpha/2$ and $\alpha/4$, and define

$$z_j = \sum_{i=j}^{r} \beta^i x_i.$$

Alice sends $A'z_1$ to Bob; this is $O(m \log n)$ bits. Bob will solve the augmented indexing problem[4]— given $A'z_1$, arbitrary $j \in [r]$, and $x_1, \ldots, x_{j-1}$, he must find $x_j$ with constant probability. This requires $A'z_1$ to have $\Omega(r \log |X|)$ bits, giving the result.
Bob receives \( A'z_1 = A(z_1 + s) \) for \( \|s\|_1 \leq n^{2.5-c} \|z_1\|_p \leq n^{2.5-c}D \). Bob then chooses \( u \in B_p^n((1 - 1/n^2)n^{4.5-c}D) \) uniformly at random. With probability at least \( 1 - 1/n \), \( u \in B_p^n((1 - 1/n^2)n^{4.5-c}D) \) by a volume argument. In this case \( u + s \in B_p^n((1 - 1/n^2)n^{4.5-c}D) \); hence the random variables \( u \) and \( u + s \) overlap in at least a \( 1 - 1/n \) fraction of their volumes, so \( z_j + s + u \) and \( z_j + u \) have statistical distance at most \( 1/n \). The distribution of \( z_j + u \) is independent of \( A \) (unlike \( z_j + s \)) so running the recovery algorithm on \( A(z_j + s + u) \) succeeds with constant probability as well.

We also have \( \|z_j\|_p \leq \frac{5}{1-\beta} D < 2(\beta^j - \beta^{r+1})D \). Since \( r = O\left(\log n\right) \) and \( \beta \) is a constant, there exists a \( c = O(1) \) with

\[
\|z_j + s + u\|_p < (2\beta^j + n^{4.5-c} - 2\beta^r)D \leq \beta^{j-1} \alpha D
\]
for all \( j \).

Therefore, given \( x_1, \ldots, x_{j-1} \), Bob can compute

\[
\frac{1}{\beta^j} (A'z_1 + Au - A' \sum_{i<j} \beta^j x_i) = A(x_j + \frac{1}{\beta^j} (z_{j+1} + s + u)) = A(x_j + y)
\]
for some \( y \) with \( \|y\|_p \leq \alpha D \). Hence Bob can use the recovery algorithm to recover \( x_j \) with constant probability. Therefore Bob can solve augmented indexing, so the message \( A'z_1 \) must have \( \Omega(\log n \log |X|) \) bits, so \( m = \Omega(\log |X|) \).

We will now prove another lemma that is useful for all four theorem statements.

Let \( x \in \{0,1\}^n \) be \( k \)-sparse with \( \text{supp}(x) \subseteq S \) for some known \( S \). Let \( \nu \in \mathbb{R}^n \) be a noise vector that roughly corresponds to having \( O(k/\epsilon^p) \) ones for \( p \in \{1,2\} \), all located outside of \( S \). We consider under what circumstances we can use a \((1 + \epsilon)\)-approximate \( \ell_p/\ell_p \) recovery scheme to recover \( \text{supp}(x) \) from \( A(x + \nu) \) with (say) 90% accuracy.

Lemma 7.4 shows that this is possible for \( p = 1 \) when \( |S| \leq O(k/\epsilon) \) and for \( p = 2 \) when \( |S| \leq 2k \). The algorithm in both instances is to choose a parameter \( \mu \) and perform sparse recovery on \( A(x + \nu + z) \), where \( z_i = \mu \) for \( i \in S \) and \( z_i = 0 \) otherwise. The support of the result will be very close to \( \text{supp}(x) \).

**Lemma 7.4.** Let \( S \subset [n] \) have \( |S| \leq s \), and suppose \( x \in \{0,1\}^n \) satisfies \( \text{supp}(x) \subseteq S \) and \( \|x_S\|_1 = k \).

