Abstract

Background: The high co-occurrence of tobacco smoking and depression is a major public health concern during the novel coronavirus disease-2019 pandemic. However, no studies have dealt with missing values when assessing depression. Therefore, the present study aimed to examine the effect of tobacco smoking on depressive symptoms using a multiple imputation technique.

Methods: This research was a longitudinal study using data from four waves of the China Health and Retirement Longitudinal Study conducted between 2011 and 2018, and the final sample consisted of 74,381 observations across all four waves of data collection. The present study employed a multiple imputation technique to deal with missing values, and a fixed effects logistic regression model was used for the analysis.
**Results**: The results of fixed effects logistic regression showed that heavy smokers were 1.2 times more likely to suffer from depressive symptoms than those who never smoked. Compared to those who never smoked, for short-term and moderate-term quitters, the odds of suffering from depressive symptoms increased by 30% and 22%, respectively. The magnitudes of the odds ratios for the variables short-term quitters, moderate-term quitters, and long-term quitters decreased in absolute terms with increasing time-gaps since quitting.

**Conclusions**: The empirical findings suggested that among Chinese middle-aged and older adults, heavy smokers and short-term and moderate-term quitters were more likely to have depressive symptoms than those who never smoked. Moreover, former smokers reported that the probability of having depressive symptoms decreased with a longer duration since quitting. These results may have important implications that support the government in allocating more resources to smoking cessation programs to help middle-aged and older smokers.

**Keywords**: smoking, depressive symptoms, multiple imputation, China

**Background**

Tobacco smoking is one of the biggest public health threats, resulting in more than 7 million deaths a year worldwide [1]. In China, 50.5% of adult men were current smokers in 2018, although the figure was only 2.1% for adult women. The prevalence of current smoking was 30.2% among adults aged 45-64 years and 23.1% among adults aged 65 years or older, implying that there are more than 163 million middle-aged and older adults who smoke in China. Even though tobacco smoking has been proven to be a major cause of diseases such as cancers, heart diseases, and respiratory diseases, only 16.1% of current smokers in China
plan to quit smoking within twelve months [2]. Meanwhile, depression is currently becoming a significant public health problem, with more than 300 million people estimated to suffer from depression worldwide [3]. The prevalence of depressive symptoms among older adults was 20.0%. Depression in late life is associated with an elevated risk of morbidity and suicide and decreased physical and cognitive functioning [4,5].

The novel coronavirus disease 2019 pandemic has led to adverse changes in health behaviors such as smoking and physical activity and widespread mental disorders such as depression and anxiety [6,7]. The high co-occurrence of tobacco smoking and depression is a major public health concern during this unprecedented crisis. The reciprocal relationships between tobacco smoking and depression have been widely documented; for example, depression is associated with later smoking behavior, and smoking exposure is associated with later depression [8-12]. Several previous studies have demonstrated an association between tobacco smoking and depression: tobacco smoking increases the risk of depressive symptoms. Such an association has been shown across different age groups, such as adolescents [13], adults[14,15], middle-aged and older adults [16,17], and elderly people [18]. Conversely, few studies have shown that tobacco smoking reduces depressive symptoms [19,20]. Furthermore, other studies have shown that depression predicts the persistence of tobacco smoking [21-25].

A previous study found that, among Chinese middle-aged and older adults, smokers were less likely to develop depressive symptoms, which is inconsistent with previous findings in developed countries [20]. The main reason for this finding may be that there were 1,965 missing 10-item Center for Epidemiologic Studies Depression Scale (CESD-10) baseline scores and 2,888 missing CESD-10 follow-up scores among respondents in both interviews. Missing values are a common challenge in most social research studies, and
the problem is often pronounced in studies using self-rated instruments. Similarly, previous studies on smoking and depression may have encountered the problem of missing values [26,27]. Missing values reduce statistical power, cause bias in the estimation of the parameters, and lessen the representativeness of the samples [28].

