ABSTRACT

Context. Blazars constitute the vast majority of extragalactic γ-ray sources. They can also contribute a sizable fraction of the diffuse astrophysical neutrinos detected by IceCube. In the past few years, the real-time alert system of IceCube has led to the multiwavelength follow-up of very high-energy neutrino events of plausible astrophysical origin. Spatial and temporal coincidences of a number of these neutrino events with γ-ray blazars provide a unique opportunity to decipher cosmic-ray interactions in the relativistic jets.

Aims. The aim of this work is to test if the γ-ray blazars associated with the IceCube neutrino events are also sources of ultra-high-energy cosmic rays (UHECRs; $E > 10^{18}$ eV).

Methods. Assuming that blazars accelerate UHECRs, we calculate the “guaranteed” contribution to the line-of-sight cosmogenic γ-ray and neutrino fluxes from four blazars associated with IceCube neutrino events. We compare these fluxes with the sensitivities of the upcoming γ-ray imaging telescopes, such as the CTA, and with the planned neutrino detectors, such as IceCube-Gen2.

Results. We find that detection of the cosmogenic neutrino fluxes from the blazars TXS 0506+056, PKS 1502+106, and GB6 J1040+0617 would require UHECR luminosity $\gtrsim 10$ times the inferred neutrino luminosity from the associated IceCube events, with the maximum UHECR proton energy $E_{p,\text{max}} \approx 10^{20}$ eV. Cosmogenic γ-ray emission from blazars TXS 0506+056, 3HSP J095507.9+355101, and GB6 J1040+0617 can be detected by the CTA if the UHECR luminosity is $\gtrsim 10$ times the neutrino luminosity inferred from the associated IceCube events and for $E_{p,\text{max}} \gtrsim 10^{19}$ eV.

Conclusions. Detection of cosmogenic neutrino and/or γ-ray flux(es) from blazars associated with IceCube neutrinos may lead to the first direct signature(s) of UHECR sources. Given their relatively low redshifts and hence total energetics, TXS 0506+056 and 3HSP J095507.9+355101 should be the prime targets for upcoming large neutrino and γ-ray telescopes.

Key words. astroparticle physics – galaxies: active – gamma rays: general – neutrinos

1. Introduction

The origin of high-energy astrophysical neutrinos is still a mystery despite their discovery by the IceCube experiment almost a decade ago (Aartsen et al. 2013). The detection of IC-170922A in spatial and temporal coincidence with the blazar TXS 0506+056 has therefore led to speculations that blazars contribute to the diffuse neutrino flux detected by IceCube (Aartsen et al. 2018a,b). This was the first detected blazar-neutrino association; the source was found to be flaring in GeV γ rays when the high-energy $\nu_\gamma$ ($E_\nu \sim 0.3$ PeV) created a “track-like” event in the South Pole ice. A chance correlation was disfavored at the $3\sigma$ confidence level. A few weeks after the neutrino alert, the Major Atmospheric Imaging Cherenkov (MAGIC) telescope detected γ rays above 100 GeV from this source for the first time (Ansoldi et al. 2018). Prompted by this observation, a search for a time-dependent neutrino signal in the archival data revealed an excess of high-energy neutrino events between September 2014 and March 2015 at $3.5\sigma$ statistical significance. However, the 160-day window was not accompanied by a γ-ray flare.

Detection of the IC-170922A event reaffirms the extragalactic origin of the most IceCube astrophysical neutrinos, which is evident from their near-isotropic sky distribution. Since the detection of sub-PeV neutrinos directly indicates cosmic-ray acceleration to at least PeV energies, they are ideal messengers of hadronic processes in astrophysical sources. Blazars, a subclass of radio-loud active galactic nuclei (AGNs), have their relativistic jets pointed toward Earth. They have been long considered as the accelerators of ultra-high-energy cosmic rays (UHECRs; Dermer et al. 2009; Dermer & Razzaque 2010; Murase et al. 2012; Tavecchio 2014; Oikonomou et al. 2014; Resconi et al. 2017; Rodrigues et al. 2018). Statistical analysis with early IceCube data indicated a weak correlation between the neutrinos, UHECRs, and AGNs (Moharana & Razzaque 2015). Other neutrino events, of lower statistical significance, have also been identified in spatial coincidence with blazars (Franczokowiak et al. 2020; Giommi et al. 2020a), for example IC-190730A and IC-200107A, coincident with the direction of blazars PKS 1502+106 and 3HSP J095507.9+355101, respectively. An analysis of archival neutrino events that satisfies the IceCube real-time alert criteria revealed a correlation of IC-141209A with the blazar GB6 J1040+0617.