Let \( p \in \{1,2\} \), and \( \nu \in \mathbb{R}^n \) satisfy \( \|\nu_S\|_\infty \leq \alpha \), \( \|\nu\|_p \leq r \), and \( \|\nu\|_\infty \leq D \) for some constants \( \alpha \leq 1/4 \) and \( D = O(1) \). Suppose \( A \in \mathbb{R}^{m \times n} \) is part of a \((1 + \epsilon)\)-approximate \( k \)-sparse \( \ell_p/\ell_p \) recovery scheme with failure probability \( \delta \).

Then, given \( A(x_S + \nu) \), Bob can with failure probability \( \delta \) recover \( x_S \) that differs from \( x_S \) in at most \( k/c \) locations, as long as either

\[
p = 1, s = \Theta\left(\frac{k}{c\epsilon}\right), r = \Theta\left(\frac{k}{c\epsilon}\right)
\]

or

\[
p = 2, s = 2k, r = \Theta\left(\frac{k}{c\epsilon^2}\right)
\]

**Proof.** For some parameter \( \mu \geq D \), let \( z_i = \mu \) for \( i \in S \) and \( z_i = 0 \) elsewhere. Consider \( y = x_S + \nu + z \). Let \( U = \text{supp}(x_S) \) have size \( k \). Let \( V \subset [n] \) be the support of the result of running the recovery scheme on \( Ay = A(x_S + \nu) + Az \).

Then we have that \( x_S + z \) is \( \mu + 1 \) over \( U \), \( \mu \) over \( S \setminus U \), and zero elsewhere. Since \( \|u + v\|_p \leq p(\|u\|_p + \|v\|_p) \) for any \( u \) and \( v \), we have

\[
\|y\|_p^p \leq p\big(\|y\|_p + \|\nu\|_p^p\big)
\]
\[
\leq p(s - k)\mu^p + r 
\]
\[
< p(r + s\mu^p).
\]
Since $\|\nu_S\|_\infty \leq \alpha$ and $\|\nu_D\|_\infty < \mu$, we have

$$\|y_U\|_\infty \geq \mu + 1 - \alpha$$
$$\|y_D\|_\infty \leq \mu + \alpha$$

We then get

$$\|y_T\|_p^p = \|y_T\|_p^p + \|y_{U \setminus V}\|_p^p - \|y_{V \setminus U}\|_p^p$$
$$\geq \|y_T\|_p^p + |V \setminus U| ((\mu + 1 - \alpha)^p - (\mu + \alpha)^p)$$
$$= \|y_T\|_p^p + |V \setminus U| (1 + (2p - 2)\mu)(1 - 2\alpha)$$

where the last step can be checked for $p \in \{1, 2\}$. So

$$\|y_T\|_p^p \geq \|y_T\|_p^p (1 + |V \setminus U| \frac{(1 + (2p - 2)\mu)(1 - 2\alpha)}{p(r + s\mu^p)})$$

However, $V$ is the result of $1 + \epsilon$-approximate recovery, so

$$\|y_T\|_p^p \leq \|y - \hat{y}\|_p \leq (1 + \epsilon) \|y_T\|_p$$
$$\|y_T\|_p^p \leq (1 + (2p - 1)\epsilon) \|y_T\|_p^p$$

for $p \in \{1, 2\}$. Hence

$$|V \setminus U| \frac{(1 + (2p - 2)\mu)(1 - 2\alpha)}{p(r + s\mu^p)} \leq (2p - 1)\epsilon$$

for $\alpha \leq 1/4$, this means

$$|V \setminus U| \leq \frac{2\epsilon(2p - 1)p(r + s\mu^p)}{1 + (2p - 2)\mu}.\tag{18}$$

Plugging in the parameters $p = 1, s = r = \frac{k}{d\epsilon}, \mu = D$ gives

$$|V \setminus U| \leq \frac{2\epsilon((1 + D^2)r)}{1} = O\left(\frac{k}{d}\right).$$