Missingness mechanisms were first introduced by Rubin in 1976 [29]. Rubin distinguished three fundamental missing-values mechanisms: missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). MCAR occurs when the missingness is unrelated to the observed and unobserved value for a unit. Under an MAR mechanism, the probability of a missing value for an item may depend on observed data but not on unobserved data. MNAR means that the probability of missingness depends on the underlying value of an item. Many researchers adopt a listwise deletion approach (complete-case analysis) to deal with missing values. This approach is based on the assumption of MCAR. However, this assumption is sometimes difficult to justify in practice [30]. Therefore, various imputation methods have been developed to compensate for missing values in survey data. The methods include random selection, preceding question, question mean, individual mean, single regression, and multiple imputation. Multiple imputation is the most accurate technique for dealing with missing values when assessing depressive symptoms [26].

Overall, the difficulty of estimating the effect of smoking status on depression has led to conflicting findings in the general population. Moreover, although the association between tobacco smoking and depression has been documented, thus far, there have been no studies dealing with missing values when assessing depression. To bridge these gaps, the present study is aimed to examine the effect of tobacco smoking on depressive symptoms using panel data with a multiple imputation technique.
Methods

Data Source

The data used in this study were obtained from the China Health and Retirement Longitudinal Study (CHARLS), launched by the National School of Development of Peking University. The CHARLS sample was drawn from 28 provinces, 150 counties/districts, and 450 villages/residential committees. Multistage stratified sampling with a probability proportional to size was used for the survey. More details on the sampling procedure and data collection process are available in the study by Zhao et al. [31]. The CHARLS questionnaires include sections on household information, demographic background, health status and physical functioning, health care and insurance, work, retirement, pension, income, expenditure, assets, housing characteristics, etc.

The CHARLS is a biennially longitudinal survey of Chinese families and individuals aged older than 45 years. In the first wave in 2011, 17,337 persons (older than 45 years old) were successfully interviewed; in the three waves of full sample follow-up surveys in 2013, 2015, and 2018, 18,248 persons, 20,083 persons, and 19,584 persons were successfully interviewed, respectively. The measured variables and their respective percentages of missing values are presented in Table 1. After eliminating the measured variables with missing values less than 1% (871 persons), the final sample consisted of a total of 74,381 persons for the data collection waves, 58,854 with no missing values and an additional 15,527 with missing values in at least one of the measured variables.

----------Table 1 about here----------

Measurements

Depressive symptoms
The CESD-10 was used to assess depressive symptoms in the CHARLS questionnaire. First, the CESD-10 was developed from the full-length version of the 20-item Center for Epidemiologic Studies Depression Scale (CESD-D), which was designed as a screening instrument for depressive symptoms in older adults [32]. Second, the CESD-10 indicated good predictive accuracy when compared to the CESD-D. Last, the CESD-10 has shown reasonable validity and reliability in the Chinese population and adequate validity across a range of ages in longitudinal studies [33,34].

In the CHARLS, each respondent was asked, ‘How often have you felt or behaved this way during the last week?’ The survey consists of 10 items (e.g., I felt depressed, I felt fearful, my sleep was restless, and I was happy), which can be rated on a 4-point Likert scale from 0 (less than 1 day) to 3 (5-7 days). The range of the CESD-10 total score is 0 to 30, and a cutoff score of 10 or higher indicates the presence of significant depressive symptoms [32]. Therefore, the variable of depressive symptoms was set as a dichotomous variable that equaled 1 if the individual self-rated CESD-10 score was equal to or greater than 10 and equaled 0 if otherwise.