The neutrino flux predicted from the IceCube observation of TXS 0506+056 can be produced inside the jet emission region. The multiwavelength spectral energy distribution (SED)
is explained well with a synchrotron self-Compton (SSC) model, with neutrinos produced by a radiatively subdominant hadronic component (Keivani et al. 2018; Cerruti et al. 2019; Gao et al. 2019). While the SED of most blazars can be well explained by leptonic models alone, a hadronic component is required to explain the observed neutrinos. Moreover, if blazars are capable of accelerating UHECRs, a cosmogenic neutrino flux is expected to be observed along their direction for a sufficiently small intergalactic magnetic field. The secondary $\gamma$ rays produced may contribute to the SED at the highest energies, leading to an unattenuated spectrum. Thus, there exists a degeneracy in explaining the blazar SED, which can be lifted by future multi-messenger observations. Ultra-high-energy (UHE) protons, if accelerated, can escape the jet when the escape timescale is shorter than the acceleration time (see, e.g., Das et al. 2020). These UHECRs can interact with photons from the cosmic microwave background (CMB) and extragalactic background light (EBL) to produce secondary neutrinos and $\gamma$ rays with a hard spectrum along the line-of-sight (Essey & Kusenko 2010; Essey et al. 2010; Kalashev et al. 2013; Das et al. 2021). In some cases, the line-of-sight $\gamma$-ray flux has shown to improve fits to the very high-energy (VHE; $E_\gamma \gtrsim 30$ GeV) spectra of BL Lacs (Das et al. 2020). However, the luminosity requirement in the UHECR spectrum may be challenging for a super-massive black hole (Razzaque et al. 2012).

Cosmic-ray protons with energy $\lesssim 10$ PeV must interact inside the blazar jets in order to produce the sub-PeV neutrinos detected by IceCube. The rate for $p\gamma$ interactions in the jet can be smaller than the escape rate, however, and a large fraction of the protons can escape the jet (see, e.g., Das et al. 2020). These cosmic-ray protons with energy $\gtrsim 1$ EeV can interact with the CMB and EBL photons to produce photopions. The corresponding $p\gamma$ opacity is $\gtrsim 1$ at energies larger than a few tens of EeV for the distances of the blazars associated with the IceCube events (cf. solid line in Fig. 1). In this work, we predict the line-of-sight cosmogenic neutrino flux from a simple scaling relation with the CMB photons, and the corresponding neutrino flux, peaking at $\sim 1$ EeV, dominates over any neutrino flux from the jets (cf. dashed line in Fig. 1). Therefore, at energies higher than a few tens of EeV, the UHECR protons dominantly interact with the CMB photons, and the corresponding neutrino flux, peaking at $\sim 1$ EeV, dominates over any neutrino flux from the jet. Upcoming neutrino detectors, such as IceCube-Gen2 and the Giant Radio Array for Neutrino Detection (GRAND), are also most sensitive in the $\sim 1$ EeV range. Hence, we only consider the cosmogenic components for neutrino flux predictions in the UHE range for the blazars considered in this study. At lower energies the jet component can be important, depending on the flux of cosmic rays that interact inside the jet.

Observations of the EeV neutrinos by next-generation telescopes with improved sensitivity will set the course for precise modeling of the emission region in the jet. The production of cosmogenic neutrinos will be accompanied by $\gamma$-ray flux resulting from the electromagnetic cascade of high-energy secondary $e^\pm$ and $\gamma$ photons. Future observations by $\gamma$-ray missions, such as the Cherenkov Telescope Array (CTA) and the Large High Altitude Air Shower Observatory (LHAASO), can constrain the flux models and the magnitude of the extragalactic magnetic field (EGMF).

We present the results of our study and discuss them in Sect. 2. We summarize our results and present an outlook in Sect. 3. 

