(March 21, 2022)

Within the path integral formalism, we derive exact expressions for correlation functions measuring the lattice charge induced by an electron and associated polarization in Fröhlich polaron problem. We prove that a sum rule for the total induced charge, already obtained within approximated approaches is indeed exact. As a consequence the total induced charge is shown rigorously to be temperature independent. In addition we perform path integral Monte Carlo calculations of the correlation functions and we compare with variational results based on Feynman method. As the temperature increases the polaron radius decreases. On the other hand at high temperatures the electron motion is not hindered by the lattice. These apparently contradictory results are discussed.

I. INTRODUCTION

An electron added to an insulating polar crystal forms a quasiparticle called dielectric polaron after Fröhlich. This has been recognized as a fundamental field theoretical problem. More recently a variety of novel materials have emerged which present interesting properties when doped away from an insulating phase, like colossal magnetoresistive manganites and high temperature superconducting cuprates. The fact that these are polar crystals has produced a renewed interest in Fröhlich polaron problem.

Roughly speaking a dielectric polaron is composed of an electron and the (opposite) charge that it induces in the lattice. Electron and induced charge attract each other so that for the electron to move it has to drag the induced charge resulting in an increase of the quasiparticle mass. In this work we study correlation functions which measure the magnitude and spatial extent of the induced charge and associated polarization field.

We derive a rigorous sum rule which states that the total induced charge equals the charge induced by a classical (static) electron and it is independent of temperature. This result, well known within perturbative and variational approaches, is proven here to be exact. The large distance behavior of the electric field is determined by this sum rule. In addition we discuss the short distance and the high temperature asymptotic limit of these quantities. These results provide constraints to approximations on the polaron problem.

Real space path integral Monte Carlo (PIMC) method is used to evaluate correlation functions. These are compared with Feynman’s variational approximation (FVA) and analytical results in weak and strong coupling. We find that the polaron radius is determined at low temperatures by the electron-phonon coupling $\alpha$ alone while at high temperatures it is proportional to the de Broglie thermal wave length ($\lambda_T = \hbar \sqrt{2\pi \beta / m}$ with $\beta$ the inverse temperature) and becomes independent of coupling. We define a polaron crossover temperature $T^*(\alpha)$. Although the electron induces a temperature independent charge in the lattice the induced charge hinders the electron motion only below $T^*(\alpha)$. At high temperatures thermal effects wash out the hindering effect of the induced charge but, we remark again, not the induced charge itself.

II. ANALYTICAL RESULTS

Our starting point is the effective action for the Fröhlich polaron problem, after the phonons have been eliminated with the usual path integral techniques, \[ S = S_0 + S_I \]

\[
S_0[x] = \int_0^{\hbar \beta} d\tau \frac{1}{2} m \dot{x}^2
\]

\[
S_I[x] = -\alpha \frac{\hbar \omega_L}{m^{1/2}} \int_0^{\hbar \beta} d\tau_1 \int_0^{\hbar \beta} d\tau_2 \frac{D(\tau_1 - \tau_2)}{|x(\tau_1) - x(\tau_2)|}
\]

here $m$ is the electron mass, $\alpha = e^2 m^{1/2} / \hbar \epsilon (2 \hbar \omega_L)^{1/2}$, is the coupling constant with $\omega_L$ the phonon frequency, $\epsilon = 1/\epsilon_{\infty} = 1/\epsilon_0$ and $\epsilon_{\infty}$ ($\epsilon_0$) is the high (zero) frequency dielectric constant.

\[
D(\tau) = \frac{\exp(\omega_L |\tau|) + \exp(\hbar \beta - |\tau|) \omega_L}{\exp(\hbar \beta \omega_L) - 1}
\]

is the phonon propagator.

