Abstract

Background Gastric cancer is a malignant type of cancer associated with many factors such as environment, behavior, infection, and genetics, which include Single Nucleotide Polymorphism. A few studies revealed polymorphisms of the Mucin 1 gene have a role and significance as a susceptible factor contributing to gastric cancer. The aim of this research is to evaluate the association between Single Nucleotide Polymorphisms of the Mucin 1 gene and Vietnamese gastric cancer patients.

Methods 302 gastric cancer patients and 304 controls were interviewed for social-economic characteristics, smoking and drinking status, personal and family history of gastric diseases. Genotyping was done using polymerase chain reaction-restriction fragment length polymorphism analysis. The association of Single Nucleotide Polymorphisms with gastric cancer was evaluated using multifactor regression models.

Results AA genotype for rs4072037 was found to be highly associated with gastric cancer (OR: 2.07 (95% CI: 1.46-2.90)). GG genotype for rs2070803 increased the risk of gastric cancer (OR: 1.96 (95% CI: 1.37-2.78)). These genotypes in combination with other factors such as old age, male gender, alcoholism and personal history of gastric disease also showed an increased risk of having gastric cancer.

Conclusions rs4072037 and rs2070803 of Mucin 1 genes are two genotypic risk factors of gastric cancer. Those in combination with other factors such as gender, family history, smoking and drinking habits significantly increase the risk of gastric cancer.

Background

Gastric cancer is a heterogeneous, multi-factorial, highly malignant type of cancer. In Vietnam, the high incidence rate and poor prognosis of the disease account for about 18,000 new cases and 15,000 deaths in 2018 according to Globocan (1). The multistep process of gastric carcinogenesis starts from chronic inflammation, followed by multifocal atrophic gastritis with intestinal metaplasia, dysplasia, and ends with gastric adenocarcinoma (2). Well-established pathological and environmental risk factors of gastric cancer include Helicobacter pylori (H. pylori) (2, 3), smoking (4), and poor diet (5). In recent years, special focus has been shifted to identification of genetic factors, characterized by single-nucleotide polymorphisms (SNPs), which exist in large numbers in the human genome (6-8). Several genome-wide association studies have indicated the association between gastric cancer and SNP of the Mucin 1 (MUC1) gene, which codes for cell surface glycoprotein mucin-1 and is used in clinical settings as tumor marker C15-3, in some Asian and European populations (6, 9, 10). Two SNPs rs4072037 and rs2070803 of the MUC1 gene were found to be associated with increased gastric cancer susceptibility. Despite a high incidence rate of gastric cancer, to date, genetic association study with a particular interest in the association between gene SNPs and gastric cancer in Vietnamese population is still very limited (11). It is, therefore, necessary to take advantage of the advancement in molecular targeted treatment technologies to gain an understanding of the genetic factors associated with the disease in order to develop new and more efficient therapeutic targets. For that purpose, we aimed to investigate the potential association of 2 SNPs of the MUC1 gene with gastric cancer risk and evaluate the combination factors relation with these SNPs.
Methods

The case-control study involving 302 cases and 304 controls was conducted from 2016 to 2018 in four national hospitals in Hanoi, Vietnam. Diagnosis of cases was based on histopathology confirmation. The control group included people who were endoscopically diagnosed with normal epithelial gastric or only acute gastritis. The participants were explained about the purpose, the benefits, the drawbacks and the confidentiality aspect of participating in the study and had given their consent. Prior to the interview, there was a training process for conducting the research questionnaire, which aimed at investigating patients’ socioeconomic and disease characteristics, and medical records procedure for researchers; the training consisted of a minimum of 24 hour training time, mock interviews and lead researcher’s approval.

We asked the participants for their socioeconomic information including gender, age, educational status, occupation, personal and family’s medical history, alcohol usage and smoking habit. Family history of participants included: Family history of gastric cancer, the number of family members having gastric cancer, their time of diagnosis and their relationship with the participants. Smoking history and alcohol abuse history were investigated using standards from the Center for Disease Control and Prevention and the World Health Organization, respectively (12, 13).

DNA extraction

Peripheral venous blood samples in EDTA containers were acquired from all subjects and were stored in appropriate condition before being transported to the Quality control center for Medical laboratories – Hanoi Medical University for gene analysis. We extracted the genomic DNA from peripheral blood lymphocytes using Exgene™ Blood SV Kit (Gene All, Korea). Following the manufacturer's protocol, we isolated the genomic DNA and stored them at -80°C until SNPs analysis of the MUC1 gene.

50% of the samples were sent to the Kyoto Institute of Technology for gene analysis using the same method, and 10% of the samples were analyzed in both laboratories for cross-checking.

