ABSTRACT

We present results from the investigation of 5-min umbral oscillations in a single-polarity sunspot of active region NOAA 12132. The spectra of TiO, Hα, and 304 Å are used for corresponding atmospheric heights from the photosphere to lower corona. Power spectrum analysis at the formation height of Hα - 0.6 Å to Hα center resulted in the detection of 5-min oscillation signals in intensity interpreted as running waves outside the umbral center, mostly with vertical magnetic field inclination > 15°. A phase-speed filter is used to extract the running wave signals with speed $v_{ph} > 4 \text{ km s}^{-1}$, from the time series of Hα - 0.4 Å images, and found twenty-four 3-min umbral oscillatory events in a duration of one hour. Interestingly, the initial emergence of the 3-min umbral oscillatory events are noticed closer to or at umbral boundaries. These 3-min umbral oscillatory events are observed for the first time as propagating from a fraction of preceding Running Penumbral Waves (RPWs). These fractional wavefronts rapidly separates from RPWs and move towards umbral center, wherein they expand radially outwards suggesting the beginning of a new umbral oscillatory event. We found that most of these umbral oscillatory events develop further into RPWs. We speculate that the waveguides of running waves are twisted in spiral structures and hence the wavefronts are first seen at high latitudes of umbral boundaries and later at lower latitudes of the umbral center.

Keywords: Sun: sunspots-oscillation — Sun: magnetic fields — Sun: chromosphere

1. INTRODUCTION

The first observational evidence of running penumbral waves (RPWs) came from Giovanelli (1972) and Zirin & Stein (1972), who detected concentric intensity waves propagating outward through the penumbra of a sunspot in Hα and having azimuthal extents of 90° – 180° and sometimes 360°. These waves are considered to be magnetoacoustic modes, were observed to propagate with a phase velocity of 10−20 km s$^{-1}$ and exhibited intensity fluctuations in the range of 10% − 20%. Brisken & Zirin (1997) and Kobanov & Makarchik (2004) have revealed how the frequencies and phase speeds of RPWs vary from 3 mHz, 40 km s$^{-1}$ to 1 mHz, 10 km s$^{-1}$ from the inner penumbral boundary to outer penumbral edge, and becomes gradually invisible while approaching the outer boundary of the penumbra. Additionally, Kobanov (2000) has observed the propagation of RPWs in the chromosphere up to $\sim 15^\prime$ ($\sim 10,000 \text{ km}$) from the outer edge of the penumbral boundary, suggesting the Quiet Sun $p$-mode oscillations dominate at greater distances, hence overpowering the signatures of any remaining RPWs.

The origin of RPWs has been under debate over years since their discovery, with current research attempting to address whether they are trans-sunspot waves of purely chromospheric origin (e.g., Tziotziou et al. 2006, 2007 and references therein) or the chromospheric signature of upwardly propagating $p$-mode waves (Christopoulou et al. 2000, 2001; Georgakilas et al. 2000; Centeno et al. 2006). Zhao et al. (2016) have acknowledged that the coupling and interaction of the $p$-mode waves with the magnetized plasma can possibly cause the running waves. More recently, it has been suggested that RPWs are slow low-$\beta$ waves propagating upwards along inclined magnetic field lines (Bogdan & Judge 2006; Bloomfield et al. 2007; Jess et al. 2013; Madsen et al. 2015) facilitating the propagation of non-thermal energy into the corona. Some studies (Alissandrakis et al. 1992, 1998; Tsiropoula et al. 1996, 2000; Rouppe van der
Voort et al. 2003) show that they are waves originating from oscillating elements inside the umbra. According to some studies, RPWs and umbral oscillatory events belong to the same traveling wave system and probably the underlying driving physical mechanisms are same. Lites et al. (1998) proposed that either the RPWs are driven by the umbral oscillatory events or they share a common physical basis. The problem is that an indisputable physical model is not available which could attribute these two phenomena to the same driving mechanism and also explain their differences (periods of 3 and 5 min).

