(Received: October 19, 2015; accepted: April 28, 2016)

INTRODUCTION

Pathological gambling is a behavioral addiction that is often accompanied by other disorders, such as anxious and depressive disorders, and drug and alcohol abuse (Barnes, Welte, Tidwell, & Hoffman, 2015; el-Guebaly et al., 2006; Griffiths, Wardle, Orford, Sproston, & Erens, 2011; Petry, 2007). Lorains, Cowlishaw, and Thomas (2011) conducted a meta-analysis in which they found that 57.5% of gamblers had a comorbid substance use disorder. This study also showed that 37.9% of gamblers suffered from a mood disorder, whereas 37.4% had anxiety disorders. Gambling and substance use disorders are related, with similarities at clinical, phenomenological, and biological levels (Wareham & Potenza, 2010). According to Problem-Behavior Theory (Jessor & Jessor, 1977), potentially harmful behaviors often co-occur, partly, because they share internal and external characteristics that would cause those behaviors.

Emotional disorders, such as anxiety and depression, are associated with concurrent difficulties in emotion regulation (Aldao, Nolen-Hoeksema & Schweizer, 2010; Hofmann, Sawyer, Fang, & Asnaani, 2012), that is, the process by which individuals influence which emotions they have, when they have them, and how they experience these emotions (Gross, 2013). Emotion regulation is proving to be a central concept in most psychological disorders because difficulties in emotion regulation are related to their etiology and maintenance (Bradley, 2000). It has been suggested that emotion regulation may constitute a common transdiagnostic factor among all of them (Kring & Sloan, 2009; Trosper, Buzzella, Bennett, & Ehrenreich, 2009). Emotion dysregulation is also closely related to impulsive behaviors. Authors such as Schreiber, Grant, and Odlaug (2012) have noted that high punctuations in impulsivity are associated with greater difficulties in regulating emotions. In particular, pathological gamblers have been shown to have difficulties in emotion regulation in clinical samples (Estévez, Herrero, Sarabia, & Jauregui, 2014; Williams, Geisham, Eerskine, & Cassidy, 2012) although few studies exist on the topic. Emotion regulation has also been related to drug abuse (Weiss, Tull, Anestis, & Gratz, 2013), alcohol (Fox, Hong, & Sinha, 2008), and other impulsive behaviors such as binge eating (Whiteside et al., 2007), problematic internet use (Caplan, 2010), or risky sexual behavior (Messman-Moore, Walsh, & DiLillo, 2010).

It has been suggested that emotion regulation might be one of the factors that explains the presence of addictive

disorders. Pathological gambling has been related to the expectancy of obtaining positive affective states or alleviating negative affective states through gambling (Shead, Callan, & Hodgkins, 2008). Khantzian (1985) proposed that substance use could be a way of self-medication for its use may alleviate distress; therefore, averse emotional states may predispose one to substance abuse (Colder, 2001; Robinson, Sareen, Cox, & Bolton, 2009). Drug intoxication, for example, may be a form of emotion regulation because substances may partly be used as a means of regulating one’s present emotional state, i.e., heightening positive affect, alleviating or improving negative affect, or reducing cravings (Kober & Bolling, 2014). Many models have followed this idea and considered that one’s desire to alter his/her mood may underlie addictive behavior (Cooper, Frone, Russell, & Mudar, 1995; Cox & Klinger, 1990; Simons, Gaier, Correa, Hansen, & Christopher, 2005). The same idea has been applied to pathological gambling (Stewart & Zack, 2008). Additionally, it has been found that individuals with both pathological gambling and another comorbid addictive disorder performed both addictive behaviors due to the same motives (Stewart, Zack, Collins, & Klein, 2008).