Detection of MUC1 gene polymorphism

The two MUC1 genotype polymorphisms (rs4072037 and rs2070803) were determined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) method with PCR primer pairs listed in Table 1

The PCR was carried out in a 30μL reaction mix containing 100 ng DNA template, 1 unit of Taq Mastermix (New England Biolabs, Beverly, MA, USA), 0.5μM forward primer, 0.5μM reverse primer. The PCR reaction was carried out in a thermocycler and reaction conditions consisted of 95°C denaturation for 5 minutes, 94°C annealing for 30 seconds, 62°C annealing for 30 seconds, 72°C annealing for 30 seconds (40 cycles) and 72°C elongation for 10 minutes. The PCR products were digested with appropriate restriction enzymes (New England BioLabs, Beverly, MA, USA) at 37°C for 8 hours. The restriction enzymes were AlwM (rs4072037 G/A), Taqal (rs2070803 G/A). The PCR and digestion
products were analyzed with a 1.5% agarose (Serva – Germany) gel with intercalating dye (ethidium bromide) staining. Selected PCR-amplified DNA samples (about 5%) were analyzed by DNA sequencing (Fig. 1)

**Statistical analysis**

Data were analyzed using STATA 12.0 (Stata Corp. LP, College Station, TX, USA). Socio-economic information, medical history, characteristic of gastric cancer disease of participants were described. Distribution of the 2 SNPs following Hardy – Weinberg equilibrium. We used student's t-test and chi-square for evaluation of the differences in the distributions of demographic characteristics, selected variables, and genotypes of the rs4072037 and rs2070803 between the cases and the controls. After that, we estimated the associations between the 3 genotypes of SNPs and risk of gastric cancer by computing the odds ratios (ORs) and their 95% confidence intervals (CIs) using unconditional logistic regression model.

**Results**

**Socioeconomic characteristics of participants**

A total of 606 participants were investigated in both groups, with male significantly outnumber female by 2 to 1. There was a significant difference between the control and case subjects in terms of personal history of gastric cancer, family history of gastric cancer, and history of alcoholism. In contrast, a high level of similarity was observed in terms of age and gender distribution, with the p values of 0.81 and 0.16, respectively (Table 2).

The logistic regression model of multiple environmental factors demonstrates a significant association between gastric cancer and family history of gastric cancer with OR = 3.69 (95% CI: 1.78 – 7.66). Alcohol abuse and history of *H. Pylori* infection also displayed significant association with the odds ratio being 0.5 and 0.42 respectively. Other factors including gender, age group, smoking history, and gastritis history showed insignificant results despite significant associations in some cases such as history of gastritis and gender.

**Distribution of participants’ genes and alleles**

For rs4072037, the most common genotype among the case group was AA (49.34%), whereas, in the control group, the majority of patients was found to have AG genotype (53.29%). There was also a significant difference in the frequency of alleles between the two groups (p=0.02). Similarly to rs4072037, rs2070803 results indicated differences in genotypes between the two groups, with predominantly identification of AG in the control group (53.95%) and GG in the case group (45.69%). The differences in those genotypic distributions were both statistically significant (p=0.00) (Table 4)
**Gastric cancer risk related genotypes and alleles**

In rs4072037, participants with AA genotype had higher gastric cancer risk compared to patients with AG and a combination of AG+GG with OR = 2.09 (95% CI: 1.48-2.96) and OR=1.85 (95% CI: 1.33-2.56), respectively. In rs2070803, GG genotype increased gastric cancer risk when compared with AG and AG+AA, OR=1.97 (95% CI: 1.39-2.80) and 1.71 (95% CI: 1.23-2.39), respectively. AG genotypes in both SNP decreased gastric cancer risk when compared with homogenous genotype, more specifically AA with OR=0.51 (95% CI: 0.35-0.72) and GG with OR=0.58 (95% CI: 0.35-0.97), respectively (Table 5).

AA genotype of rs4072037 in combination with factors include age > 60, male gender, alcohol abuse history, personal history gastritis, and family history of gastric cancer significantly increased gastric cancer risk with adjusted OR from 1.57 to 6.47. AA genotype in combination with a family history of gastric cancer was the highest risk factor with OR = 6.47 (95% CI: 2.21-18.89). GG genotype of rs2070803 combine with family gastric cancer history increased gastric cancer risk with OR=6.18 (95% CI: 2.11-18.10) (Table 6).

**Discussion**

Two SNPs rs4072037 and rs2070803 of the *MUC1* gene were found to be genotypic risk factors of gastric cancer. Those SNPs in combination with other socioeconomic risk factors show a significantly increased risk of gastric cancer.