On the other hand, there is also evidence that umbral oscillatory events of the chromosphere are not the source of RPWs (Giovanelli 1972; Moore & Tang 1975; Christopoulou et al. 2000, 2001; Tziotziou et al. 2002; Kobanov & Makarchik 2004; Bloomfield et al. 2007). For example, Christopoulou et al. (2001) reported that RPWs are more closely associated with photospheric umbral oscillations than the chromospheric ones. Freij et al. (2014) observed RPWs within a solar pore and interpreted it as upwardly propagating waves (UPWs). They found that the power enhanced at the boundary of the pore at about 3-5 min whereas in the chromosphere where the UPWs are observed, the power reduced. Moreover, Kobanov & Makarchik (2004) found that in most cases the running umbral waves terminate rather abruptly at the umbral boundary and show no direct linkage with RPWs. That means not all 3-min wave fronts can be traced out from the umbra into penumbra. However, the question is where do the RPWs initially emerge in chromosphere: is it from the inner umbra or umbral boundary of sunspots? Further, how are they linked with umbral oscillatory events - this remains an open question. Here, we present the first observations of RPWs linked to previously occurring RPWs and their further development into new RPWs. We discuss, here, the study of the origin of emergence of RPWs from sunspots using the spectra of TiO, Hα, and 304 Å for various atmospheric heights from the photosphere to lower corona. By employing time series analysis of imaging observations, we track umbral oscillatory events and their association with the preceding and following RPWs. The paper is organized as follows. Section 2 details the observations and reduction of the data presented, Section 3 describes the analysis of the data and studies the umbral oscillatory events at different heights, and Section 4 summarizes and concludes.

2. OBSERVATIONS AND DATA PROCESSING

High-resolution observations were carried out of the leading sunspot of Active Region NOAA 12132, on August 5, 2014, from New Solar Telescope (NST, Cao et al. 2010) operating at Big Bear Solar Observatory (BBSO). We have employed the dataset already investigated by Su et al. 2016 to study the spiral structures of wavefronts in the sunspot. The sunspot of our observation is located at S09E08 as shown in Figure 1(a). Observations begun at 18:19 UT for a duration of 60 minutes. We used the broad-band filter imager of NST, with a field of view (FOV) of 70″ at 0.034′′ pixel−1 image scale to acquire continuum photospheric images every 15 s in TiO band (705.7 nm, 10 Å bandpass). We also employed the Visible Imaging Spectrometer of NST that has a single Fabry-Pérot etalon to produce a narrow 0.07 Å bandpass over a 70″ wide circular FOV at 0.034′′ pixel−1 image scale. The chromospheric images were thus acquired every 23 s by scanning the Hα spectral line from its blue wing -1 Å to red wing +1 Å with a step size of 0.2 Å. In addition, we also acquired the simultaneous space observations taken in 304 Å line (formed in the transition and lower corona) of the Atmospheric Imaging Assembly on Solar Dynamics Observatory (SDO/AIA, Lemen et al. 2012). We chose the first Hα – 1.0 Å image as a reference image to align all other images in this passband. The relative shifts were recorded, and used to register the images in the other passbands of Hα.

Similarly, using the reference image, alignment was easily executed for TiO images and one white-light image at 17:15 UT taken with the Helioseismic and Magnetic Imager (HMI, Schou et al. 2012) on board SDO. The aligned white light image was then used to co-align the 304 Å images. Finally, Fast Fourier Transform (FFT) was applied to the time-series images to generate the filtered component images, either in phase speeds of \( v_{ph} > 4 \) km s\(^{-1}\) (see Su et al. 2016) or centering at certain frequency (e.g., 3.33 mHz, 5.55 mHz, etc).

3. ANALYSIS AND DISCUSSION

3.1. High and low frequency oscillations at different heights

In Figure 1(a), we show the map of sunspot in TiO image and its corresponding magnetic field inclination map in Figure 1(b) acquired on 2014-08-05. The magnetic field inclination of different range (15°, 35° and 45°) is shown by different contours. We use these range of inclination to understand how the strength of oscillation varies from umbral center to umbral boundary.

Figure 2 shows the power maps of 3.8 − 8.0 min oscillations for the sunspot in the passbands of TiO, Hα = 1.0, -0.8, -0.6, -0.4, -0.2, 00 Å and 304 Å, respectively. It is clear from Figures 2 (a) and (b) that the power is much weaker in the sunspot than in the quiet Sun at the photosphere. However, the power in penumbrae becomes stronger with the increasing height (see Figures 2 (c) – (e)). Evidently, even with such high-resolution (0.1″) observations we still cannot
confirm the existence of 5-min oscillations in the chromospheric umbras (see Figure 2 (d) – (g)). Zhao & Chou (2013) suggested that resonant oscillations exist inside the sunspot, primarily inside the sunspot penumbra. In addition to the overall power enhancement over the penumbra, there are tiny speckles of power scattered everywhere. These tiny speckles are associated much with the bright superpenumbral fibrils. We made a circular slit as shown in Figure 2(e) and plot the intensity curve for TiO and power of Hα – 0.4 Å which is shown in Figure 3. It shows that there is probably, a slightly higher power concentration in the bright superpenumbral fibrils. We normalized the power spectra by adopting the method of division, wherein each point is divided with the value of maximum intensity inorder to compare the power spectra at different wavelengths and positions. The correlation coefficient for the two normalized intensity ≈ 0.36 showing a weak correlation between the intensity and power.