![Fig. 1. Optical depth of photopion production inside and outside the source emission region for TXS 0506+056. The target photons for $p\gamma$ interactions inside the jet are leptonic synchrotron and SSC radiation, as shown in Fig. 3 of Gao et al. (2019) for their favored hybrid model. The parameter values given in their supplementary Table 1 for the flare state are used to calculate the photon flux in the comoving jet frame.](image1)

2. Results and discussions

The UHECRs that escape from the blazar jets are deflected by the EGMF from our line of sight. Therefore, only a fraction of the secondary neutrinos and $\gamma$ rays, produced by interactions of UHECRs with the CMB and EBL, will be propagating within a narrow cone around the line-of-sight. We calculated this fraction from the distribution of angular deflection of UHECRs upon arrival at the Earth from the blazars associated with IceCube events. We assumed the UHECR injection spectrum of the form $dN/dE \propto E^{-2.2}$ in the energy range $10$ PeV to $E_{\text{max}}$, and simulated their propagation using CRPropa 3 (Alves Batista et al. 2016), including all relevant energy loss processes. The observer, in this case, was considered to be a sphere of $R_{\text{obs}} = l_\text{i}$ to increase the number of observed events in the simulation. We incorporated a random turbulent EGMF with a Kolmogorov power spectrum of magnitude $B_{\text{rms}} = 10^{-15} - 10^{-17}$ G and a turbulence correlation length $l_c = 0.1$ Mpc for the extragalactic propagation. The choice of the $B_{\text{rms}}$ range is consistent with the lower bound obtained by Neronov & Vovk (2010) from observations of $\gamma$-ray blazars by the Fermi Large Area Telescope (Fermi-LAT).

Figure 2 shows the distribution of UHECR deflection in the EGMF, binned over $1^\circ$ intervals, for TXS 0506+056 at a redshift of $z = 0.3365$ and various $B_{\text{rms}}$ values. A conservative limit to
the flux of γ rays and neutrinos arriving at Earth can be obtained by multiplying the total flux with the UHECR survival fraction within 1° of the jet emission direction. For track-like events in IceCube, the angular resolution is 0.5° for a neutrino of energy $E_\nu \sim 30$ TeV. We denote this survival fraction within $0 - 1°$ by $\xi_B$ (i.e., the fraction observable at Earth). The value of $\xi_B$ is fairly constant for $E_{p,\text{max}} = 1, 10$, and 100 EeV when all other parameters are kept fixed.

2.1. TXS 0506+056

The all-flavor neutrino luminosity, $L_\nu$, is three times the $\nu_\mu + \bar{\nu}_\mu$ flux reported in the case of TXS 0506+056 for $\Delta T = 0.5$ yrs and 7.5 yrs (Aartsen et al. 2018a). The factor of three corresponds to an initial production of neutrino flavors $\nu_\mu, \nu_\tau, \nu_e$ in the ratio $1 : 2 : 0$ from pion decay. In the top-left panel of Fig. 3 we show the all-flavor neutrino fluxes with the solid and dashed black data points. We calculated the luminosity of UHECRs by assuming $L_{UHECR} = \alpha L_\nu$, where $\alpha$ is a scaling factor that takes into account the escaping UHECR luminosity due to various physical effects. At $E \lesssim 10$ PeV, $\nu \gamma \rightarrow n\pi^+$, $\nu \gamma \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$, 3-body interactions inside the jet produce IceCube neutrinos, and the neutron escapes as a cosmic ray with $\approx$80% of the proton’s energy. The three $\nu$ carry 15% of the parent proton energy, and hence $\alpha \approx 16/3$. In the UHE range, a higher value is possible as protons can escape dominantly, but we considered the conservative lower bound for this study.

We used CRPropa 3 and the EBL model of Gilmore et al. (2012) to calculate cosmic photon and neutrino fluxes. The secondary electron and photons are propagated via the DINT code, which solves the transport equation to yield the respective spectra after taking the electromagnetic cascade into account (Lee 1998; Heiter et al. 2018). For $\Delta T = 0.5$ yrs, $L_\nu = 6.2 \times 10^{46}$ erg s$^{-1}$, and for $\Delta T = 7.5$ yrs, $L_\nu = 4.3 \times 10^{45}$ erg s$^{-1}$. We show the cosmogenic fluxes for $\Delta T = 0.5$ yrs in Fig. 3, with $\alpha = 16/3$ and $\xi_B = 0.7$ for $E_{p,\text{max}} = 10^{16}$ G (see Fig. 2). The data points shown with green filled circles represent the γ-ray flux in the quiescent state as reported in the Fermi-LAT third source catalog 3FGL (Acero et al. 2015).

