Abstract

Objective: Idiopathic trigeminal neuralgia (TN) is characterized by paroxysms of severe facial pain but without the major sensory loss that commonly accompanies neuropathic pain. Since neurovascular compression of the trigeminal nerve root entry zone does not fully explain the pathogenesis of TN, we determined whether there were brain gray matter abnormalities in a cohort of idiopathic TN patients. We used structural MRI to test the hypothesis that TN is associated with altered gray matter (GM) in brain areas involved in the sensory and affective aspects of pain, pain modulation, and motor function. We further determined the contribution of long-term TN on GM plasticity.

Methods: Cortical thickness and subcortical GM volume were measured from high-resolution 3T T1-weighted MRI scans in 24 patients with right-sided TN and 24 healthy control participants.

Results: TN patients had increased GM volume in the sensory thalamus, amygdala, periaqueductal gray, and basal ganglia (putamen, caudate, nucleus accumbens) compared to healthy controls. The patients also had greater cortical thickness in the contralateral primary somatosensory cortex and frontal pole compared to controls. In contrast, patients had thinner cortex in the pregenual anterior cingulate cortex, the insula and the orbitofrontal cortex. No relationship was observed between GM abnormalities and TN pain duration.

Conclusions: TN is associated with GM abnormalities in areas involved in pain perception, pain modulation and motor function. These findings may reflect increased nociceptive input to the brain, an impaired descending modulation system that does not adequately inhibit pain, and increased motor output to control facial movements to limit pain attacks.

Introduction

Idiopathic trigeminal neuralgia (TN) is a chronic neuropathic pain disorder characterized by recurring highly intense electric shock-like pain in the distribution of one or more branches of the trigeminal nerve. The pain is usually unilateral, occurring either spontaneously or precipitated by innocuous sensory stimuli and movements. Although some sensory abnormalities have been reported in TN using detailed quantitative sensory testing [1,2], there is typically no major sensory loss detectable with bedside clinical tests, as observed in other neuropathic pains [1,3]. For example, in a large multi-center study examining somatosensory abnormalities in different neuropathic pain syndromes, typical sensory abnormalities in TN were mechanical hyperalgesia without sensory loss; an uncommon combination in all other syndromes examined [1].

Many theories have been proposed to explain the unique pain characteristics of idiopathic TN. In general, theories of TN focus on either central or peripheral nervous system pathogenesis [4]. Given that patients with TN are typically initially responsive to anticonvulsant medications, it has been suggested that the pain paroxysms characteristic of TN originate in the central nervous system and are analogous to epileptic seizures in brainstem trigeminal structures [4,5]. Alternatively, proponents of a peripheral etiology suggest that TN results from damage to the trigeminal nerve or its myelin, with the most prevalent theory proposing neurovascular compression of the trigeminal nerve root entry zone (REZ) by a nearby arterial branch [3]. Although neurovascular contact (NVC) or compression of the trigeminal nerve is frequently observed, a significant number of idiopathic TN cases do not demonstrate clear evidence of neurovascular compression [6]. As the putative pathogenesis of TN is unique, so are its clinical features. While tumors or other structural abnormalities can result
in the perception of a trigeminal neuropathic pain, characterized by persistent pain and sensory changes, idiopathic TN patients are mostly pain-free between attacks and without major sensory abnormalities [7]. Since NVC or compression alone does not fully explain this unique syndrome, central abnormalities may significantly contribute to TN pain [8,9].