As noted, pathological gambling and alcohol and drug abuse are related to the presence of anxious and depressive symptomatology, as well as difficulties in emotion regulation. According to Tice, Bratslavsky, and Baumeister (2001), negative emotional states can lead to impulsive behaviors such as gambling, alcohol or drug use, as a way of regulating negative emotions and as a consequence of failures in self-control. In the same line, Weiss, Tull, Viana, Anestis, and Gratz (2012) found that difficulties in emotion regulation mediate the relationship between post-traumatic stress disorder and impulsive behaviors. These authors suggested that impulsive behaviors are associated with maladaptive responses to emotions or difficulties controlling behaviors in the presence of emotional distress. In the case of pathological gambling, the only similar study is the one conducted by Estévez et al. (2014), which showed that difficulties in emotion regulation may be mediators of the relationship between pathological gambling, internet and mobile abuse, and dysfunctional psychological symptomatology in young adults and adolescents. However, adolescence is a period of emotional development (Silk, Steimberg, & Morris, 2003), so these results could be different in other age ranges. Additionally, in that study, the effect of other addictions was not measured, which may have affected to the results.

Therefore, this study had three primary aims. First, we aimed to measure the differences in emotion regulation and anxious and depressive symptomatology as a function of the presence or absence of pathological gambling. Second, we aimed to analyze the relationship and predictive role of emotion regulation with pathological gambling, drug and alcohol abuse, and depressive and anxious symptomatology. Finally, our third aim was to analyze the mediating role of emotion regulation between anxious and depressive symptomatology and pathological gambling, measuring the effect of drug and alcohol abuse.

METHODS

Participants

The study sample contained 274 participants from centers of treatment for pathological gambling, mostly associated with FEJAR (Spanish Federation of Rehabilitated Gamblers), as well as social networks and university centers. Participants also had to be greater than 18 years of age to be eligible for the study. The sample was divided into two subsamples. Individuals who were rated as pathological gamblers on the South Oaks Gambling Screen (SOGS; Lesieur & Blume, 1987) and came from centers for treatment for pathological gambling were included in the group of pathological gamblers. The other group comprised individuals who scored as non-gamblers and came from universities and social networks. Finally, to balance the groups, women were excluded because only 7 women with pathological gambling were recruited compared to 211 women in the non-gambler group. The group with pathological gambling consisted of 167 male participants between 18 and 69 years of age and the group without pathological gambling consisted of 107 male participants between 18 and 69 years of age. The sociodemographic data for the two subsamples are shown in Table 1.

Measures

Pathological gambling. Pathological gambling was assessed by the SOGS (Lesieur & Blume, 1987). The Spanish version was adapted by Echeburúa, Báez, Fernández-Montalvo, and Páez (1994). The SOGS is a tool for screening pathological gambling that was developed for clinical populations, containing 32 items. Scores above 4 points suggest the probable presence of pathological gambling. Regarding its reliability, the SOGS has high internal consistency, with a Cronbach’s α of .94. Moreover, its test–retest reliability over an interval of 4 weeks was .98 (p < .001), and the convergent validity with the DSM-IV criteria was .94. In this study, Cronbach’s α for the SOGS was .91.

Drug and alcohol abuse. The MULTICAGE CAD-4 (Pedroso-Pérez et al., 2007) is a measure of impulsivity and addictive behavior, with or without substance use, including pathological gambling, alcohol abuse or dependency, substance addiction, eating disorders, addiction to the internet, addiction to video games, compulsive shopping, and addiction to sex. It contains 32 items. The internal consistency of the MULTICAGE CAD-4 is satisfactory (Cronbach’s α for the total scale = .86 while subscales show values greater than .70). The test–retest reliability over 20 days is r = .89. The criterion validity is also adequate (it detects between 90 and 100% of cases already diagnosed). In this study, the alcohol (Cronbach’s α = .77) and drugs (Cronbach’s α = .85) subscales were used.