Plugging in the parameters $p = 2, q = 2, r = \frac{k}{d\epsilon^2}, \mu = \frac{1}{d\epsilon}$ gives

$$|V \setminus U| \leq \frac{12\epsilon(3r)}{2\mu} = \frac{18k}{d}.\tag{19}$$

Hence, for $d = O(e)$, we get the parameters desired in the lemma statement, and

$$|V \setminus U| \leq \frac{k}{2c}.\tag{20}$$

Bob can recover $V$ with probability $1 - \delta$. Therefore he can output $\hat{x}$ given by $\hat{x}_i = 1$ if $i \in V$ and $\hat{x}_i = 0$ otherwise. This will differ from $x_S$ only within $(V \setminus U \cup U \setminus V)$, which is at most $k/c$ locations. \qed
7.1 $k > 1$

Suppose $p, s, 3r$ satisfy Lemma 7.4 for some parameter $c$, and let $q = s/k$. The Gilbert-Varshamov bound implies that there exists a code $V \subset [q]^r$ with $\log |V| = \Omega(r \log q)$ and minimum Hamming distance $r/4$. Let $X \subset \{0, 1\}^r$ be in one-to-one correspondence with $V$: $x \in X$ corresponds to $v \in V$ when $x_{(a-1)q+b} = 1$ if and only if $v_a = b$.

Let $x$ and $v$ correspond. Let $S \subset [r]$ with $|S| = k$, so $S$ corresponds to a set $T \subset [n]$ with $|T| = kq = s$. Consider arbitrary $\nu$ that satisfies $\|\nu\|_p = \alpha \|x\|_p$ and $\|\nu\|_\infty \leq \alpha$ for some small constant $\alpha \leq 1/4$. We would like to apply Lemma 7.4, so we just need to show we can recover $x$ from $A(x + \nu)$ with constant probability. Let $\nu' = x_T + \nu$, so

\[
\begin{align*}
\|\nu'\|_p^p &\leq p(\|x_T\|_p^p + \|\nu\|_p^p) \\
\|\nu'_T\|_\infty &\leq 1 + \alpha \\
\|\nu'_T\|_\infty &\leq \alpha
\end{align*}
\]

Therefore Lemma 7.4 implies that with probability $1 - \delta$, if Bob is given $A(x_T + \nu') = A(x + \nu)$ he can recover $\hat{x}$ that agrees with $x_T$ in all but $k/c$ locations. Hence in all but $k/c$ of the $i \in S$, $x_{\{i-1\}q+1, \ldots, iq} = \hat{x}_{\{i-1\}q+1, \ldots, iq}$, so he can identify $v_i$. Hence Bob can recover an estimate of $v_S$ that is accurate in $(1 - 1/c)k$ characters with probability $1 - \delta$, so it agrees with $v_S$ in $(1 - 1/c)(1 - \delta)k$ characters in expectation. If we apply this in parallel to the sets $S_i = \{k(i-1) + 1, \ldots, ki\}$ for $i \in [r/k]$, we recover $(1 - 1/c)(1 - \delta)r$ characters in expectation. Hence with probability at least $1/2$, we recover more than $(1 - 2(1/c + \delta))r$ characters of $v$. If we set $\delta$ and $1/c$ to less than $1/32$, this gives that we recover all but $r/8$ characters of $v$. Since $V$ has minimum distance $r/4$, this allows us to recover $v$ (and hence $x$) exactly. By Lemma 7.3 this gives a lower bound of $m = \Omega(\log |V|) = \Omega(r \log q)$. Hence $m = \Omega(\frac{1}{c^2}k \log \frac{1}{\epsilon})$ for $\ell_1/\ell_1$ recovery and $m = \Omega(\frac{1}{e^2}k)$ for $\ell_2/\ell_2$ recovery.

7.2 $k = 1, \delta = o(1)$

To achieve the other half of our lower bounds for sparse outputs, we restrict to the $k = 1$ case. A $k$-sparse algorithm implies a 1-sparse algorithm by inserting $k - 1$ dummy coordinates of value $\infty$, so this is valid.