Patients with chronic pains other than TN can show abnormal gray matter (GM) in brain regions associated with pain and its modulation, sensory-discriminative and cognitive-affective dimensions of pain, emotion, and motor function [10,11,12,13], the latter of which may be related to alterations in muscular activity aimed at limiting movements to protect the system from further injury and support healing [14,15]. Therefore, GM abnormalities may reflect maladaptive plasticity arising from long-term pain and/or nociceptive input to the brain [16], impaired pain modulation [17], and/or compensatory/nocifensive motor behaviors to avoid triggering pain [15]. Importantly, while most chronic pain syndromes are also accompanied by prominent sensory deficits, TN is predominantly characterized by pain, but not major sensory loss [1]. This provides a unique window to our understanding of how pain impacts central GM. GM abnormalities may be dynamic, progressive, and pain-driven over time [10,12,18]. Based on the described studies and in consideration of the unique features of neuropathic pain in TN, we hypothesized that compared to healthy controls TN patients would have GM (i) increases in areas associated with pain perception and emotion (e.g., thalamus, primary and secondary somatosensory cortex (S1, S2), amygdala, anterior and mid-cingulate cortex (ACC; MCC), insula and prefrontal cortex (PFC), (ii) decreases in areas associated with pain modulation (e.g., periaqueductal gray (PAG)), (iii) increases in motor regions (e.g., primary motor cortex (M1), basal ganglia), and (iv) abnormalities that progress due to pain chronicity.

Methods

Ethics Statement

The University Health Network Research Ethics Board approved this retrospective study of idiopathic TN patients. There was no active participation in this study by patients, as patient data were analyzed retrospectively. Additionally our Research Ethics Board provides study approval, but does not require individual patient consent for retrospective studies. All scans were anonymized prior to analysis and stored in secure databases. Recruitment of healthy control subjects and the procedure whereby their consent was obtained was also approved by the University Health Network Research Ethics Board. Each healthy control participant provided written informed consent.

Participants

Twenty-four right-handed idiopathic TN patients from the Toronto Western Hospital seen between May 2008 and February 2011 were included in the study. Inclusion criteria were: (1) unilateral (right-sided) pain involving at least the maxillary or mandibular (V2 or V3) branches of the trigeminal nerve, (2) intense, sharp, superficial or stabbing paroxysmal facial pain precipitated from trigger areas or by trigger factors; stereotyped attacks for each patient; no clinically evident neurological or sensory deficit or not attributed to another disorder [19], and (3) no previous surgical procedures for TN. Demographic and clinical details for patients were obtained via retrospective chart reviews. Patients were sex-matched to a cohort of 24 healthy pain-free control participants and the mean ages between the groups were not statistically different (p = 0.81, see results). At the individual level, all but 2 control participants were within 3 years of the patients.

Imaging Protocol

Brain imaging data were acquired using a 3T GE Signa HDx MRI system fitted with an eight-channel phased array head coil. T1-weighted 3D FSPGR axial images were obtained from the top of the head to the upper cervical levels of C1–C2 (0.9 × 0.9 × 1.0 mm³ voxels derived from a 256 × 256 matrix and field of view of 24 cm (controls) or 22 cm (patients), echo time = 5 ms, repetition time = 12 ms, inversion time = 300 ms).

Cortical Thickness Analysis

To examine cortical GM, cortical thickness analysis (CTA) was performed using FreeSurfer software v. 4.5.0 [http://surfer.nmr.mgh.harvard.edu/]; methods have been described in detail elsewhere [20]. Briefly, T1-weighted scans were registered to the Talairach atlas [21]. Images underwent intensity normalization to identify tissue types, and the skulls were removed. White matter (WM) voxels were used to estimate the GM/WM boundary, which was deformed outward to the GM/cerebrospinal fluid (CSF) boundary. Thickness was computed as the distance measured...
between these boundaries at every point in each hemisphere. A
general linear model (GLM) was used to evaluate group
differences, with age included as a variable of no interest. We
restricted analyses to a mask including our hypothesized regions of
interest (ROI) (Fig. 1A–D) created with a predefined cortical
parcellation scheme (aparc2005) implemented in FreeSurfer [22].

Data were smoothed with a 6 mm full-width half-maximum
(FWHM) spatial smoothing kernel, and thresholded at a corrected
\( p < 0.05 \) (from a combination of an uncorrected image-wide
\( p \)-value of 0.01, and a cluster threshold of 183 and 188 contiguous vertices
for left and right hemispheres, respectively, based on Monte Carlo
simulations with 5000 iterations (AlphaSim, implemented in
Analysis of Functional NeuroImages (AFNI) (http://afni.nimh.nih.gov/afni), as done previously [10,12,23].