Smoking status

In the CHARLS, each adult was asked, ‘Have you ever chewed tobacco, smoked a pipe, smoked self-rolled cigarettes, or smoked cigarettes/cigars?’ and ‘Do you still have a smoking habit or have you totally stopped smoking?’. According to these two questions, all adults were divided into three mutually exclusive groups: never smoked, current smokers, and former smokers. For further analysis, the present study categorized current smokers into three subgroups (light, moderate, and heavy smokers) based on their average cigarette consumption (‘In one day about how many cigarettes do you consume?’). Light smokers were current smokers who reported consuming from 1-10 cigarettes per day, moderate smokers were those who
consumed from 11-19 cigarettes per day, and heavy smokers were those who consumed 20 cigarettes or more per day. Former smokers were categorized into three subgroups (short-term, moderate-term, and long-term quitters) based on the total number of years since the respondents had quit smoking (‘At what age did you totally quit smoking?’): short-term quitters were former smokers who had quit smoking ≤1 year age, and moderate-term quitters and long-term quitters were former smokers who had quit smoking 2-5 years and ≥6 years age, respectively [35].

Covariates

The analysis also considered the following three categories of variables as covariates to explain depressive symptoms: (1) current health-related factors, including self-rated health, functional limitations, and chronic conditions; (2) several demographic characteristics that may also affect depressive symptoms, such as sex, age, educational attainment, marital status, and rural residency; and (3) in addition to smoking, another health behavior factor included in the analysis was drinking. The definitions of the covariates are provided in Table 2.

---Table 2 about here---

Multiple imputation of missing values

During the CHARLS investigation, the respondents were not required to answer any question in the cognition and depression section that they do not want to answer, and the interviewers went on to the next question. Moreover, the CESD-10 must be answered by the respondents themselves and cannot be answered by other family members. As a result, the proportion of missing values for the CESD-10 items was approximately 10% (see Table 1). In addition, the respondents who smoked filtered or unfiltered cigarettes answered the question about average cigarette consumption. The respondents who smoked a
pipe, self-rolled cigarettes, cigars, or water cigarettes skipped the average cigarette consumption question. Therefore, missing values accounted for approximately 12% of the values for the variable of smoking status. The present study adopted the MAR assumption and employed a multiple imputation technique to deal with missing values.

Multiple imputation is a simulation-based statistical technique that allows researchers to increase the availability of data points, thus reducing biases associated with the deletion of observations due to missing values [36]. Multiple imputation has three elemental phases: imputation, analysis, and pooling. In the imputation phase, \( m \) copies of the dataset are created, with the missing values replaced by imputed values using an appropriate model. Rubin suggested that \( m=5 \) should be sufficient to obtain valid inference [37]. Therefore, 5 copies were created in this study to reduce the sampling error due to imputations. The imputation process was carried out based on multiple imputation by chained equations (MICE). MICE is a practical approach to impute missing data for multiple variables based on a set of univariate imputation models [38]. The present study selected conditional models based on the type of variables. MICE allows the use of logistic and Poisson regression models to impute binary variables, such as rural residency, and count variables, such as chronic conditions. Moreover, ordered logistic and multinomial logistic regression models can impute ordered categorical variables such as the CESD-10 items, educational attainment, and self-rated health, and unordered categorical variables, such as smoking status. Multiple imputation should include variables associated with the probability of missing values [39]. The variables listed in Table 2 were used in the imputation models.

In the analysis phase, each of the 5 completed datasets was analyzed using a desired statistical method. The results obtained from 5 the completed datasets were combined into a single multiple-imputation result
in the pooling phase. The single parameter estimate is calculated as the mean of the \( m = 5 \) parameter estimates of \( \hat{Q} \):

\[
\bar{Q} = m^{-1} \sum_{i=1}^{m} \hat{Q}_i
\]

The estimated variance of this MI estimate is calculated based on Rubin’s rules as expressed below:

\[
T = \bar{U} + (1 + \frac{1}{m})B
\]

where \( \bar{U} = m^{-1} \sum_{i=1}^{m} U_i \) is the estimated within imputation variance and \( U_i \) is the estimated variance from imputed data. \( B = (m - 1)^{-1} \sum_{i=1}^{m} (\hat{Q}_i - \bar{Q})^2 \) is the between imputation variance [30].