In Fig. 3 we also show the sensitivities of currently operating and upcoming neutrino telescopes, as well as the flux upper limit from 9 years of IceCube observations (Aartsen et al. 2018c). The projected sensitivity from 5 years of observation by the IceCube Gen2 radio upgrade is the shaded region corresponding to the uncertainties in the extrapolation (Aartsen et al. 2019a). The projected sensitivity of the full 200k radio antenna configuration of the GRAND detector is for 3 years of observation (Álvarez-Muñiz 2020). Assuming the telescopes have the same sensitivity within a zenith angle of $\theta_\pi$, the solid angle they cover is $\Omega = 2\pi(1 - \cos \theta_\pi) \sim 0.38 - 3.14$ sr for $\theta_\pi = 20 - 60$ degree, which is of the order 1. Hence, we plot the actual neutrino flux sensitivity curves reported by the current and upcoming telescope collaborations in units of erg cm$^{-2}$ s$^{-1}$ sr$^{-1}$.

The CTA is a ground-based imaging telescope that observes γ rays at very high energies, from 20 GeV to hundreds of TeV. A northern and a southern array are currently under construction. In Fig. 3 we show the predicted differential point-source sensitivity as a function of reconstructed energy in the northern array...
site of the CTA, assuming a 50 h observation time and pointing to 20 degrees zenith (Gueta 2021). The LHAASO is another air shower observatory that aims to detect γ rays up to PeV energies. We show the LHAASO 1-year sensitivity to Crab-like γ-ray point sources (Vernetto 2016). The sensitivity of the MAGIC telescope corresponding to 50 hrs of observation is displayed (Aleksić et al. 2016). It can be seen from Fig. 3 that for \( E_{p,\text{max}} > 10 \text{EeV} \) the cosmogenic γ-ray flux exceeds the MAGIC observation (Ansoldi et al. 2018) of the TXS 0506+056 post-IceCube detection in the enhanced VHE γ-ray emission state (data points shown by open violet squares in the top-left panel) if the IceCube neutrino flux is at the \( \Delta T = 0.5 \) yr level. The MAGIC data points, therefore, serve as upper limits to the line-of-sight γ-ray flux contribution in the sub-TeV energy band if emission from the jet also contributes to the observed flux, which does not show any significant variability in the MAGIC data. If the CTA detects γ-ray variability in the multi-TeV energy band, then the cosmogenic origin will be disfavored. The spectral index of the VHE emission in the TeV range will be crucial to understanding the origin. If it matches with the synchrotron, one can expect the yield to be leptonic, whereas gamma rays of hadronic origin are expected to have more cascade interactions inside the jet due to their higher energy. In any case, the jet component is expected to give a softer γ-ray spectrum after EBL correction compared to the cosmogenic component. For the cosmogenic component, a hard spectrum is expected at a few TeV energies, as shown in Fig. 3. IceCube Gen-2 will be able to detect cosmogenic neutrino flux for \( \alpha \gtrsim 10, E_{p,\text{max}} = 10^{20} \text{eV at the } \Delta T = 0.5 \text{ yr flux level, whereas } \alpha \gtrsim 30 \) will be required for detection at the \( \Delta T = 7.5 \text{ yr flux level.} \)

### 2.2. PKS 1502+106, 3HSP J095507.9+355101, and GB6 J1040+0617

We conducted a similar study for a few other IceCube neutrino events that are significantly associated with blazars. The number of muon neutrino and antineutrino events observed at IceCube in a given operational time, \( \Delta T \), is given by

\[
N_{\nu} = \Delta T \int_{E_{\text{min}}}^{E_{\text{max}}} \frac{d \Phi_{\nu}}{d \epsilon_{\nu}} \langle A_{\text{eff}}(\epsilon_{\nu}) \rangle \, d \epsilon_{\nu},
\]

where \( \langle A_{\text{eff}}(\epsilon_{\nu}) \rangle \) is the effective detector area averaged over the zenith angle bin concerned (Aartsen et al. 2019b). For neutrino flux calculations, we used an updated effective area for event selection as a function of neutrino energy from Stettner (2020). We assumed a muon neutrino flux of the form \( d \Phi_{\nu} / d \epsilon_{\nu} = k \epsilon_{\nu}^{-\alpha} \) and an operation time \( \Delta T = 10 \) years (i.e., from when IceCube became fully operational in 2010 up until 2020). The all-flavor neutrino flux can be approximated as three times the \( \nu_\gamma + \bar{\nu}_\gamma \) flux.