Voxel-Based Morphometry

To examine subcortical GM group differences, we used voxel-
based morphometry (VBM) [24] in FMRIB’s Software Library v.4.1.8 (http://www.fmrib.ox.ac.uk/fsl/). Non-brain tissues were
removed from structural images using the Brain Extraction Tool
(BET) [25]. Tissue-type segmentation classified tissue using
FMRIB’s Automated Segmentation Tool (FAST4) [26]. The
GM-classified tissue was aligned to the Montreal Neurologic
Institute (MNI) 152 standard 2 mm template (voxel size = 2×2×2 mm) using a linear registration tool [27]. Images
were averaged creating a study-specific template, to which GM
images were non-linearly re-registered. Jacobian modula-
tion allowed group differences in GM to be reported as normalized
volumes. The modulated images were then smoothed with an
isotropic Gaussian kernel with a sigma of 2 mm
(FWHM = 4.6 mm). Using the Harvard-Oxford subcortical struc-
tural atlas, a mask was constructed to restrict analyses to the
thalamus, amygdala, hippocampus, basal ganglia, and brainstem
(Fig. 1E–G). A voxelwise GLM was applied with age as a variable
of no interest. Statistical significance was determined using
permutation-based non-parametric testing and thresholded at
\( p < 0.05 \) using Randomise, implemented in FSL, corrected for
multiple comparisons with threshold-free cluster enhancement
[28]. For consistency with the CTA, VBM results were converted
from MNI to Talairach coordinates using the Yale Nonlinear
MNI to Talairach Conversion Algorithm [29] implemented on the
BioImage Suite 2.0 website (http://www.bioimagesuite.org/
Mni2Tal/).

We performed a secondary analysis to determine if prolonged
nociceptive activity (i.e., pain duration) was related to GM
changes. In this analysis, TN duration was treated as a regressor
of interest. Analyses were restricted to the CTA and VBM masks
described above. The same statistical correction methods were
used to determine significant correlations between GM and pain
duration.

### Table 1. TN Patient Demographic Information.

| Patient | Sex | Age | Pain Dist | Pain Duration (years) | Age at Pain Onset | Medication |
|---------|-----|-----|-----------|----------------------|------------------|------------|
| R1      | F   | 45  | V2        | 10                   | 35               | CBZ        |
| R2      | M   | 67  | V2, V3    | 8                    | 59               | CBZ        |
| R3      | F   | 62  | V3        | 11                   | 51               | CBZ, PGB   |
| R4      | F   | 68  | V2, V3    | 3                    | 65               | CBZ, GBP   |
| R5      | M   | 52  | V1, V2    | 5                    | 47               | CBZ        |
| R6      | F   | 44  | V2, V3    | 2                    | 42               | None       |
| R7      | F   | 55  | V2        | 6                    | 49               | None       |
| R8      | F   | 40  | V2        | 10                   | 30               | CBZ        |
| R9      | M   | 50  | V1, V2, V3| 6.5                  | 44               | –          |

Results

Patient Demographics

Patient demographic information is shown in Table 1. The TN group (n = 24) was comprised of 15 women and 9 men (mean age \(6 \pm 12.7\) years) who had right-sided TN pain for \(6.3 \pm 3.0\) years with a mean age at pain onset of \(43.0 \pm 12.9\) years. The majority of patients were on medications for TN at the time of scan acquisition, with the most common being carbamazepine (Table 1). The healthy control group consisted of 15 women and 9 men with a mean age \(6 \pm 12.3\) years, which was not significantly different (\(p = 0.81\)) from the patient group.