We are interested in the correlation function between the electron charge density $-e\delta(\mathbf{r})$ and the charge induced in the lattice $e\delta(\mathbf{r})$ normalized to the probability density to find an electron at a given point i.e. the inverse of the volume $V$. Dropping the charges this is defined as,
\[ \langle \hat{n}(0)\hat{n}_i(r) \rangle / V^{-1} \equiv g(r)/\bar{\epsilon} \quad (3) \]

Averages are defined as path integrals weighted by \( S \)
\[ \langle \ldots \rangle = \frac{\int \mathcal{D}x e^{-S/k}(\ldots)}{\int \mathcal{D}x e^{-S/k}} \quad (4) \]

where the paths entering in Eq. (3) depart and arrive at the same point. Further integration over such a point is not performed and this assigns to Eq. (3) the meaning of a constrained average with \( x(0) = x(\beta) = 0 \). Those averages are however equivalent to the unconstrained ones because of translational invariance. We used the spherical symmetry of the problem to define \( g(r) \), and we divided by \( \bar{\epsilon} \) on the right hand side of Eq. (3) for later convenience. Another quantity of interest is the induced lattice polarization
\[ \mathbf{P}(r) \equiv \langle \hat{n}(0)\mathbf{P}(r) \rangle / V^{-1} \quad (5) \]

\[ \nabla \mathbf{P}(r) = -\epsilon \mathbf{e}(r) \] is the density of polarization operator. The correlation function in Eq. (3) is related to the induced electrostatic potential \( \nabla^2 V(r) = -4\pi \epsilon g(r)/\bar{\epsilon} \)

considered in Ref. 11 and which will not be discussed here. We stress that these quantities have the meaning of correlation functions measuring average induced charge, polarization and induced potential at a distance \( r \) from the electron position.

The charge density operator for the phonons is
\[ \epsilon \mathbf{e}(r) = -\sqrt{\hbar \omega_L / 4\pi V \bar{\epsilon}} \sum_k \mathbf{Q}_k e^{i\mathbf{k} \cdot \mathbf{r}}. \quad (6) \]

where \( \mathbf{Q}_k \) is the dimensionless displacement for momentum \( \mathbf{k} \) phonons. Inserting Eq. (3) in Eq. (3) we obtain an equation for \( g(r) \) as a function of the density displacement correlation function \( \langle \hat{n}(0)\hat{Q}_k \rangle \). The phonon variables can be traced out by standard methods. We have found that it is possible to give an exact expression for the correlation functions in terms of path integrals weighted by the effective electronic action of Eq. (3). We find for the density-induced-density correlation function
\[ g(r) = \int_0^\beta d\tau U(\tau) \langle \delta[\mathbf{r} - \mathbf{x}(\tau)] \rangle \quad (7) \]

and for the polarization field
\[ \mathbf{P}(r) = -\frac{\epsilon}{4\pi \bar{\epsilon}} \int_0^\beta d\tau U(\tau) \left( \frac{\dot{\mathbf{r}}}{|\mathbf{r} - \mathbf{x}(\tau)|^2} \right) \quad (8) \]

where \( \dot{\mathbf{r}} \equiv \mathbf{r}/r \) and
\[ U(\tau) = \hbar \omega_L \sinh(\omega_L \tau) + \sinh[\omega_L(\hbar \beta - \tau)] / 2 \tanh(\beta \hbar \omega_L / 2) \sinh(\beta \hbar \omega_L) . \quad (9) \]

Within FVA, the variational quadratic action can be exploited in Eqs. (8) (9) to analytically perform the averages and to recover the results of Refs. 10 and 11.

Eqs. (8) (9) have a simple physical interpretation. The induced charge can be seen as “distributed” along the electron path with weight \( U(\tau) \). The polarization is the superposition of polarizations associated with those elementary induced charges.

