Traditional travel survey methods have been widely used for collecting information about urban mobility although Global Position System (GPS) has become an automatic option for collecting more precise data of the households since mid-1990s. Many studies on mobility patterns have focused on the GPS advantages leaving aside its issues such as the quality of the data collected. However, when it comes to extract the frequency of the trips and travelled distance, this technology faces some gaps due to the related issues such as signal reception and time-to-first-fix location that turns out in missing observations and respectively unrecognised or over-segmented trips. In this study, we focus on two aspects of GPS data for a car-mode, (i) measurement of the gaps in the travelled distance and (ii) estimation of the travelled distance and the factors that influence the GPS gaps. To assess that, GPS tracks are compared to a ground truth source. Additionally, the trips are analysed based on the land use (e.g. urban and rural areas) and length (e.g. short, medium and long trips). Results from 170 participants and more than a year of GPS-tracking show that around 9% of the travelled distance is not captured by GPS and it affects more short trips than long ones. Moreover, we validate the importance of the time spent on the user activity and the land use as factors that influence the gaps in GPS.

**1. INTRODUCTION**

Traditional travel survey methods have been widely used in transportation research as a tool for collecting information at an individual or household level (e.g. description of demographics, travel patterns, trip purpose and mode choice) (Handy, 1996). Yet, respondents have the tendency to omit short stops such as the post office and ATM and when it comes to numerical answers, travel time is rounded to simple values like 10, 15, 30-minute interval. Similar happens to the travelled distance (Wagner, 1997). Nonetheless, since the introduction of the Global Positioning System (GPS) and its first adoption in transportation studies in mid-1990s, where Wagner (Wagner, 1997) reports one of the first studies that uses GPS for collecting information of 100 households through logger devices installed in their vehicles, it has been extensively used in combination with others datasets. Studies (Yalamanchili et al., 1999; Draijer et al., 2000; Wolf et al., 2000) have already demonstrated the possibility to use GPS data in Transportation research by capturing the characteristics of different types of trips. Later studies (Bolbol et al., 2012; Schuessler et al., 2015) evaluated the use of processed GPS data for both trip tracking and transportation mode detection without the support of questionnaires. Their results showed that trip identification deviates slightly from the census data, whereas
for mode detection it was not possible to distinguish between transportation modes with similar speed such as bus and car trips. Trip reporting and therefore travelled distance are challenging issues that can be achieved by detecting the transition between transportation modes although, if many transitions are detected for a single-mode trip, it turns out in over-reporting of trips and under-reporting of distance. In other studies (Zhang et al., 2013; Zheng et al., 2010), where the GPS trajectories are split using features such as speed and distance, it applies a good common-sense knowledge of the world describing that the start and end points of a walk segment may be changes of transportation mode. Liao et al. (2007) use the probabilistic approach to estimate those changes. Zheng et al. (Zheng et al., 2008) show that extracting trip frequencies is a challenging task despite his method’s classifying transportation-mode with an accuracy of 76 %, the precision for trip counting is below 30 % due to the over-segmentation, which actually shows that many studies report the classification error as a proportion of miss-classification regardless the over-segmentation. A way to overcome that is by merging the consecutive trips with similar transportation mode using heuristics on the distance and time between trips or by smoothing the classification outcomes (Lopez at al., 2015).

However, signal reception and time-to-first-fix (TTFF) are well known issues of GPS, both of them affecting the reported distance (Flamm et al., 2007). Signal reception is mainly influential for external factors that can block or reflect the signal, it can lead with either signal loss due to poor satellite reception (e.g. underground travel, bridges and tunnels) or multi-path errors referred to as urban canyoning errors because they appear in urban canyons where the signal is reflected by buildings (Schuessler and Axhausen, 2008). TTFF also referred to as cold / warm start is the delay in getting the first observation when the GPS device has been off for a period of time, which turns out in missing observations at the beginning of the trip (Stopher et al., 2005).

In this study, we use tracking data from a fleet of shared cars to (i) assess the gaps present in the GPS-based distance and their possible effect in mobility studies, and (ii) to estimate the travelled distance and the relevant factors that influence the GPS gaps. To accomplish the previous points, we need a ground truth source that reports the driven kilometres when the car is used, therefore the odometer-sensor is chosen and its data is accessible through the Controller Area Network bus (CAN-bus) (I. S. O. Standard, 1993). CAN-bus is known as a protocol for high performance and highly reliable serial communication links between electronic control units in the field of automotive and industrial control applications (Turski, 1994), e.g. it is typically used to control and automatically calibrate the engine performance in a vehicle. It was developed as a multi-master message broadcast system (Farsi et al., 1999) where each element on the network can send a message (e.g. temperature, state of charge) independently to the entire network, the bus priority being defined by the message identifier (Bosch, 1991). The dataset contains information about the car reservation including the total distance, reservation period (e.g. duration), identifiers (cars/client/reservation), start and ending times.