Regions of Abnormal Cortical Thickness in TN Patients

All CTA results are provided in Table 2 and prominent findings are illustrated in Figure 2. Compared to controls, TN patients had 14–16% greater cortical thickness within three regions: the left (contralateral to side of pain) S1 including the putative face area (Fig. 2D, inferior S1 cluster), frontal pole (FP) (BA 10) bilaterally, and M1 bilaterally. CTA also revealed several cortical regions that were 10–19% thinner compared to controls. The most prominent areas of thinning were located bilaterally in the pregenual ACC (pgACC) (BA 24) and the ventral orbitofrontal cortex (OFC) (BA 11) (Fig. 2A & C). Cortical thinning was also observed in the right dorsal posterior insula (dpINS), ventral anterior insula (aINS) (Fig. 2B), and posterior cingulate cortex (PCC).

Larger Subcortical Volumes in TN Patients

Subcortical regions that had significantly different GM volumes in the TN patients compared to controls are listed in Table 3. Although the ventral pons had significantly less GM volume in the TN group compared to controls, for all other subcortical regions that were significantly different between groups, patients had larger volumes. The TN group had greater GM volumes than controls bilaterally in several thalamic regions that spanned the medial dorsal (MD) nucleus, the ventral posteromedial (VPM) nucleus (Fig. 3A), the pulvinar, and the ventral lateral (VL) nucleus. The TN group also had greater GM than controls in the right amygdala (Fig. 3B), an increase of 13%, and in a cluster spanning the nucleus accumbens (NAc), caudate, and anterior putamen (19% increase) (Fig. 3C). Bilaterally, a substantially greater volume of the posterior putamen (average increase of 30%) and in the PAG (increase of 27%) (Fig. 3D & E) was observed in the TN group compared to the control group.

No Correlation between Gray Matter Abnormalities and Pain Duration

TN pain duration was not significantly related to cortical thickness or subcortical volume for any region within the CTA and VBM masks, nor within areas of GM abnormality when specifically examined (\(p > 0.05\)).
Table 2. Cortical Thickness Abnormalities in TN.

| Hemis | Region | BA | Peak Coordinates (TAL) | # Vert | Peak T-Score | % Change | Change (cf. Controls) |
|-------|--------|----|------------------------|--------|-------------|----------|----------------------|
| Right (ipsi) | FP | 10 | 29 53 11 | 770 | 9.12 | 16.0 | incr |
| OFC | 11 | 14 20 13 | 418 | 4.86 | 17.2 | decr |
| pgACC | 24 | 8 29 9 | 203 | 2.57 | 13.2 | decr |
| PCC | 23 | 7 39 30 | 305 | 2.85 | 9.5 | decr |
| S. temp | 42 | 39 31 12 | 295 | 3.55 | 12.3 | decr |
| dpINS | 32 | 20 16 | 362 | 4.46 | 12.9 | decr |
| aINS | 41 | 10 12 | 206 | 3.15 | 12.3 | decr |
| M1 | 4 | 25 64 205 | 3.32 | 12.1 | incr |

| Left (contra) | FP | 10 | 32 52 11 | 680 | 6.59 | 15.8 | incr |

Discussion

In this study, we provide novel evidence that TN, a neuropathic pain thought to arise from a peripheral event, characterized primarily by pain and the absence of major sensory loss is associated with pronounced alterations in brain GM. These abnormalities occur in neuroanatomical regions that contribute to sensory-discriminative and cognitive-affective dimensions of pain, pain modulation, and motor function. Specifically, we identified that compared to controls, TN patients have: (1) greater GM in the thalamus, contralateral S1 (putative face area), amygdala, FP, PAG, M1, and basal ganglia (including the putamen and NAc), and (2) cortical thinning in the OFC, pgACC, and insula. Abnormalities in these brain regions have been reported in other chronic pain disorders [13]. However, in previous studies, the contributions of sensory loss and pain are often intertwined. Our findings raise the possibility that the CNS contributes to the development and/or maintenance of TN pain and help advance our knowledge of how a peripheral event is associated with central grey changes.