Figure 5 displays the power spectra of oscillations in the sunspot averaged over some circular slits with inclination in the range of 5 ° interval between 0° and 35° (e.g. 0 – 5°, 5 – 10°, upto 30 – 35°) in the passband of Hα – 0.4 Å (top panel), and averaged over a circular slit with 0 – 15° inclination in the passbands of TiO, Hα – 1.0, -0.8, ... and 304 Å (bottom panel). The noise in the data is removed by performing numerical differentiation on all time series of intensity. We concentrate more on low frequencies as low frequencies introduces less noise than the high frequencies. In Hα, beyond the photospheric penumbra, the high frequency power is almost undetectable while the low frequency power enhances. We find that most of the power in high-frequency oscillations (period = 1.7-3.8 min), is concentrated in the umbra (see Figure 4) whereas the power in low-frequency oscillations (period = 3.8-8 min) is concentrated in the penumbra. We arbitrarily take 3.8 min as the cut-off point of 3-min and 5-min band oscillations. In Figure 5(a), 5-min oscillations show their strongest signal appearing in the inclination range of 30 – 35°, which is close to umbral boundaries (see Figure 1). Subsequently, they decrease while approaching the umbra center and are nearly undetectable in the range of 15 – 20°. Figure 5(b) show 5-min oscillations are stronger at the formation heights of TiO and Hα – 1.0 Å. However, they become nearly invisible at the formation height of Hα – 0.8 Å.

We divided the power spectra in Figures 5(a) and 5(b) into two periodic ranges, 1.7 < P < 3.8 min (short) and 3.8 < P < 8 min (long), and the average power in the two ranges are shown in Figure 6. The variation in power with inclination is plotted in Figure 6(a). For the curve of 3.8 – 8 min, the power increases exponentially with inclination in the range of ~ 15 – 36°. Figure 6(b) demonstrates the variation in power with height. For the 3.8 – 8 min curve, it falls off exponentially with increase in height, and fades out while approaching the formation height of Hα – 0.4 Å. Generally, it is less than 5% for the transmission rate of 5-min oscillation power from TiO to Hα – 0.4, -0.2 and 0.0 Å. Thus, it seems no 5-min p-mode waves can propagate vertically from photospheric to chromospheric umbra (e.g., within 15° inclination range).

3.2. Time-distance diagram for umbral oscillatory events and RPWs

We constructed time-distance diagrams of the Doppler shift (difference of Hα – 0.4 Å and +0.4 Å), Hα – 0.4 Å and AIA 304 Å as seen in Figure 7, derived for the intensity averaged along a slit of ~ 3′ width shown in Figure 1. The connection between the events of umbral oscillations and RPWs are demonstrated in general. In terms of morphology, there is not much difference between panels (a) and (b) and they both show oscillations in umbral regions and wave propagations in penumbral regions. However, they are different from panel (c), that shows the oscillatory features in both umbra and penumbral regions. In the time-distance diagrams, we see a fork pattern forming around the umbral boundary in Figure 7 (a) and (b). This pattern is similar to the fork pattern seen by Chae et al. (2014) but the explanation is quite different. We speculate that the formation of this fork pattern indicates that the umbral oscillatory event emerges close to umbral boundary and propagates higher up and then a part of the wavefront segregates from the propagating wavefront as it reaches the umbral boundary and moves into the umbral center. This is explained in more detail in the following section. To gather more information, we use a slit and produce two other diagrams in the two time intervals of 18:29:53–18:42:52 UT and 18:43:15–18:56:14 UT, respectively as shown in Figure 8. In both the panels, there are 5 individual complete umbral oscillatory events, e.g., at 18:31:25 UT, 18:34:05 UT, etc (named after their kick-off time), but corresponds to 4 RPWs in panel Figure 8 (a) and only 3 RPWs in panel Figure 8 (b), respectively, which might be due to the merging of some of the umbral oscillatory events together or may be it could not propagate at all. Another puzzling feature is the association of some events of umbral oscillations with their preceding RPWs. For example, events of 18:31:25 UT and 18:34:05 UT were connected to their preceding RPW by some stripes, which indicates the inward propagation of the associated wavefront towards umbral center. In this paper, we report on 24 events of umbral oscillations in the time interval 18:19 to 19:19 UT (as shown in Table 1). We then proceed to investigate in detail two of these events by employing time series of imaging observations.