Eq. (9) can be integrated in the whole space using the properties of the Dirac’s \( \delta \) function. Since \( \int d\tau U(\tau) = 1 \), we conclude that \( g(r) \) is normalized to one. The total induced charge \( q \) is computed by integrating the density-induced density correlation function in Eq. (9):
\[ q = e \int_0^\infty d\tau 4\pi r^2 g(r)/\bar{\epsilon} = e/\bar{\epsilon} \quad (10) \]

which completes the proof of the sum rule. The total induced charge amounts to the charge the electron would induce if it were a static classical particle. In other words there are no quantum corrections to the total induced charge.

An alternative derivation can be work out following Quémerais. From the time derivative \( i\hbar \dot{\mathbf{P}} = [\dot{\mathbf{P}}, \mathbf{H}] \) one obtains
\[ \mathbf{P} = \omega_L^2 \left( \frac{1}{4\pi \epsilon} \mathbf{D} - \mathbf{P} \right) \quad (11) \]

Here \( \mathbf{H} \) is the Hamiltonian, \( \mathbf{D} \) is the electric displacement operator due to the electron \( \nabla \cdot \mathbf{D} = -4\pi \epsilon \mathbf{e} \) and \( i\hbar \dot{\mathbf{P}} = [\mathbf{P}, \mathbf{H}] \). Taking the divergence we obtain a relation for the charge operators:
\[ \nabla \cdot \mathbf{P}(r) = \omega_L^2 e \left( -\frac{\hat{n}(r)}{\bar{\epsilon}} + \hat{n}_i(r) \right) \quad (12) \]

We can integrate this expression in all space and take the thermodynamic average. The left hand side is proportional to the average of the net force felt by the lattice at the boundary of the system which should vanish at equilibrium. The right hand side gives Eq. (10).

Eq. (10) shows that the induced charge is independent of temperature. This contradicts the naive argument that all polaron effects should disappear at high temperatures. To understand this behavior one can do an analogy with the behavior of an harmonic oscillator in an external field. In that case, because of harmonicity, one gets a displacement which is temperature independent. Here roughly speaking the harmonic oscillator represents the phonon coordinates and the external field is the field produced by the electron on the phonons. The induced charge is a measure of how much the ions displace from their bare equilibrium positions in the presence of the electron. As for the single harmonic oscillator, this “displacement” is independent of temperature. Only anharmonicities can make the induced charge temperature dependent.

Using the sum rule it is easy to see that at distances much larger than the polaron radius, as defined below, the polarization field goes as \( \mathbf{P}(r) = -e\mathbf{r}/(4\pi \bar{\epsilon} r^2) \).

Clearly the distortion produced by the electron is long
range, a fact that is not always recognized in the literature. The total electric field (always in the sense of a correlation function) is given by $E = D - 4\pi p$ where we should include in $D = -e\dot{\epsilon}/(\epsilon_\infty r^2)$ the high frequency screening. At long distances we have $E(r) = -e\dot{\epsilon}/(\epsilon_\infty r^2)$ which means that the electric field generated by the electron gets screened by the static dielectric constant. This is generally expected but to the best of our knowledge has never been proven for all coupling and temperatures.

Now we discuss the short distance behavior. At distances much smaller than the polaron radius we expect that the effect of the interaction becomes irrelevant in the functional integrals. This is because the latter are dominated by electron paths with short wave length or equivalently high kinetic energy. We can then replace the total action by the free electron action in Eqs. (7),(8). We obtain the asymptotic result:

$$\lim_{r\to 0} P(r) = \frac{e}{8\pi d^2 \tanh(\beta \hbar \omega_L/2)} \hat{r}. \quad (13)$$

where $l = \sqrt{\hbar/2m\omega_L}$ is the harmonic oscillator characteristic length. Using the same argument we obtain that $g(r) \propto r^{-1}$ for $r \to 0$ and the proportionality coefficient can also be obtained with the same method. The latter behavior has been obtained in Ref. 8 within the FVA. These results coincide with lowest order perturbation theory.