Let $p, s, 51r$ satisfy Lemma 7.4 for some $\alpha$ and $D$ to be determined, and let our recovery algorithm have failure probability $\delta$. Let $C = 1/(2r\delta)$ and $n = Cr$. Let $V = [(s - 1)C]^r$ and let $X = \{0, 1\}^{(s-1)C}$ be the corresponding binary vector. Let $X = \{0\} \times X'$ be defined by adding $x_0 = 0$ to each vector.

Now, consider arbitrary $x \in X$ and noise $\nu \in \mathbb{R}^{1+(s-1)C}$ with $\|\nu\|_p < \alpha \|x\|_p$ and $\|\nu\|_\infty \leq \alpha$ for some small constant $\alpha \leq 1/20$. Let $e^{0.5}$ be the vector that is 1/5 at 0 and 0 elsewhere. Consider the sets $S_i = \{0, (s - 1)(i - 1) + 1, (s - 1)(i - 1) + 2, \ldots, (s - 1)i\}$. We would like to apply Lemma 7.4 to recover $(x + \nu + e^{0.5})_{S_i}$ for each $i$.

To see what it implies, there are two cases: $\|x_{S_i}\|_1 = 1$ and $\|x_{S_i}\|_1 = 0$ (since $S_i$ lies entirely in one character, $\|x_{S_i}\|_1 \in \{0, 1\}$). In the former case, we have $\nu' = x_{S_i} + \nu + e^{0.5}$ with

\[
\begin{align*}
\|\nu'\|_p^p &\leq (2p - 1)(\|x_{S_i}\|_p^p + \|\nu\|_p^p + \|e^{0.5}\|_p^p) \\
\|\nu'_{S_i}\|_\infty &\leq 1 + \alpha \\
\|\nu'_{S_i}\|_\infty &\leq 1/5 + \alpha \leq 1/4
\end{align*}
\]

Hence Lemma 7.4 will, with failure probability $\delta$, recover $\hat{x}_{S_i}$ that differs from $x_{S_i}$ in at most $1/c < 1$ positions, so $x_{S_i}$ is correctly recovered.
Now, suppose $\|x_{S_i}\|_1 = 0$. Then we observe that Lemma 7.4 would apply to recovery from $5A(x + \nu + e^0/5)$, with $\nu' = 5x + 5\nu$ and $x' = e^0$, so
\[
\|\nu'\|_p^p \leq 5^p p(\|x\|_p^p + \|\nu\|_p^p) \leq 5^p p(r + \alpha^p r) < 51r
\]
\[
\left\| \frac{\nu_{S_i}'}{S_i} \right\|_\infty \leq 5 + 5\alpha
\]
\[
\left\| \nu_{S_i}' \right\|_\infty \leq 5\alpha.
\]
Hence Lemma 7.4 would recover, with failure probability $\delta$, an $\hat{x}_{S_i}$ with support equal to $\{0\}$.

Now, we observe that the algorithm in Lemma 7.4 is robust to scaling the input $A(x' + \nu')$ by 5; the only difference is that the effective $\mu$ changes by the same factor, which increases the number of errors $k/c$ by a factor of at most 5. Hence if $c > 5$, we can apply the algorithm once and have it work regardless of whether $\|x_{S_i}\|_1$ is 0 or 1: if $\|x_{S_i}\|_1 = 1$ the result has support $\text{supp}(x_i)$, and if $\|x_{S_i}\|_1 = 0$ the result has support $\{0\}$. Thus we can recover $x_{S_i}$ exactly with failure probability $\delta$.

If we try this to the $CR = 1/(2\delta)$ sets $S_i$, we recover all of $x$ correctly with failure probability at most $1/2$. Hence Lemma 7.3 implies that $m = \Omega(\log |X|) = \Omega(r \log \frac{1}{\delta})$. For $\ell_1/\ell_1$, this means $m = \Omega\left( \frac{1}{\delta} \log \frac{1}{\delta} \right)$; for $\ell_2/\ell_2$, this means $m = \Omega\left( \frac{1}{\sqrt{\delta}} \log \frac{1}{\delta} \right)$.