3.3. Imaging observations of umbral oscillatory events and RPWs
Table 1. Umbral oscillatory events and RPWs in the period of 18:19–19:19 UT.

| Umbral oscillations | Start time (UT) | θa (degree) | ă (degree) | Precedingb | Followingc | vrpw km s⁻¹ |
|---------------------|----------------|-------------|------------|------------|------------|-------------|

a Range of magnetic field inclination at the initial emergence of the umbral oscillatory event.

b Whether was the event related to its preceding RPW?

c Whether did the event develop into the following RPW?

Note—Symbol * denotes the following wavefront catching up and merging with its preceding one.

We investigate upon two typical umbral oscillatory events starting at 18:31:25 UT in panel (e) of Figure 9 and at 18:51:39 UT in panel (d) of Figure 10, respectively. For the first event, the three dark patches, A, B and C highlighted by red squares appeared initially close to/on umbral boundaries. It has central field inclinations of ∼35° (A), 25° (B) and 20° (C) respectively (see Figures 9(b) and (c)). A and B patches separated off from the umbral boundaries (see white arrows in panel Figure 9 (c)) and patch C stayed where it was. The three patches become enhanced at 18:31:02 UT and then shrink towards the umbral center (see the movie). At 18:31:25 UT the first event of umbral oscillation began as shown in Figure 8 (a).

Later, a dark circular patch formed at 18:31:48 UT in umbral center and the wavefront began to expand at 18:32:10 UT. In the meantime, the propagation in clockwise direction at the top takes a spiral form along the trajectory of wavefront (See Figure 9(g) – (i)). In Figure 9 (i), the spiral’s top end marked in a red square (denoted as A) separated from its main part and pushed itself towards the umbral center (see red circles in Figure 9 (j)) and a new oscillatory event began again (see Figure 9 and 8). We also notice that the spiral’s tail which has moved to umbral boundaries made anticlockwise motions along the boundaries as shown by arrows in Figure 9 (h) and (i). At 18:34:05 UT we mark it by a red square (denoted as B) in Figure 9(j) and at next time, it suddenly dived into umbral center to
merge with patch A. From then on, the merged patch expanded in radial direction (see Figure 9(j) – (l)). Also, it is immediately noticeable that the main part of the preceding wavefront crossed the umbral boundaries and became a circular trajectory of RPW.

It is seen in Figure 8 that the stripes are stacked reversely, slightly slanted from 18:33:42 UT to 18:35:14 UT suggesting an inward propagation of wavefronts. Figure 9(i) and (j) clearly show the spiral’s top end propagated downward which provided evident proof for this explanation. It is interesting that the stripes preceding and following the above ones also show this slanted feature.

Similarly, the second event occurring at 18:51:39 UT and in the period of 18:43:15-18:56:14 UT visualized in Figure 8 and Figure 10 showed similar behavior wherein the wavefront propagate towards the umbral center and merges with the preceding wavefront. A part of the merged wavefront jumps into the umbral center forming a new wavefront which ultimately results into a new umbral oscillation while the remaining wavefront crosses umbral boundaries to form RPW.

In summary, we have interpreted the developments of features of dark patches A or B in the above 5 events with the wavefront initially reaching umbral boundaries without showing any further propagation along radial and azimuthal directions. Then, it begins to propagate towards the umbral center the next moment. Hence, it appears to build a connection between the preceding and the following running waves. Some of the major features of umbral oscillatory events and RPWs are summarized in Table 1. It is important to emphasize that the wavefronts in some events were having multi-spiral structures and are complicated to determine their initial emergence, whether related to the preceding RPW or not, e.g., event 17 in the table.