The high-energy astrophysical muon neutrino candidate IC-190730A was detected by IceCube with energy \( \epsilon_{\nu} \approx 300 \text{TeV} \). The Fermi catalog source 4FGL J1504.4+1029, associated with the flat-spectrum radio quasar PKS 1502+106 at \( z = 1.84 \), was found to be within the 50% uncertainty region, at an offset of 0.31 degrees from the best-fit neutrino direction (IceCube Collaboration 2019). Assuming this to be the only event from this source in 10 yrs, the estimated all-flavor neutrino flux using Eq. (1) is \( \approx 4.1 \times 10^{-10} \text{ erg cm}^{-2} \text{s}^{-1} \), and hence \( L_\nu \approx 10^{49} \text{ erg s}^{-1} \). We find the survival fraction of UHECRs, \( \epsilon_{\Phi} = 0.25 \), within 1° of the initial emission direction toward the Earth.

IC-200107A has been associated with the γ-ray blazar 3HSP J095507.9+355101, a BL Lac at \( z = 0.557 \), which is listed in the Fermi-LAT 4FGL catalog (IceCube Collaboration 2020). It is an extreme blazar with a peak synchrotron frequency \( \nu_s > 10^{17} \text{ Hz located at an angular separation of 0.63 degrees from the best-fit neutrino direction. There is another source, 4FGL J0957.8+3423, within the 90% localization region but 1.5 degrees from the neutrino event. The integrated all-flavor neutrino flux needed to produce the single event of \( \epsilon_{\nu} = 0.33 \text{PeV} \) in 10 years is found to be \( 3 \times 10^{-11} \text{ erg cm}^{-2} \text{s}^{-1} \) (Giommi et al. 2020b). The corresponding all-flavor neutrino luminosity is \( L_\nu = 4.1 \times 10^{46} \text{ erg s}^{-1} \). For a source at this redshift, we find \( \epsilon_{\Phi} = 0.52 \).

An archival neutrino event, IC-141209A, which satisfies the IceCube real-time trigger criteria, was found to be spatially coincident with the γ-ray source GB6 J1040+0617 (Garrappa et al. 2019). The chance probability of this coincidence was found to be 30% after trial correction. The source is listed in the Fermi-LAT 3FGL catalog at \( z = 0.7351 \) and lies within the 90% uncertainty region of the best-fit neutrino direction. The event deposited 97.4 TeV energy in the IceCube detector. We calculated the survival fraction to be \( \epsilon_{\Phi} = 0.4 \) and the all-flavor neutrino flux to be \( \Phi_{\nu} \approx 4.4 \times 10^{-10} \text{ erg cm}^{-2} \text{s}^{-1} \), and thus \( L_\nu = 1.1 \times 10^{48} \text{ erg s}^{-1} \).

In Fig. 3 we show the line-of-sight cosmogenic fluxes for the three blazars discussed above, with \( \alpha = 16/3 \) and the respective UHECR survival fraction \( \epsilon_{\Phi} \) and three values of \( E_{p,\text{max}} \), namely 1, 10, and 100 EeV. Also shown are the γ-ray flux data from Fermi-LAT as well as the sensitivities of different telescopes. The inferred neutrino luminosities from the associated IceCube events in the case of PKS 1502+106 and GB6 J1040+0617 are much higher than the Eddington luminosity of a super-massive black hole, \( L_{\text{Edd}} = 1.3 \times 10^{47} \text{ erg s}^{-1} \). Therefore, it is unlikely that these are the source of the detected IceCube neutrinos. Because of its high redshift, the cosmogenic γ-ray flux from PKS 1502+106 is very low. However, CTA-North will be able to constrain the cosmogenic γ-ray flux from GB6 J1040+0617. The cosmogenic neutrino flux for both blazars can be tested with IceCube Gen-2 for such an extreme blazar luminosity. The case of 3HSP J095507.9+355101 is the most compelling among these three blazars as a plausible IceCube neutrino source. The hard γ-ray spectrum observed by Fermi-LAT could be explained as cosmogenic γ rays for \( E_{p,\text{max}} \approx 10 \text{ EeV} \). If a hard spectrum is also detected at a few TeV energies by the CTA, it may be the signature of cosmogenic origin because such hardening may not be seen for intrinsic emission from the jet due to EBL attenuation resulting in a soft spectrum. The sensitivity of CTA-North is comparable to the plotted flux level in Fig. 3 and will be in a position to constrain the parameter \( \alpha \). Detection of cosmogenic neutrinos from 3HSP J095507.9+355101 by IceCube Gen-2 will require \( \alpha \gtrsim 10 \).