Emotion regulation. The Difficulties in Emotion Regulation Scale (DERS; Gratz & Roemer, 2004) was used to measure emotion dysregulation through the analysis of different deficits that may affect optimal emotional regulation. We used the Spanish version of the DERS in this study (Hervás & Jódar, 2008). The total number of items was
reduced (28 items) in the Spanish version compared to the original version (36 items). Items were rated along a 5-point Likert scale ranging from “Almost never/0–10% of the time” to “Almost always/90–100% of the time.” The distribution of items on the Spanish version was also different; specifically, the original version comprised six factors while the Spanish adaptation had five factors. Factors included: 1) Lack of emotional awareness: reflects an inattention to, and lack of awareness of, emotional responses; 2) Non-acceptance of emotional responses: reflects a tendency to have negative secondary emotional responses to one’s negative emotions, or nonaccepting reactions to one’s distress; 3) Lack of emotional clarity: reflects the extent to which individuals know (and are clear about) the emotions they are experiencing; 4) Difficulties engaging in goal-directed behavior: reflects difficulties concentrating and accomplishing tasks when experiencing negative emotions; and 5) Lack of emotional control: reflects difficulties remaining in control of one’s behavior when experiencing negative emotions and the belief that there is little that can be done to regulate emotions effectively, once an individual is upset. The level of internal consistency of the DERS is optimal, with a Cronbach’s α of .93 for the total scale and ranging from .73 and .91 for the others. Moreover, test–retest reliability measured in a lapse of 6 months was adequate, indicating a good temporal stability (Hervás & Jódar, 2008). In this study, the Cronbach’s α was .94 for the overall scale and ranged from .79 and .93 in the five subscales.

Anxious and depressive symptomatology. Anxious and depressive symptomatology was assessed using the Anxiety and Depression subscales of the Symptom Assessment-45 Questionnaire (SA-45; Davison et al., 1997), a short version of the Symptom Checklist 90-R (SCL-90-R; Derogatis, 2002), which was adapted into Spanish by Sandín, Valiente, Chorot, Santed, and Lostao (2008). It is an instrument for evaluating psychopathological symptomatology. On the SA-45, participants indicate the degree to which each of the 45 symptoms had been present during the last week along a Likert scale ranging from 0 (“Nothing at all”) to 4 (“Extremely”). The questionnaire measures the following nine factors: depression, anxiety, phobic anxiety, hostility, interpersonal sensitivity, somatization, psychotism, paranoid ideation, and obsessive-compulsivity. In this study, two subscales were used, Anxiety and Depression. The SA-45 has high internal consistency, with Cronbach’s α of .95 for the total scale, .85 for the Depression subscale, and .84 for the Anxiety subscale. Moreover, the convergent validity and discriminant validity are adequate. In this study, Cronbach’s α was .83 in the Depression subscale and .84 in the Anxiety subscale.

Procedure

Participants were recruited to this study in different ways. Pathological gamblers, who were in treatment at the time of their participation (average months in treatment = 3.36), were recruited from centers and associations for the treatment of pathological gambling, where gamblers in treatment were invited to participate. Non-gamblers were recruited from university centers (12.1%) and social networks (87.9%). Participants completed a questionnaire, in either an online or offline format. In both cases, the questionnaire contained a cover letter that included an explanation of the study, its aims, the voluntary nature of participation, informed consent, and the confidentiality and anonymity of the obtained data. Contact details for the researchers were also provided.

Statistical analysis

A cross-sectional correlational analysis was conducted. All analyses were conducted in SPSS 22. First, Student’s t was used to measure the differences between gamblers and non-gamblers in pathological gambling, emotion regulation difficulties, anxiety, depression, drug abuse, and alcohol abuse. Effect sizes of identified differences were measured by using Cohen’s d, where a value lower than .20 indicates a small effect size, near .50 indicates a moderate effect size, and above .80 indicates a high effect size (Cohen, 1992). Second, correlation coefficients were calculated among all
the variables by using Pearson’s $r$ in the group of pathological gamblers. Third, stepwise multiple linear regression analyses were conducted in this group to evaluate the predictive role of difficulties in emotion regulation relative to pathological gambling, drug abuse, alcohol abuse, and anxious and depressive symptomatology.

Second, after bivariate relationships were verified between the variables in the case of anxiety but not in the case of depression, a mediation analysis was conducted to analyze how the independent variable X (anxiety) affects the dependent variable Y (pathological gambling) through multiple mediators M (lack of emotional awareness; non-acceptance of emotional responses; lack of emotional clarity; difficulties engaging in goal-directed behavior; lack of emotional control) in the group of pathological gamblers. The analysis was conducted by using bootstrapping, which is an adequate technique for multiple mediation models and can be used in small and moderate samples (Preacher & Hayes, 2008). Two separate models were examined using the macro INDIRECT for SPSS (Preacher & Hayes, 2008). First model included the subscales of Drugs and Abuse of the MULTIC-INDIRECT for SPSS (Preacher & Hayes, 2008). First model included the subscales of Drugs and Abuse of the MULTIC-INDIRECT for SPSS (Preacher & Hayes, 2008). The results indicated that the differences were significant for all variables except alcohol. According to Cohen’s criterion (1992), the effect sizes were medium for drug abuse, anxiety, depression, lack of awareness, lack of clarity, and difficulties in goal-oriented behavior while effect sizes were high for non-acceptance, lack of control, total emotion dysregulation, and pathological gambling.