A limitation of this dataset concerns its granularity at the reservation level. Therefore, the reservation period represents the total duration of the reservation rather than the travel time. As an illustration, a reservation starts when the car is picked up from the car charging station and it ends when the car returns back to the charging station. Consequently, the reservation period contains not only the travel time, but also the time spent on the participant activities, e.g. doing shopping, visiting someone, etc. Nonetheless, the travelled distance and the starting time (the first
Trip segment) are not affected by the aforementioned limitation.

GPS has been used in several studies (Section 1). It allows tracking targets through their geographical location, where a GPS logger is a device for collecting locations and other measurements such as speed, altitude, heading, accuracy and timestamp. It can have either a built-in or external antenna and the data can be stored in the internal memory for being downloaded later on, or sent to a centralised repository through the network. For collecting the data, a GPS logger GenLoc 53e (Erco and Gener genlog53e, 2016) is installed in the cars. The device can send the tracking data through the cellular network to a centralised system in which it is processed. The frequency of 1 Hz is used for collecting the GPS data and the logger only collects observations when the car is turned on (i.e. the GPS logger automatically starts when the car is turned on and stops when the car is turned off); therefore, it can occur that a single reservation includes more than one trip, which is expressed as follows:

\[ R_i = \{ S_{i1}^{(1)}, \ldots, S_{im}^{(i)} \} \] (1)

where \( R_i \) represents the ith reservation, \( S_{ij}^{(i)} \) is the jth trip segment within a reservation \( R_i \), such as \( S_{ij}^{(i)} \in \{ S_{i1}^{(i)}, \ldots, S_{im}^{(i)} \} \) and \( m \) is the number of trip segments per reservation.

### 2.2. Data Quality

To assess the quality of the GPS-based distance, we calculate the missing distance and the TTFF using the following formulas:

\[
\text{Missing distance}_{\text{prop}} = \frac{\sum_{S_{ij}^{(i)} \in R_i} d(S_{ij}^{(i)})}{\sum_{j=1}^{N} d(R_i)}
\] (2)

\[
\text{Missing distance}_{\text{avg}} = \frac{1}{N} \sum_{j=1}^{N} \left( d(R_i) - \sum_{S_{ij}^{(i)} \in R_i} d(S_{ij}^{(i)}) \right)
\] (3)

\[
\text{TTFF}_{\text{avg}} = \frac{1}{N} \sum_{j=1}^{N} \left( t(S_{ij}^{(i)}) - t(R_i) \right)
\] (4)

where \( d() \) and \( t() \) are functions to extract the distance and start time respectively, \( S_{ij}^{(i)} \) represents the first trip segment of a reservation \( R_i \) and \( N \) is the number of observations.

Equation 2 is the proportion of the missing distance and it calculates the overall missing distance for all reservations. Nevertheless, it can also be applied to a set of trips based on some conditions such as land use and trip groups. However, this formulation faces two possible outcomes: when the outcome is positive, it represents an under-reported distance, whereas it is negative when the distance is over-reporting. This last scenario can be explained by the GPS accuracy because under certain conditions (e.g. tunnel, bridge, parking lots) it turns out in jumps around the same location. Those points can add an extra distance to the trip.

Equation 3 is the average missing distance and it is expressed in kilometres. Equation 4 is the average of time-to-first-fix; it calculates an average of time difference between the reservation start time and the timestamp of the first GPS location.

### 2.3. Land Use

The key research focus of this study is to assess the GPS gaps, where the land use provides an extra perspective to analyse those gaps in rural and urban areas, given that the GPS signal reception could be affected due to the high density of large structures (e.g. buildings, bridges). A GIS tool allows to identify the land use of a trip (Stopher et al., 2008), i.e. whether a trip was performed on a rural or urban area, in such a way that trips are matched within an administrative area (boundary area classified as rural or urban) using the origin and destination points. Consequently, a precise land use identification relies on the completeness of the geographical information for the administrative areas.

The administrative areas (in which the trips were performed) are extracted from ©OpenStreetMap contributors (OSM) (OpenStreetMap contributors, 2016). OSM is an open access platform for geospatial vector data and it is often considered complete and appropriate for planning studies in comparison to other commercial counterparts (Hochmair et al., 2013).