Genotypic distribution of the patient group from our study was found to be similar to the one reported by Song et al. in 2014, and Zhang et al. in 2011, with AA being the most common genotype (14, 15). The results indicated the association between allele A of rs4072037 and an increased risk of gastric cancer. The risk was also elevated in the AA genotype group. Our results were supported by research done by Xu et al. in 2009 (16), by Jia et al. in 2010 (17), by Palmer et al. in 2013, and by Song et al. in 2014 (18, 19). Higher risk of cancer in patients with allele A compared to those with allele G was also pointed out by Saeki et al. in 2011 (27). On the contrary, a decreased risk of gastric cancer in patients with the G allele was found in research by Abnet et al. in 2010, and Shi et al. in 2011 (20, 21). This result was similar to multiple studies in Japanese, Korean, and Chinese population (OR ranging from 0.26 to 0.69) (15, 22, 23).

The rs4072037 located in the 5’ end of the 2nd exon of *MUC1* gene allows determination of the splicing point. The G allele and the A allele belong to two different variants: 2 and 3, respectively. Via mutation of amino acids in the 2nd exon, the structural differences between the two variants affect the N-terminal signal peptide, which in turn lead to a variation in function of the encoded protein. The A allele associates with gastric cancer by lowering *MUC1* expression on the surface of epithelial cells lining the gastric mucosa. Mucins play a crucial role in forming protective mucous barriers on the epithelial surface of the stomach. The low expression of *MUC1* may increase susceptibility to gastric cancer due to the reduced protective function of the stomach (24, 25).
As for rs2070803, in comparison with research by Fang Li et al. in 2012, despite a difference in genetic distribution, there was a similarity regarding the higher risk of gastric cancer in GG genotype when compared to AA+AG genotype OR = 0.46 (95% CI = 0.32 - 0.67) (26). The quantification of association between alleles and gastric cancer risk show G compared to A with OR=2.73 but with no significant p-value. On the contrary, the research by Saeki et. al in 2011 with 3 independent data sets: Tokyo, Aichi, and Korea demonstrate a significant association between allele G and both intestinal and diffuse gastric cancer (27). This difference may be due to the limited sample size of the study. Rs2070803 on the 1q22 chromosome is an SNP located in between MUC1 and Tripartite Motif Containing 46 (TRIM46), both of which locate in a region of strong disequilibrium and are convergently transcribed (28). Numerous sources have reported the association between MUC-1 and the carcinogenesis of various tumor including gastric cancer (29, 30). However, there is no expression of TRIM46 in the gastric mucosa. This suggests rs2070803 being a tagging SNP for variants in MUC1 gene, which are associated with gastric carcinogenesis.

Regarding combinations of risk factors, old age (>60 years old) together with AA genotype of rs4072037 and GG genotype of rs 2070803 showed a notable increase in gastric cancer risks with OR=1.57 (95% CI: 1.05 – 2.34) and OR=1.5 (95% CI: 1.00 – 2.25) respectively. The majority of gastric cancer is primary and occurs in patients between the ages of 60 and 80, especially in Eastern Asia region (31, 32). Research on the Vietnamese population also reports a high incidence rate of gastric cancer in elderly people (11). The cancer growth process may involve several risk factors with different time and levels with which cells are affected. The affected cells need to be able to survive the apoptosis program in the immune system so that they can divide and multiply until tumors are formed. Due to the better immune system and shorter exposure time to most environmental risk factors that can accumulate gradually, young people tend to have a significantly lower risk of cancer in comparison to the elderly.

Gastric cancer risk was found to be increased roughly 1.8 times (p<0.05) when both genotypic (rs4072037 AA genotype or rs2070803 GG genotype) and gender (male) factors were considered. The gastric cancer incidence rate in males was reported to be approximately double that in females, particularly in countries with a high prevalence of gastric cancer. Various characteristics such as smoking, alcohol drinking, that attribute mostly to males, contribute to that fact (33). Another reason for the lower cancer rate in the female is the hormone estrogen, which was reported to have a protective effect in decreasing stomach cancer risk (34-37). A multicenter cohort study in Korea has pointed out similar results with isoflavone and phytoestrogen (38). This is further supported by several studies indicating an increased risk of gastric cancer in both genders treated with tamoxifen (an estrogen blocker) (39, 40). The result on the association between gastric cancer risk and a combination of MUC1 polymorphisms (rs4072037, rs2070803) and male gender once again showed that rs4072037 AA and rs2070803 GG are the two genotypic risk factor for stomach cancer. In our study, no notable association was found between history of alcohol abuse and gastric cancer; however, that factor together with rs4072037 AA genotype or rs2070803 GG genotype both increased risk of gastric cancer significantly with OR=2.06 (95% CI: 1.32 – 3.23) and OR= 1.98 (95% CI: 1.22 – 3.04). The effect of alcohol on gastric cancer is still in debate. Some empirical studies have suggested a carcinogenesis mechanism in which
metabolic products of ethanol facilitate cancer risk factors penetration to damaged gastric mucosa, while other studies have pointed out possible protective function of ethanol due to its destructive effect on *H. Pylori* (40, 41). Research done on alcohol consumption rate and stomach cancer have shown divergent results, with a few authors pointing to heavy drinking of various alcohol-based beverage posing an even greater risk compared to standard alcohol (42-45).