The correlations among pathological gambling, emotion regulation, anxiety, depression, alcohol abuse, and drug abuse were then analyzed in the group of gamblers (Table 3). Difficulties of emotion regulation were found to correlate with all of these variables. Alcohol abuse and drug abuse correlated positively and significantly with difficulties of emotion regulation as well as with one another; drug abuse also correlated with depression, anxiety, and pathological gambling, while alcohol did not. Anxiety and depression correlated significantly with all of these variables except for lack of awareness and alcohol abuse, although depression did not correlate with pathological gambling.

Stepwise multiple linear regression analyses were also conducted to evaluate the predictive role of difficulties in emotion regulation relative to pathological gambling, drug abuse, alcohol abuse, and anxious and depressive symptomatology. The results showed that difficulties in emotion regulation were predictive of all of these variables (Table 4). Based on correlational analyses, the mediating role of difficulties in emotion regulation between anxiety and pathological gambling was measured through a multiple mediation model, controlling and not controlling for the effect of drug and alcohol. These analyses were not conducted in the case of depression, as it did not correlate with the University of Deusto approved the study. All subjects were informed about the study and all provided informed consent.

**RESULTS**

First, mean differences were measured between pathological gamblers and non-gamblers in pathological gambling, emotion regulation, anxiety, depression, drug abuse, and alcohol abuse (Table 2). The results indicate that the differences were significant for all variables except alcohol. According to Cohen’s criterion (1992), the effect sizes were medium for drug abuse, anxiety, depression, lack of awareness, lack of clarity, and difficulties in goal-oriented behavior while effect sizes were high for non-acceptance, lack of control, total emotion dysregulation, and pathological gambling.

**Ethics**

The study procedures were carried out in accordance with the Declaration of Helsinki. The Ethics Committee of the University of Deusto approved the study. All subjects were informed about the study and all provided informed consent.

**Table 2. Comparison between pathological gamblers and non-gamblers in pathological gambling, emotion regulation, drug and alcohol abuse, and anxious and depressive symptomatology**

| Pathological gamblers (n = 167) | Non-gamblers (n = 107) | t(df) | d   |
|-------------------------------|------------------------|-------|-----|

Figure 1. Mediation effect of emotion regulation between anxiety and pathological gambling (*p < .001, **p < .05)
pathological gambling. In both models, a-path, b-path, and c-path were significant, and the c’-path was not significant, showing a full mediation effect of the difficulties in emotion regulation in the relationship between anxiety and pathological gambling, both controlling and not controlling for the effect of drug and alcohol abuse (Figures 1 and 2). The partial effect of control variables on the dependent variable was not significant in either model, meaning that none of the covariates included in both models had a significant effect on the relationship. Additionally, indirect effects were measured by employing 5000 bootstrap samples. A specific indirect effect of lack of control was found in the model controlling for the effect of drug and alcohol abuse [β = .15, 95% BC CI (.02–.31)] and in the model without controlling for drug and alcohol abuse [β = .15, 95% BC CI (.03–.31)].