3.4. Dominant oscillatory frequency in the sunspot umbra

The distribution of dominant oscillating frequency in the sunspot umbra for event 18:51:39 UT is shown in three phases (see Figure 11(a) – (c)): The initial emergence followed by its propagation towards umbral center and finally its development into RPW. The power of short period oscillation was weak at umbral center, before and after the wavefront propagation (see Figure 11 (a) – (b)). Also, one can see that the dominant periods are very much different along the wavefront direction, and the averaged periods over the wavefront edges in the panels are $2.7 \pm 5.3$ min, $2.8 \pm 5.9$ min and $4.0 \pm 7.0$ min, respectively. This may indicate that the running waves in the sunspot are broadband waves.

3.5. Active Region NOAA 12127

We find similar phenomena occurring in a sunspot of AR NOAA AR 12127. This AR has a complicated morphology due to its light bridges. Figure 12(b) – (d) show power maps of 3.8 – 8.0 min oscillations of the sunspots in the passbands of TiO, Hα – 0.4 Å and Hα-line center. The complicated morphology of the object may impede the revealing of the general regularities and patterns in the observed phenomenon. Inspite of this, it is clearly seen in Figure 13 that the wavefront emerged at the center of the umbra, then expanded and rotated clockwise. The wavefront propagates in both azimuthal and radial directions. It takes a spiral form and moves towards the umbral center and a new oscillatory event begins similar to the events in AR NOAA 12132.

4. CONCLUSIONS

We have performed high-resolution imaging observations of active region NOAA AR 12132 to investigate umbral oscillatory events and RPWs. The main results are the following: The long period (e.g., 3.8 – 8.0 min) oscillations are hardly detectable within 15° field inclination range in the chromospheric umbra which is consistent with the theory of MHD waves propagating in a simple, vertically gravitationally stratified atmosphere. The power observed in passbands of Hα – 0.4, Hα – 0.2 and Hα line center is only 5% of that observed in TiO, suggesting that there is only 5% transmission rate for 5-min oscillation power from TiO to Hα – 0.4, -0.2 and line center. Moreover, with imaging filtered observations we find that most of the umbral oscillations initially emerges either at or close to umbral boundaries and also are a part of the preceding RPWs. This new result is also consistent with MHD wave propagation in inclined magnetic field embedded in gravitationally stratified plasma. These fractional wavefronts are found to be separated from the preceding wavefronts and moves into the umbral center, where they expand radially and begins as a new oscillation (An animation showing this phenomena is available online). A closer look at Figures 7(f) reveals that the new wavefront emerges at the umbrel center. The panels in Figures 7(a) – (e) shows that the umbral oscillatory events are related to the preceding RPWs whereas the panels in Figures 7(g) – (l) shows that the umbral oscillatory events are related to the following RPWs. In this way, nearly all umbral oscillatory events connect to the earlier occuring RPWs and also develop into new RPWs . This kind of connection between the umbral oscillatory events and
RPWs is reported for the first time through this work. Also, along the wavefront edges, the period of running waves show a large spread. We finally remark that our new results contribute to an observational evidence about how an umbral oscillation is associated with a preceding and following RPWs.

Figures 7 and 9 clearly demonstrates that the wavefronts form a spiral structure suggesting the waveguides to be twisted (see, e.g. Bharti et al. 2010). This observational fact might be the reason why we first see wavefront at high latitudes and then at lower latitudes at umbral center. However, the problem is still not resolved: RPWs being closely associated with the events of umbral oscillation, but outside the umbral boundaries 5-min signals go undetected. It has been interpreted earlier that on highly inclined magnetic flux tubes, with the cutoff period increase generates magnetoacoustic portals for the propagation of long-period magnetoacoustic waves in the chromosphere which is also referred to as the leakage of p-modes or photospheric oscillations (see, e.g. De Pontieu et al. 2004) into the chromosphere. It is worth mentioning that through MHD simulations Khomenko et al. (2008) demonstrates that 5 minute oscillations can leak into the chromosphere through small-scale vertical magnetic flux tubes due to the efficiency of energy exchange by radiation in the solar photosphere that can lead to a significant reduction of the cutoff frequency and may allow the propagation of the 5 minute waves vertically into the chromosphere. We interpret that, to a certain extent, this mechanism strongly supports our observation.