**Statistical analysis**

Depressive symptoms may be both an antecedent and a consequence of tobacco smoking [10]. Panel data, also referred to as longitudinal data in epidemiology, are a dataset in which observations of multiple subjects are collected over time. The benefit of panel data is that it is possible to control for the unknown or unmeasured determinants of depressive symptoms that are constant over time. Furthermore, since panel data cover repeated measures of tobacco smoking and depression symptoms, it is much easier to estimate whether changes in tobacco smoking precede changes in depressive symptoms or vice versa [40]. Based on a four-wave unbalanced panel dataset, the current study estimated the effect of tobacco smoking on depressive symptoms and used a logistic regression model. The logistic regression model built a latent regression and was defined as follows:

\[
y_{it} = x_{it}' \alpha + \beta_1 Hsmoker_{it} + \beta_2 Msmoker_{it} + \beta_3 Lsmoker_{it} + \beta_4 STsmoker_{it} + \beta_5 MTsmoker_{it} \\
+ \beta_e LTsmoker_{it} \mu_i + \varepsilon_{it}, \quad i = 1, \ldots, n, t = 1, \ldots, T_i
\]
$y_{it}$ is an unobserved latent variable linked to the observed binary response variable (with or without depressive symptoms). $x_{it}'$ is the vector of the demographic characteristics and health status of an individual. $Hsmoker_{it}$, $Msmoker_{it}$, $Lsmoker_{it}$, $STsmoker_{it}$, $MTsmoker_{it}$, and $LTsmoker_{it}$ are dummy variables that were defined as heavy smokers, moderate smokers, light smokers, short-term quitters, moderate-term quitters, and long-term quitters. $\mu_{i}$ is the unobserved and individual-specific heterogeneity, and $\epsilon_{it}$ is a time-varying error term.

A logistic regression model was performed to analyze the impact of tobacco smoking on depressive symptoms among middle-aged and older adults in China. The first step in the analysis, pooled logistic regression, was a starting point. After that, this study treated the data as a panel structure and made a choice between the fixed effects and random effects logistic model. In this study, a possible unobserved variable was attitudes toward smoking, which was correlated with the time-varying explanatory variables (tobacco smoking) in the model. With such correlated heterogeneity, a fixed effects logistic model should be preferred over a random effects logistic model; however, when estimating a fixed effects logistic model, many pieces of information are lost. A random effects logistic model was also presented in this study [40,41]. The results are presented as odds ratios (ORs) along with 95% confidence intervals (CIs). All statistical analyses were conducted employing the Stata 15 statistical software package.

**Results**

A descriptive summary of all variables over time is displayed in Table 3. The total sample size was 74,381 respondents, with 51.76% of the respondents being female and 32.61% aged 65 years or older. In addition, 77.88% of the respondents reported living in rural areas, and approximately 34% of the respondents completed at least middle school. The proportions of respondents with depressive symptoms were 37.55%
in Wave 1, 32.26% in Wave 2, 33.68% in Wave 3, and 38.50% in Wave 4, implying that the proportions of respondents with depressive symptoms first decreased and then increased. Approximately one in four respondents has been current smokers over the years, and the proportions of light, moderate, and heavy smokers were approximately 9%, 2%, and 14%, respectively. Moreover, approximately 10% of the respondents were former smokers from 2011 to 2018. Among former smokers, the proportions of short-term, moderate-term, and long-term quitters were approximately 2%, 2%, and 6%, respectively.