**DISCUSSION**

The results showed significant differences between gamblers and non-gamblers in emotion regulation difficulties, anxiety, depression, and drug abuse. In the case of emotion regulation, the results were in accordance with those obtained by Williams, Geisham, Eerskine, and Cassidy (2012) who found that pathological gamblers scored higher on measures of emotion regulation difficulties. However, that study did not find significant differences in non-acceptance, whereas in this study, differences were found in that variable and with a high effect size. The results of this study support those from previous studies showing that individuals with addictions may have greater difficulties with emotion regulation. Previous studies of substance abuse disorders have found similar results, such as the study from Fox, Axelrod, Paliwal, Sleeper, and Sinha (2007), which found higher levels of emotion dysregulation, except for lack of clarity. As mentioned before, pathological gambling may be a way of regulating negative emotions and a consequence of failures in self-control (Tice, Bratslavsky, & Baumeister, 2001). Nevertheless, few studies have measured difficulties of emotion regulation in pathological gamblers (Estévez et al., 2014; Williams, Geisham, Eerskine, & Cassedy, 2012), so this study strengthens the scarce evidence in this field. Pathological gamblers also had more anxiety and depression, consistent with the scientific literature (Parhami, Mojtabai, Rosenthal, Affifi, & Fong, 2014). Moreover, there were significant differences in drug abuse, in accordance with previous studies that documented a co-occurrence of drug use and pathological gambling (Rush, Bassani, Urbanoski, & Castel, 2008). However, unexpectedly, significant differences were not found in alcohol use, despite previous studies that have reported comorbidity of alcohol abuse in gamblers (Griffiths, Wood, Orford, Sproston, & Erens, 2011; Lorains, Cowlishaw, & Thomas, 2011)). According to previous research, pathological gambling and alcohol abuse are typically not concurrent in treatment-seeking samples (Ladd & Petry, 2003; Stinchfield & Winters, 2001) in spite of their epidemiological association. This finding may apply to the sample of this study, as pathological gamblers were recruited in centers of treatment for pathological gambling. Moreover, pathological gamblers with a high alcohol abuse may have sought treatment in or have been referred to centers of treatment for alcohol abuse. Also, the existence of differences in socio-demographic data such as age, educational level, or marital status may have biased these results. Further studies with more balanced samples and including pathological gamblers from different clinical settings may provide additional data on this result.

Besides, correlation analyses also showed that difficulties of emotion regulation correlated significantly with all of these variables: pathological gambling, alcohol and drug abuse, and anxious and depressive symptomatology. These
results are consistent with the few previous studies available in this regard (Estévez et al., 2014; Veilleux, Skinner, Reese, & Shaver, 2014; Williams, Geisham, Eerskine, & Cassidy, 2012) and remark that difficulties of emotion regulation may be related to pathological gambling and the associated disorders. Regression analyses showed that emotion regulation difficulties predicted pathological gambling, drug abuse, alcohol abuse, and anxious and depressive symptomatology in the group of gamblers. This supports previous theories that point to difficulties in emotion regulation as a transdiagnostic factor that may predict numerous psychological disorders (Kring & Sloan, 2009; Trosper, Buzzella, Bennett, & Ehrenreich, 2009).

Nevertheless, the specific subscale that was predictive was not the same in each case. One variable that stood out was non-acceptance, which predicted pathological gambling, anxiety, and depression. This subscale measures the tendency of individuals to negatively judge their inner emotional experience, and as a consequence, to react with shame or discomfort to their own emotions. The non-acceptance of emotional experiences is a defining aspect of factors such as experiential avoidance or distress tolerance, which can drive individuals to engage in addictive behaviors to avoid unpleasant inner experiences (Luciano, Páez-Blarrina, & Valdivia-Salas, 2010). Pathological gambling has been associated with experiential avoidance (Riley, 2014), in the same line as other addictions that have also been related to experiential avoidance (Levin, Lillis, Seeley, Hayes, Pistorello, & Biglan, 2012) or lower distress tolerance (Howell, Leyro, Hogan, Buckner, & Zvolensky, 2010; Hsu, Collins, & Marlatt, 2013). Therefore, gambling as a way of avoiding unpleasant emotions may be related to a greater tendency to reject them. Gambling may be used by some gamblers as a coping strategy to regulate unwanted private events (Riley, 2014). In fact, the presence of emotion regulation difficulties may stem from the evaluation of internal experience, rather than actual greater levels of arousal and distress (Tull & Roemer, 2007). Previous research has pointed to gambling as a way of alleviating depression and anxiety (Blaszczynski & Nower, 2002), but this is the first one to find non-acceptance as a common predictor of gambling, anxiety, and depression. Lack of control, for its part, was found to be a predictor of both drug and alcohol abuse in pathological gamblers. These results are also novel and may be in accordance with the pathway model postulated by Blaszczynski and Nower (2002). Pathway model proposes that gamblers with associated substance abuse would form a group of gamblers with an antisocial/impulsive profile characterized by higher impulsivity. The Lack of Control subscale includes items that in the original English version of the DERS were included in the subscale of “Difficulties in the Control of Impulsivity.” These results, therefore, are in accordance with the postulates of the pathway model (Blaszczynski & Nower, 2002).