Smoking is one of the primary risk factors that contribute to the manifestation of gastritis, atrophic gastritis, and gastric cancer in both the cardiac and non-cardiac region. Nishino et al. in 2006 have reported 1.56 times higher risk coming from patients with a history of smoking (46). According to Gonzalez, approximately 18% of gastric cancer cases can be traced back to heavy smoking. In addition, gastric cancer risk has been found to increase with long smoking time and decrease after 10 years of cessation (47). Tobacco smoke has been proven to be a mixture of many harmful chemicals relating to human gastric carcinoma (48). The smoking-related DNA adducts that bind to DNA of the gastric mucous membrane have been found in samples from smokers (49). The smoking risk factor together with AA genotype of rs4072037 and GG genotype of the rs2070803 increased risk of gastric cancer with OR= 1.72 (95% CI: 1.11 – 2.67) and OR= 1.68 (95% CI: 1.07 – 2.63) respectively. There are many studies supporting the high gastric cancer risk of patients that have a combination of genotypic risk factors (SNPs) and environmental factors (alcohol drinking/smoking). Research by Boccia et al. in 2007 has pointed out the increased gastric cancer risk in smokers with *Sulfotransferase Family 1A Member 1* (*SULT1A1*) gene, and drinkers with CYRS2070803E1 gene (*5A allele or *6 allele) (50). *Cyclooxygenase-2* (*COX-2*) polymorphisms together with a history of smoking play an important role in the development of gastric cardia adenocarcinoma (51). TNF-alpha-857 C/T genotypic polymorphism is an independent risk factor, and gastric cancer caused by tumor necrosis factor (TNF) gene has been argued to be related to smoking habit (52). Research by Xu et al. in 2014 has demonstrated a MUC1 mechanism, in which the inflammation signal is activated by macrophages, that contribute to the manifestation of lung cancer in patients who smoke (53).

Family history of gastric cancer is one of the major factors that double or even triple the risk of gastric cancer (54, 55). The percentage of patients who have a family history of gastric cancer in our research was 12.4%, lower than other research done in Italian (21.9%) (56), and Spanish population (17.6%) (57). A study by Dhillon et al. in 2006 on 695 cases and 629 controls in America has estimated the association between gastric cancer and family history with OR= 2.2 (95% CI: 1.5–3.3). This is further increased in individuals who have 2 or more family member diagnosed with gastric cancer, with OR=12.1 (95% CI 1.4–108) (55). Nine studies that were done in Turkey, Italia, Finland, German, and Spain also show a significant connection with OR ranging from 1.8 to 10.1 depending on different countries (58-61). Five studies on Japanese population also demonstrate the same association with OR from 1.5 to 3.5 (62, 63). Our study also show similar result (Table 3), with OR = 3.69 (95% CI: 1.78 – 7.66). The detailed mechanism of the cause and effect relationship between family history and gastric cancer is not fully understood; however, special focus has been put on genetic characteristics. In our research, patient with a family history of gastric cancer in conjunction with rs4072037 AA genotype and rs2070803 genotype elevate gastric cancer risk significantly with OR=6,47 (95% CI: 2.21 – 18,89) and OR =6,18 (95% CI: 2.11 –
This indicates the importance of family history of gastric cancer as a major risk factor for gastric cancer, especially in combination with other genotypic risk factors of rs4072037 and rs2070803. Therefore, a classification of patients according to different kinds of risk factor is necessary for management, monitoring, and prevention of gastric cancer. This could be benefited by the implementation of a complete system that focuses on the management of cancer among individuals who have a history of cancer.

**Conclusions**

In summary, our case-control study investigated the effect of two SNPs rs4072037, rs2070803 in *MUC1* gene as the risk factor for gastric cancer. It was found for the first time in the Vietnamese population that participants carrying rs4072037, rs2070803 polymorphisms would be more susceptible to gastric cancer. Furthermore, those genetic factors when interplay with some environmental factors such as smoking, alcohol abuse, and family history of gastric cancer significantly increase risk of having gastric cancer.