At high temperatures we also expect that the effect of the interaction becomes irrelevant and so we can replace again the total action by the free electron action in the functional integrals. The high temperature asymptotic result for $g(r)$ is

$$4\pi r^2 g(r) = \frac{2r}{l^2 \beta \hbar \omega_L} \exp\left(-\frac{r^2}{2l^2 \beta \hbar \omega_L}\right) \quad \beta \hbar \omega_L << 1. \quad (14)$$

This result has also been obtained in Ref. 8 within FVA. We remark that although the density-induced density correlation function does not vanish for large temperatures the polaron effective mass tends to the bare electron mass.

### III. NUMERICAL RESULTS

Now we discuss the spatial extent of the induced charge at general couplings and temperatures. We have evaluated averages in Eq. (7) using PIMC. Eqs. (7),(8) being expressed in real space rather than in Fourier components are more suitable for this purpose. We have performed Metropolis PIMC calculations within the imaginary time discretization scheme. In order to regularize the attractive divergence of the retarded action at short distance, and to improve the convergence with the number of the imaginary time discretization points, we have developed a preaveraging procedure similar to the one used for local actions. Details of the method and more extensive results will be given in a separate publication. Here we just say that the results for the $g(r)$ are well converged as checked by doubling the number of imaginary time slices. Previous MC studies of the Fröhlich polaron were limited to small ($\alpha \leq 4$) or intermediate ($\alpha \leq 7$) couplings and were focused to the calculation of the ground state energy, and effective mass.

Following Ref. 9 we have also computed $g(r)$ in the FVA, i.e. using Feynman’s quadratic action to evaluate the average appearing in Eq. (7). We remark that although the density-induced density correlation function does not vanish for large temperatures much smaller than the polaron radius we expect that the effect of the interaction becomes irrelevant and so we can replace the total action by the free electron action in Eqs. (7),(8). We obtain the asymptotic result:

$$\lim_{r\to 0} P(r) = \frac{e}{8\pi d^2 \tanh(\beta \hbar \omega_L/2)} \hat{r}. \quad (13)$$

where $l = \sqrt{\hbar/2m\omega_L}$ is the harmonic oscillator characteristic length. Using the same argument we obtain that $g(r) \propto r^{-1}$ for $r \to 0$ and the proportionality coefficient can also be obtained with the same method. The latter behavior has been obtained in Ref. 8 within the FVA. These results coincide with lowest order perturbation theory.

At high temperatures we also expect that the effect of the interaction becomes irrelevant and so we can replace again the total action by the free electron action in the functional integrals. The high temperature asymptotic result for $g(r)$ is

$$4\pi r^2 g(r) = \frac{2r}{l^2 \beta \hbar \omega_L} \exp\left(-\frac{r^2}{2l^2 \beta \hbar \omega_L}\right) \quad \beta \hbar \omega_L << 1. \quad (14)$$

This result has also been obtained in Ref. 8 within FVA. We remark that although the density-induced density correlation function does not vanish for large temperatures the polaron effective mass tends to the bare electron mass.

This result has also been obtained in Ref. 8 within FVA. We remark that although the density-induced density correlation function does not vanish for large temperatures the polaron effective mass tends to the bare electron mass.
phonons relax shrinking the spatial extent of the electron till the increase in electron kinetic energy balances the gain in electron-phonon interaction energy. At high temperatures, however, a typical electron has energy $E = 3/2\beta$ and momentum $\hbar k = \sqrt{3m/\beta}$. One can construct a wave packet of width $\Delta k$ in momentum space using plane waves with higher and smaller energy without affecting the electron internal energy. The biggest $\Delta k$ which will not affect the electron internal energy is of order of $\bar{k}$ itself. One can then achieve a localization of the electron of order $1/k \sim \hbar/\sqrt{3m/\beta} \sim \lambda_T$. It follows that the phonons can relax at practically no cost till the polaron radius stabilizes at a value of this order. In fact at high temperatures the asymptotic value of the polaron radius can be obtained from Eq. (14): $\lim_{\beta \rightarrow 0} r_m = l\sqrt{\beta \hbar \omega_L/\beta} = 0.2\lambda_T$. This scaling has been found by Sethia et al.[2] for the mean square displacement of the electron in imaginary time. Notice that the polaron radius becomes independent of the coupling.