These findings could be important in this field, since it is the first study to explore difficulties of emotion regulation as a common predictor of pathological gambling and the associated dysfunctional symptomatology. Future studies may be conducted exploring if the treatment of emotion regulation difficulties could be beneficial for reducing pathological gambling and comorbid disorders.

Finally, we found difficulties in emotion regulation to fully mediate the relationship between anxiety and pathological gambling. These results are similar to those obtained by Weiss, Tull, Viana, Anestis, and Gratz (2012) who also found a full mediation effect in the relationship between post-traumatic stress disorder and drug abuse. This is one of the first studies to point to difficulties of emotion regulation as mediators of the relationship between anxiety and pathological gambling. Previous research has found only a partial mediation effect between pathological gambling and anxiety in adolescents (Estévez et al., 2014). In our study, however, with adult pathological gamblers and controlling for the effects of drug and alcohol abuse and age, a full mediation effect was found. In both cases, lack of control stood out as a mediator variable of that relationship. This subscale measures the feeling of being overwhelmed due to the emotional intensity and persistence of negative emotional states. Therefore, greater difficulties to regulate emotions may result in greater attempts to gamble as a way of managing anxiety. These results are consistent with the literature that postulates that gambling may be a way to regulate emotions and cope with anxiety (Blaszczynski & Nower, 2002; Shead, Callan, & Hodgins, 2008; Stewart & Zack, 2008).

This study has some limitations. First, due to its correlational design, causal relationships cannot be stated, and the relationships found could also be bidirectional. Longitudinal studies would help to determine the directionality of our findings. Additionally, drug and alcohol abuse, and anxiety and depression were measured with screening instruments. The instruments were also self-report measures, which may have biased the results and could have been affected by social desirability in the case of addictions. Moreover, the sample comprised pathological gamblers in treatment. Future replications with samples of gamblers who are not in treatment would be advisable to enhance the generalizability of these results. Another potential limitation is the lack of measures of other disorders, such as borderline personality disorder, which has also been associated with emotion regulation difficulties and addictive behaviors (Axelrod, Perepletchikova, Holtzman, & Sinha, 2011). That factor could have influenced our results; so, it should be included in future studies to measure its effect. Finally, the sample comprised only males. Future studies should also include women because it has been found that women may have a greater tendency to engage in gambling behavior as a form of escape (Zangeneh, Blaszczynski, & Turner, 2008).

CONCLUSIONS

In conclusion, pathological gamblers may present emotion regulation difficulties, which may also constitute a common predictor of pathological gambling and comorbid disorders. Also, difficulties of emotion regulation mediated the relationship between anxious symptomatology and pathological gambling, either when controlling or not controlling for the effect of drug and alcohol abuse. These results are novel in pathological gambling and provide relevant information for clinical practice. The treatment of emotion regulation difficulties, included in approaches such as dialectic-behavioral
therapy (Lynch, Chapman, Rosenthal, Kun, & Linehan, 2006) or mindfulness-based cognitive therapy (Hayes & Feldman, 2004), might be useful for the common treatment of pathological gambling and other pathological entities associated with it. Authors such as Petry and Champine (2012) have suggested the integration and unification of treatments oriented to treat pathological gambling and other substance and alcohol use disorders, and emotion regulation may be a useful element in that integration. Therefore, the treatment of pathological gambling and comorbid disorders may benefit from an added focus on improving emotion regulation abilities.

**Funding sources:** This research was supported by grants from the University of Deusto “Programa de Ayudas para Formación de Personal Investigador” and Basque Government’s “Programa Predoctoral de Formación de Personal Investigador No Doctor.”

**Authors’ contribution:** PJ contributed to study concept and design, analysis and interpretation of data, statistical analysis, obtained funding. AE contributed to study concept and design, study supervision, analysis and interpretation of data. IU contributed to analysis and interpretation of data, study supervision. All authors had full access to all data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

**Conflict of interest:** The authors declare no conflict of interest.