----------Table 3 about here----------

The results of the logistic regression analysis are shown in Table 4 as ORs. Column III of Table 4 presents the effect of tobacco smoking on depressive symptoms using the fixed effects logistic model. The results revealed that smoking status was associated with depressive symptoms. Heavy smokers were 1.2 times more likely to suffer from depressive symptoms than those who never smoked (OR=1.20; 95% CI: 1.05, 1.37). Compared to those who never smoked, for short-term and moderate-term quitters, the odds of suffering from depressive symptoms increased 30% and 22%, respectively (OR=1.30; 95% CI: 1.04, 1.63, OR=1.22, 95% CI: 1.02, 1.47). In particular, long-term quitters had an increased likelihood of suffering from depressive symptoms than those who never smoked, but the difference was not statistically significant. The magnitudes of the ORs for the variables short-term quitters, moderate-term quitters, and long-term quitters decreased in absolute terms with increasing time-gaps since quitting. Therefore, among former smokers, the probability of suffering from depressive symptoms decreased with increasing duration of since quitting smoking.

Irrespective of the estimation method, heavy smokers showed an increased probability of suffering from depressive symptoms compared to those who had never smoked. Short-term quitters showed an
increased probability of suffering from depressive symptoms compared to those who had never smoked (see Columns I-III of Table 4).

Discussion

To the best of our knowledge, this is the first research study that examined the effect of tobacco smoking on depressive symptoms among individuals aged 45 years or older in China using a nationally representative survey with a multiple imputation technique. The results indicated that among Chinese middle-aged and older adults, heavy smokers and short-term and moderate-term quitters were more likely to have depressive symptoms than those who never smoked after controlling for other relevant variables. Our findings are consistent with the findings for European middle-aged and older adults [16] and American middle-aged adults [17]. Therefore, local communities and primary care facilities should consider promoting health education programs for middle-aged and older smokers and improving their understanding of the hazards of tobacco smoking.

This type of analysis, however, does not identify pathways between tobacco smoking and depressive symptoms. One possible explanation is that smoking or chewing tobacco releases nicotine affecting an individual’s neurocircuitry, which increases their susceptibility to depression [13,15]. Another possible explanation is from a self-medication model, suggesting that smokers use nicotine to alleviate depressed mood [9,18,42].

This study found that short-term and moderate-term quitters were more likely to have depressive symptoms than those who never smoked regardless of the time elapsed since quitting, but the likelihood of having depressive symptoms declined with increasing time gaps since stopping smoking. Although the
causality between smoking cessation and depression cannot be established without a longitudinal follow-up design, the decline in the prevalence of depressive symptoms after one year of quitting implies that smoking cessation and depressive symptoms are related. These results are comparable to other findings in the literature [43-45]. In this study, former smokers reported that the probability of having depressive symptoms decreased with a longer duration since quitting, and hence, the earlier a smoker stops smoking, the greater the impact of smoking cessation on not being depressed. In other words, smoking cessation is an effective way to reduce middle-aged and older adults’ risk of depression. Therefore, the government should consider allocating more resources to smoking cessation programs to help adults and adolescent smokers quit as early as possible and/or to remain nonsmokers. It is also essential to tailor smoking cessation programs for middle-aged and older adults and help them quit smoking and prevent relapse.

Extensive health-related surveys, such as the CHARLS, provide numerous data regarding health-related behaviors and health outcomes. However, almost every analysis faces the annoying problem of missing data. Multiple imputation recovers a fully observed sample size. More importantly, multiple imputation restores the natural variability of the missing values. Recovering information and restoring variability may reduce bias or increase precision, which results in a valid statistical inference from multiple imputation [28,46]. It will be essential to employ multiple imputation in future analyses, when survey items on smoking status and depressive symptoms have a large number of missing values.

Although the current study employs a national survey with multiple imputation to analyze the effect of smoking status on depressive symptoms in Chinese middle-aged and older adults, several limitations should be emphasized. First, since the CESD-10 is a self-reported screening instrument for symptoms of depression and not a diagnostic tool, our analysis may have resulted in an underestimation of the
association between tobacco smoking and depressive symptoms. Second, the data were obtained via
surveys, and thus the limitations of all self-reported data exist, such as recall bias and the unreliability of
responses when respondents are under pressure. Third, when the respondents’ unchanging depressive
symptoms across all four waves did not contribute to the likelihood, the results of the fixed effects model
could be less precise and have larger standard errors.