5. ACKNOWLEDGMENTS

This work is supported by National Basic Research Program of China under grant 11427901, 11773038, 11373040, 11303052 and 11303048. BBSO operation is supported by NJIT, US NSF AGS-1250818 and NASA NNX13AG14G, and NST operation is partly supported by the Korea Astronomy and Space Science Institute and Seoul National University, and by strategic priority research program of CAS. T.G.P would like to acknowledge the financial support from CAS-TWAS Presidents PhD fellowship - 2014. R.E is grateful to the Science and Technology Facilities Council (STFC) UK and The Royal Society, UK. R.E also acknowledges the support received by the CAS Presidents International Fellowship Initiative, Grant No. 2016VMA045, and the warm hospitality received at NAOC of CAS, Beijing, where part of his contribution was made. We thank referee for the review and for useful comments and suggestions.

**Figure 1.** Maps of the leading sunspot in active region NOAA 12132 on August 5, 2014. (a) is a TiO image, in which a rectangle region marked by dotted lines is selected to be analyzed later. White contours represent the inclinations of 15°, 35° and 45° and blue contour in (a)–(c) denotes the umbral boundaries (45% of the maximum intensity). (b) is a Hα – 0.4 Å image. (c) is a field inclination image.

**Figure 2.** Power maps of the sunspot. (a)–(h) are spatial distribution of the normalized Fourier power for 3.8 – 8.0 min oscillations taken in the indicated passband. Umbral regions of sunspots are shown in white contours and penumbral regions in yellow contours (see Figure 1).
Figure 3. TiO intensity and Hα − 0.4 Å oscillation power averaged over the circular slits shown in Figure 2.

Figure 4. Similar to Figure 2 but for the higher frequency oscillations in a range of 1.7 − 3.8 min.
Figure 5. (a) Averaged power as a function of field inclination in the passband of \( \text{H} \alpha - 0.4 \text{ Å} \). (b) shows averaged power in a range of \( 0 - 15^\circ \) as a function of passbands TiO, \( \text{H} \alpha - 1.0 \text{ Å} \), ... and 304 Å.

Figure 6. (a) Power spectra of \( \text{H} \alpha - 0.4 \text{ Å} \) averaged over a circular slice with inclination range of \( 0 - 5^\circ \), \( 5 - 10^\circ \), ..., and \( 30 - 35^\circ \) in the sunspot, where the dotted-line gives the limits of the umbra and the penumbra. (b) shows spectra of TiO, \( \text{H} \alpha - 1.0 \), ..., 0.0 Å and 304 Å, averaged over a circular slice with \( 0 - 15^\circ \) inclination. For better visualization, each curve added with 9 starting from \( 5 - 10^\circ \) line in (a) and 6 from \( \text{H} \alpha - 1.0 \) Å in (b).
Figure 7. Time-distance diagrams of the Doppler shift (difference of Hα ± 0.4 Å), Hα – 0.4 Å and AIA 304 Å, derived for the intensity averaged along the width of the slice shown in Figure 1 for the entire time sequence. White dashed line marks umbral boundary. The data in (b) marked by the arrows are to be analyzed in the following figure.
Figure 8. Time-distance diagrams for the slice shown in Figure 1 within the periods of 18:29:53–18:42:52 UT (a) and 18:43:15–18:56:14 UT (b). White dashed line marks umbral boundary.

Figure 9. (a) is a TiO map for reference and white dotted contours in it and the other panels mark umbral boundaries. (b) – (l) are the time series of filtered Hα – 0.4 Å images with phase speeds > 4 km s⁻¹, on which circles are superposed to highlight the trajectories of running wavefronts. Red squares and capital letters A,B and C mark initial emerging locations of the next umbral oscillatory event. An animated movie is available online.
Figure 10. Similar to Figure 9, but for umbral oscillatory events of 18:51:39 UT and 18:53:57 UT.

Figure 11. (a) – (c) are distributions of dominant oscillatory frequency in the sunspot umbra, obtained with wavelet analysis for the time series of Hα – 0.4 Å filtered images. (d) – (e) are the corresponding Hα – 0.4 Å filtered images for event of 18:51:39 UT in the three phases, first emerging, propagating to umbral center and developing into RPW highlighted with circles. White contours in all panels denote umbral boundaries.
Figure 12. Maps of main sunspots of AR 12127. (a) show the location of sunspots in TiO image. (b) – (d) are corresponding spatial distribution of normalized Fourier power for 3.8 – 8.0 min oscillations taken in the indicated passband. Note that umbral regions of sunspots are shown in white contours.

Figure 13. (a) is a TiO map for reference and the white dotted contours marks the umbral boundaries. This shows the temporal evolution of the filtered Hα – 0.4 Å images with phase speeds $v_{ph} > 4$ km s$^{-1}$. Blue dots show the directions of wave propagation.