### 2.4. Regression Method

To explain gaps in the GPS data, the factors that influence data collection are identified through a linear regression. Linear regression methods are techniques for modelling the relationships between a scalar dependent variable and its explanatory or independent variables known as covariates. That relationship is modelled by an error term \( \epsilon \), a random variable that adds noise to the linear relationship between the dependent and independent variables (Neter et al., 1996). Therefore, the model is expressed as follows:
where $y$ is the dependent variable or response variable, $X$ represents the explanatory variables, $\beta$ the regression coefficients or effects and $\varepsilon$ is the error term.

\[ y = X\beta + \varepsilon \]  

**Figure 1.**
Travelled distance density based on land use for GPS logger and CAN-bus data.

### 3. CASE STUDY

The data on this study are part of the Olympus project, a Flemish initiative to promote the introduction of electric vehicles in Belgium. It was a common project between suppliers, integrators and users of shared mobility, aiming at developing tools and systems to enhance multimodal travel behaviour. Therefore, the multimodal travel behaviour was monitored both from the vehicle perspective and from the personal perspective. From the vehicle perspective, GPS loggers were installed on shared electric cars, showing how these were used in terms of frequency, trip length, origins and destinations.

Data collection was performed between 2012 and 2013 in the Belgian cities Ghent, Antwerp and Leuven, involving 170 participants.

#### 3.1. Descriptive Analysis

A summary of the travelled distance reported by the CAN-bus data and GPS logger is depicted in Table 1, where we can notice clear differences on the reported average distances.
In order to obtain an analysis at different levels, we group the trips based on the travelled distance into three categories such as short, medium and long trips. The conditions for those groups are depicted in Table 2.

### Table 1.
A summary of the travelled distance (km).

| Data         | Min | Median | Mean | Max  |
|--------------|-----|--------|------|------|
| CAN-bus      | 2.0 | 19.0   | 23.9 | 106.0|
| GPS Logger   | 0.6 | 17.2   | 21.8 | 104.6|

3.2. Distance Measurement Gaps

For the travelled distance by car, we consider the missing distance as the difference between the odometer distance (e.g. distance obtained from the CAN-bus data) and the logging distance (e.g. distance reported by the GPS logger) as it Equation (2) shows. It shows that on average 9% of the travelled distance is not captured by the GPS logger (Figure 2). This means that for an average trip with distance 23.9 km the GPS will report on average 2.1 km less (Table 1).

From the groups, we calculate the travelled distance for both GPS and CAN-bus data. Figure 3 shows the missing data for short, medium and long trips within groups of different land use.

Figure 1 shows the distance density on rural and urban areas based on CAN-bus and GPS data, where the GPS density curve is shifted to the left side with respect to CAN-bus in both rural and urban areas. This is another indication of missing distance based on different land use.

Those groups and the land use allow to identify which type of trips are mainly affected when it comes to GPS tracking.

**Table 2.**
Group of trips based on the travelled distance.

| Group   | Description      |
|---------|------------------|
| Short trip | less than 10 km. |
| Middle trip | between 10 and 25 km. |
| Long trip   | more than 25 km- |

**Figure 2.**
Global missing distance for a car mode using GPS.
Table 3 shows that short and medium trips in urban areas are the ones that report high values of missing distance, logging around 81% and 83% of the travelled distance respectively. It also shows that long trips in both urban and rural areas perform better than the rest, logging 92% and 95% respectively. On average, trips on rural areas report less missing data than urban areas.

| Group | Trips | Median (min) | Average (min) | Average (km) | Percentage |
|-------|-------|--------------|---------------|--------------|------------|
| Rural | Short | 82 | 4.6 | 7.8 | 0.9 | 11.9% |
|       | Medium | 190 | 6.1 | 7.0 | 1.9 | 10.1% |
|       | Long | 292 | 5.6 | 8.3 | 2.0 | 4.6% |
| Urban | Short | 161 | 5.5 | 16.5 | 1.4 | 19.3% |
|       | Medium | 326 | 5.9 | 10.8 | 2.9 | 16.9% |
|       | Long | 189 | 6.2 | 7.8 | 3.6 | 8.5% |

To our understanding, part of the missing data could be related to the cold / warm start issue that is present on the GPS technology, where it is required a period of time before fixing the first location. Therefore, we assess TTFF with Equation (4) that uses the starting time of the trip.

![Figure 3](image-url)

**Figure 3.** Percentage of missing data for different group of trips, logging distance is the distance reported by the GPS logger and missing distance is the difference with respect to ground truth (CAN-bus).
3.3. Explanatory Factors

To explain the travelled distance a regression model is fitted to the GPS data, where the dependent variable is provided by the CAN-bus data as a travelled distance and from the GPS data we extract the covariates such as distance, duration, average speed and number of trips per reservation.