Potential mechanisms underlying MR-detectable GM differences have been broadly divided into two categories: neuronal and non-neuronal mechanisms, including alterations in vasculature, the size or numbers of glia and/or dendritic spines/branches [30,31]. Evidence for the activity-dependent alteration of these structures has been demonstrated as a result of experience and learning, with the majority of studies reporting non-neuronal mechanisms as the primary contributor to GM differences in regions outside of the hippocampus [31]. GM abnormalities in TN patients may also occur via these mechanisms, elicited by experience-dependent factors such as changes in nociceptive input to the CNS, affect, and learned compensatory/nocifensive motor behaviors. Alternatively, it is possible that some individuals are more susceptible to developing chronic pain because of pre-existing GM abnormalities [13]. This possibility cannot explicitly be tested in a cross-sectional study. In the current study, we did not find any evidence to support this possibility based on assessing disease duration-related GM abnormalities. However, we cannot totally rule out the contribution of some pre-existing functional or structural vulnerability as was found in other chronic pain studies [13,32].

Consistent with our a priori hypothesis, we found that TN patients had more GM in the thalamic nuclei compared to controls. Although we included patients with only right-sided pain, the greater thalamic volume was found bilaterally. This bilateral finding is in line with a previous functional MRI study on TN patients that showed bilateral thalamic activity when unilateral stimuli were used to evoke pain attacks [33]. Also, certain thalamic neurons, including MD neurons, have been shown to have large, bilateral receptive fields [34], which may in part account for this finding. Previous studies of chronic facial pain have reported mixed findings with regard to patient thalamic volume relative to controls [11,12,18]. This variability may be due to the heterogeneity of pain symptomology between chronic facial pains [35]. For example, patients with trigeminal neuropathic pain have constant pain accompanied by numbness [36]. Indeed, one study examining different chronic facial pains found that only trigeminal neuropathy patients had significantly smaller thalamic volume compared to controls [11]. It is possible that this difference reflects a system that is steadily receiving nociceptive, but not discriminative touch input, fitting with trigeminal neuropathy symptomology. However, a barrage of nociceptive input, in combination with mostly intact discriminative touch sensations (i.e., no numbness), may induce GM increases in the medial and lateral thalamic nuclei of TN patients. Similarly, this theory may account for our finding of a thicker putative face S1 in TN. The barrage of nociceptive input to the thalamus from the trigeminal nerve may in turn lead to activity-dependent plasticity in S1 [37] via
thalamocortical projections. Indeed, repeated noxious stimulation in healthy individuals can increase S1 GM volume [38]. With pain chronicity, thicker S1 cortex, particularly of the contralateral putative face region, may reflect enhanced intensity and localization of nociceptive information from the face. Increased S1 GM has previously been reported in chronic pain disorders involving the trigeminal system including migraine, temporomandibular disorder (TMD), and trigeminal neuropathic pain [12,39,40].

We further observed that TN patients had thinner cortex in the pgACC, aINS, and OFC compared to controls, a finding that has been reported in numerous chronic pain conditions [13]. These regions have been implicated in aspects of the cognitive-affective dimension of pain as well as other functions including attention, salience, interoception, and top-down mechanisms such as placebo analgesia, and pain modulation [17]. The pgACC is thought to contribute to pain unpleasantness, salience, and the regulation of emotional information [13], while the aINS has been implicated in salience as well as pain intensity and anticipation, and negative emotions such as anxiety [41]. The role of the OFC includes sensory, pain, and emotion regulation [42]. Less GM in these regions may then reflect the high degree of pain unpleasantness and/or emotional responses to TN or chronic pain in general, as similar findings have been reported in several chronic pain populations [13].