Conclusions

The purpose of this study was to empirically ascertain the effect of tobacco smoking on depressive symptoms
among individuals aged 45 years or older in China using multiple imputed datasets. The empirical findings
suggest that among Chinese middle-aged and older adults, heavy smokers, and short-term and moderate-term
quitters were more likely to have depressive symptoms than those who never smoked. Moreover, former
smokers reported that the probability of having depressive symptoms decreased with a longer duration since
quitting. These results may have important implications that support the government in allocating more
resources to smoking cessation programs to help middle-aged and older smokers.

| **Educational attainment** | 73,461               | 97.62      | 1,791               | 2.38      |
| **Marital status**        | 75,145               | 99.86      | 107                 | 0.14      |
| **Rural residency**       | 72,725               | 96.64      | 2,527               | 3.36      |
| **Self-rated health**     | 72,089               | 95.80      | 3,163               | 4.20      |
| **Functional limitations**| 74,781               | 99.37      | 471                 | 0.63      |
| **Chronic conditions**    | 72,614               | 96.49      | 2,638               | 3.51      |
| **Drinking**              | 74,607               | 99.14      | 645                 | 0.86      |

Note: ‘Don’t know’, ‘Refused’ and ‘Blank’ equal missing.
| Variable | Description |
|----------|-------------|
| Sex | 1 if the individual was male; 0 for females |
| Age | Continuous variable, actual age in years |
| Educational attainment | |
| Illiteracy | 1 if the individual was illiterate; 0 if otherwise |
| Elementary school | 1 if the individual attended elementary school; 0 if otherwise |
| Middle school | 1 if the individual graduated from middle school; 0 if otherwise |
| High school | 1 if the individual graduated from high school; 0 if otherwise |
| Above three-year of college | 1 if the individual graduated from an above three-year college; 0 if otherwise |
| Marital status | |
| Never married | 1 if the individual was never married; 0 if otherwise |
| Married | 1 if the individual was married; 0 if otherwise |
| Separated or divorced | 1 if the individual was separated or divorced; 0 if otherwise |
| Widowed | 1 if the individual was widowed; 0 if otherwise |
| Rural residency | 1 if the individual was rural resident; 0 if otherwise |
| Self-rated health | |
| Poor | 1 if the individual reported their health status to be poor or very poor; 0 if otherwise |
| Fair | 1 if the individual reported their health status to be fair; 0 if otherwise |
| Good | 1 if the individual reported their health status to be good or very good; 0 if otherwise |
| Functionally limitations | |
| None | 1 if the individual could eat, toilet, dress, bathe/shower, get in/out of bed, and walk without difficulty; 0 if otherwise |
| Mild | 1 if the individual had one or two difficulties in eating, toileting, dressing, bathing/showering, getting in/out of bed, or walking; 0 if otherwise |
| Moderate | 1 if the individual had three or four difficulties in eating, toileting, dressing, bathing/showering, getting in/out of bed, or walking; 0 if otherwise |
| Severe | 1 if the individual had five to six difficulties in eating, toileting, dressing, bathing/showering, getting in/out of bed, or walking; 0 if otherwise |
| Chronic conditions | The number of chronic conditions diagnosed by a doctor. |
| Drinking | 1 if the individual drank at least once a month; 0 if otherwise |
Table 3 Description of variables in three waves (percentage)

| Variable                  | Wave 1 (2011) | Wave 2 (2013) | Wave 3 (2015) | Wave 4 (2018) | All waves N=74,381 |
|---------------------------|---------------|---------------|---------------|---------------|-------------------|
|                          | N=17,108      | N=17,940      | N=19,832      | N=19,501      |                   |
| **Depressive symptoms**   |               |               |               |               |                   |
| Yes                       | 37.55         | 32.26         | 33.68         | 38.50         | 35.49             |