Others covariates such as land use are obtained using GIS, where the origin and destination points are used for classifying the trips within a rural or urban area. Finally, the time spent on the user activity (purpose of mobility) is calculated from the reservation time and the trip duration. A full description of the covariates is presented in Table 4.

A summary of the fitted models is depicted in Table 5, where the covariate coefficient is estimated using a regression model and its significant level is based on the p-value. Based on model

| Covariate                  | Description                                           | (1)  | (2)  | (3)  | (4)  | (5)  | (6)  | (7)  |
|----------------------------|-------------------------------------------------------|------|------|------|------|------|------|------|
| Distance                   | Logging distance from the GPS data (km)               | 0.976***  | 1.032***  | 1.044***  | 0.888***  | 0.905***  | 0.920***  | 0.930***  | 0.013 |
| Duration                   | Travelled time for the logging distance (min)         | -0.047***  | -0.061***  | 0.019 (0.024) | 0.019 (0.024) | 0.019 (0.024) | 0.019 (0.024) | 0.013 |

| Urban area                 | Land use for the trip (e.g. urban, rural)             | 1.062***  |                             |                             |                             |                             |                             | 1.062 |
| Constant                   |                                                        | 2.837***  | 3.698***  | 3.247***  | 0.535 (1.060) | 0.457 (0.477) | 0.709 (0.482) | -0.076 (0.565) | 0.324 |
| AIC                        |                                                        | 1967  | 1957  | 1956  | 1949  | 1928  | 1923  | 1916  | 1916 |
| BIC                        |                                                        | 1979  | 1972  | 1976  | 1968  | 1947  | 1946  | 1940  | 1940 |
| R²                         |                                                        | 0.944  | 0.946  | 0.946  | 0.948  | 0.950  | 0.951  | 0.952  | 0.944 |
| Adjusted R²                |                                                        | 0.944  | 0.946  | 0.946  | 0.947  | 0.950  | 0.951  | 0.952  | 0.944 |

Note: *p<0.1; **p<0.05; ***p<0.01

Covariates: coefficient and coefficient error in brackets.
AIC: Akaike information criterion, BIC: Bayesian information criterion.
3 the number of trip segments does not seem to be significant. On the other hand, from model 4 we can notice that the average speed is a good predictor and makes the duration less significant.

Time spent shows significant results on model 5. It means that the waiting time within trips (e.g. time when the car is parked) is an important factor for modelling the travelled distance because it adds more periods of cold / warm start to the GPS logger (i.e. a longer waiting time increases the chances of missing data). It is even more significant when it is combined with the trip segments as an average of time spent on a particular activity per trip segment (e.g. time spent over trip segments). Land use is another influential variable; its coefficient indicates that for each trip in the urban area it will add around a kilometre to the total distance. Based on the R² model 7 explains better the travelled distance as a function of the covariates: distance, average speed, time spent per trip and land use.

4. CONCLUSION

In this paper, the gaps in the GPS-based distance using CAN-bus data as a ground truth are measured; likewise, the factors that influence those gaps were identified through regression models. It was found that 9% of the travelled distance is not captured for the GPS logger. This is important considering that many mobility studies are being conducted using GPS data, and their outcomes might underestimate the actual travelled distance. However, it will depend on the type of land use where the trips are carried out. In our findings, the rural area reports 6% of missing distance whereas the urban area reports about 13%. It is a clear indication that urban areas are more susceptible to issues related to the signal reception affected in around one kilometre to the reported distance (based on the model 7).

Moreover, the model also includes the cold / warm start as a function of the time spent on the user activity per trip, which provides an average waiting time between trips. This last factor should be considered when it comes to the trip reporting because in real situations round trips have more than a single trip and long periods of waiting time. Consequently, it adds a delay for getting the first valid location.

Part of the missing distance could be corrected by interpolating the missing GPS points within a trip. Using a road network is feasible to route (provide alternative trajectories between two points by a given transportation mode) and align the points to a valid location. However, it becomes complicated when the missing part is at the beginning of the trip because there is not any reference point to interpolate that part. This is the case of the cold / warm start.

Our findings contrast with another study (Vlassenroot et al., 2014) that reports 4% of the missing data (comparison among theoretic GPS points rather than travelled distance) for a driving mode using smartphones as tool for GPS data collection. However, a smartphone does not have long periods of being off; hence, we could assume that TTFF does not have much influence on the data collection.

Future directions are focused on the GPS data quality for other transportation modes (e.g. walking, biking and public transportation) and also the comparison among the methods for collecting data such as passive and active logging.