The mechanism of pain-related cortical thinning is not yet established. One possibility, as described in other patient populations, is that there are focal losses of cortical inhibitory interneurons, making these regions hyperactive [43]. In the chronic pain literature, evidence to support alterations in cortical inhibition comes from studies using transcranial magnetic stimulation (TMS) on patients with chronic pain [44]. By applying magnetic pulses to the cortex of chronic pain patients and measuring peripheral muscle activity, TMS studies have demonstrated changes in cortical inhibition mediated by gamma aminobutyric acid (GABA) receptors [44]. Although these studies have focused on the motor cortex, it is possible that similar mechanisms are taking place in other cortical regions and will be an avenue of future research [44]. An alternate explanation is that thinner cortex reflects pruning due to use-dependent synapse elimination, as associated with the development of cognitive abilities and behavior [45]. Thus, thinner cortex in these regions could indicate an enhanced or more efficient system for processing the affective dimension of pain.

Interestingly, the FP was thicker in TN patients; a finding also reported in TMD [12]. The precise function of the FP is not well understood, but it has been implicated in a number of complex cognitive functions including multitasking, monitoring, and evaluating expected outcomes [46]. It is possible that the thicker cortex in the FP may occur because there is a greater cognitive load associated with having TN. Future behavioral studies are thus needed to determine the role of cognitive factors on the structural abnormalities reported in the current study.

Similar to findings in migraine [47], another paroxysmal pain disorder, we report greater PAG volume in TN patients. It has been proposed that the descending pain modulatory system is altered in chronic pain such that there is either dysfunction in nociceptive inhibition, or enhancement in nociceptive facilitation.
Although evidence for pain-related lateralization is controversial, it is presumed to mediate the emotional response to pain and pain modulation [49]. Activation of the right-hemispheric lateralization using functional neuroimaging has been linked to the emotional response to pain and pain modulation [50].

In our study, we show these regions to be abnormal in TN patients. Additionally, and consistent with our results, there is evidence to suggest that the emotional response to pain and pain modulation may reflect differences in the psychological modulation of TN pain. In our study, we show these regions to be abnormal in TN patients. Additionally, and consistent with our results, there is evidence to suggest that the emotional response to pain and pain modulation may reflect differences in the psychological modulation of TN pain.

Greater PAG volume may reflect activity-dependent changes in the psychological modulation of TN pain. In our study, we showed that regions involved in sensory-discriminative and cognitive-affective dimensions of pain, such as the amygdala, are abnormally activated in TN patients. Additionally, and consistent with our results, there is evidence that the amygdala is activated in response to the emotional response to pain and pain modulation [49].

Although evidence for pain-related lateralization is controversial, it is presumed to reflect the emotional response to pain and pain modulation. In our study, we showed that regions involved in sensory-discriminative and cognitive-affective dimensions of pain, such as the amygdala, are abnormally activated in TN patients. Additionally, and consistent with our results, there is evidence that the emotional response to pain and pain modulation may reflect differences in the psychological modulation of TN pain.

Some previous studies of chronic pain have found correlations between pain duration and brain GM [10,12], suggesting that long-term pain drives neuroplasticity [38]. We did not find evidence for this relationship in our TN patients. However, TN is quite different since it consists of repetitive paroxysmal pain rather than the sustained ongoing pain characteristic of other neuropathic pains. Additionally, TN patients are heterogeneous with regard to the number of pain attacks they have per day, and thus the use of pain duration may not be an adequate index of total pain over time for the purposes of assessing pain-driven brain changes in this patient group. Future longitudinal studies are needed to explore this factor.

Additionally, nearly all of our patients were taking medication for TN, with the most common being the anticonvulsant, carbamazepine. Although the precise impact of these medications on brain morphology is not known, it is possible that they influence structural abnormalities. Future studies are needed to examine the effects of these drugs on brain GM.

Taken together, our study demonstrates for the first time, that patients with idiopathic TN have prominent GM abnormalities in brain regions involved in sensory-discriminative and cognitive-affective dimensions of pain, pain modulation, and motor function. Unlike other facial pains, TN patients have paroxysmal pain, frequently triggered by innocuous stimuli, and are without major sensory loss. The GM abnormalities reported in the current study likely reflect this unique symptomology. Understanding the contribution of central GM abnormalities in this population is a unique neuropathic pain.