The same behavior of $r_m$ has been obtained in Ref. [1] within FVA. The authors of Ref. [1] ascribe the high temperature behavior of the polaron radius to the increased fluctuations of the phonon field. We conversely think that the thermal fluctuations of the electron are responsible of the high temperature behavior of the polaron radius and the phonon field acts only as a probe of the intrinsic thermal length of the electron as explained above.

The polaron radius $r_m$ is independent of the coupling and is determined by the electron in Fröhlich polaron problem and the associated polarization field. We have derived relations which express the charge-induced density correlation function in terms of path integral involving only the electronic degree of freedom which are suitable to be evaluated by PIMC method. A rigorous sum rule was derived that determines the total induced charge and the long distance behavior of the polarization field. We give also the asymptotic limits of these quantities at short distances and at high temperatures. We have compared results obtained using

![FIG. 3. The polaron radius as a function of coupling for different inverse temperatures. Results from FVA are shown as dash-dotted ($\beta\hbar \omega_L = 0.1$), dashed ($\beta\hbar \omega_L = 1.0$), thick-solid ($\beta\hbar \omega_L = 20$) and thin-solid lines ($\beta\hbar \omega_L = \infty$). Dotted line is the Landau Pekar approximation. Results from PIMC calculations are shown as triangles ($\beta\hbar \omega_L = 0.1$), circles ($\beta\hbar \omega_L = 1.0$) and squares ($\beta\hbar \omega_L = 20$).](image)

In the low temperature regime ($T < T^*$) the polaron radius becomes almost temperature independent and is determined by the coupling $\lambda_T$. The high temperature regime $T > T^*$ is characterized by a polaron radius which is independent of the coupling and is determined by the temperature alone ($r_m = 0.2\lambda_T$).

**IV. CONCLUSIONS**

We have studied the charge induced in the lattice by an electron in Fröhlich polaron problem and the associated polarization field. We have derived relations which express the charge-induced density correlation function in terms of path integral involving only the electronic degree of freedom which are suitable to be evaluated by PIMC method. A rigorous sum rule was derived that determines the total induced charge and the long distance behavior of the polarization field. We give also the asymptotic limits of these quantities at short distances and at high temperatures. We have compared results obtained using

![FIG. 2. $4\pi r^2 g(r)$ as a function of $r$ at $\alpha = 6$. From left to right curves (FVA after the formalism of Ref. [1] and points (PIMC) refers to $\beta\hbar \omega_L = 0.1, 1.0, 20$, respectively.](image)
FVA through the lines of Refs. 9–11 and those obtained by PIMC method. To the best of our knowledge this is the first PIMC computation of real space correlation functions in Fröhlich model. From the spatial dependence of the induced charge we obtained a polaron radius. The polaron radius is determined by the coupling at low temperatures and by the thermal wave length at high temperatures with a crossover temperature that we evaluated in FVA.

At high temperature a polaron with small radius and small effective mass is achieved. These results are not in contradiction because the small radius at high temperatures is a thermal effect of the electron and it is not related to the lattice response. The lattice acts only as a probe of the intrinsic electron localization radius namely $\lambda_T$. Obviously this small radius polaron has nothing to do with the Holstein zero-temperature small polaron which induces almost local lattice displacements and moves coherently with a large effective mass.

The PIMC polaron radius is always smaller than the FVA calculation in the range of coupling and temperature studied. This effect is more pronounced at intermediate couplings. The overall temperature dependence agrees with the findings of Ref. 9–11 however our physical interpretation is different.