### 3. Summary and outlook

In the last few years, there has been growing evidence of blazar candidates for several high-energy IceCube events (Francowkiak et al. 2020). With observations of several well-reconstructed track events by the new Gold-alert system and the electromagnetic follow-up observations, the detection of neutrino events associated with transient phenomena is now possible. The IceCube events considered here have been studied in the past for self-consistent modeling of the blazar SED and emission of neutrinos from the jets (Banik et al. 2020; Petropoulou et al. 2020; Rodrigues et al. 2021a). In some scenarios, a significant fraction of neutrinos at EeV energies can be attributed to that produced from inside the sources (Rodrigues et al. 2021b).
We have presented cosmogenic neutrino and γ-ray fluxes from these blazars along the line-of-sight, assuming that UHECRs with energies from $10^{16} \text{–} 10^{20}$ eV can be accelerated and can escape from the jets. We used a suitable value of the injection spectral index in the aforementioned energy range, in the absence of an unequivocal choice. The neutrino flux may vary moderately for other values, while the cosmogenic γ-ray spectrum depends more on the cosmic background photons. For comparison, we also show the neutrino flux for lower values of $E_{p,\text{max}} = 1$ and 10 GeV while keeping the value of $\alpha = 16/3$. In these cases, the cosmogenic neutrino fluxes are practically undetectable.

We used a realistic value of $10^{-16}$ G for the intergalactic magnetic field for deflection of UHECRs from the line-of-sight. The normalization of the cosmogenic fluxes was set by assuming that the UHECR luminosity of the source is a factor $\alpha$ times the sub-PeV neutrino luminosity inferred from the respective IceCube event. The line-of-sight cosmogenic fluxes appear with harder spectra compared to the fluxes directly from the jets and can be identified by the neutrino and γ-ray telescopes. In cases where the cosmic rays are not accelerated to $10^{20}$ eV, the cosmogenic neutrino fluxes will be lower than we estimate here. Both higher luminosity in UHECRs and a higher value of $E_{p,\text{max}}$ can aid in the detection of cosmogenic neutrinos. But given the sensitivity of future detectors, an observation of a cosmogenic neutrino event at $\approx 1$ TeV is more likely if the maximum rigidity of cosmic-ray injection is near the Greisen-Zatsepin-Kuzmin limit.

We find that the inferred sub-PeV neutrino luminosities of PKS 1502+106 and GB6 J1040+0617 are already above the Eddington luminosity because of their relatively high redshifts, and a further requirement of a factor $\geq 5$ times this luminosity in UHECRs for cosmogenic neutrino detection by IceCube Gen-2 is unrealistic. Because of the high redshift, cosmogenic γ-ray flux from PKS 1502+106 is very low. In the case of GB6 J1040+0617, the CTA will be able to constrain the cosmogenic γ-ray flux.

We also find that the blazars TXS 0506+056 and 3HSP J095507.9+355101 are very promising sources for the detection of cosmogenic neutrino and γ-ray fluxes. The required luminosities in UHECRs are $\sim 100$–1000 times (for $E_{p,\text{max}} \approx 10^{20}$ eV) the sub-PeV neutrino luminosities inferred from $\sim 10$ years of IceCube data but are consistent with the Eddington luminosity. The upcoming CTA will be able to detect or constrain the cosmogenic γ-ray fluxes and shed light on the question of whether sub-PeV neutrino sources are also the sources of UHECRs.
