Abstract. The evolution of NO$_2$, considered as a proxy for air pollution, was analyzed to evaluate the impact of the first lockdown (17 March–10 May 2020) over the Île-de-France region (Paris and surroundings). Tropospheric NO$_2$ columns measured by two UV-Visible Système d’Analyse par Observation Zénithale (SAOZ) spectrometers were analyzed to compare the evolution of NO$_2$ between urban and suburban sites during the lockdown. The urban site is the observation platform QualAir ($48^\circ50’$N/$2^\circ21’$E) at the Sorbonne University Pierre and Marie Curie Campus in the center of Paris. The suburban site is located at Guyancourt ($48^\circ46’$N/$2^\circ03’$E), Versailles Saint-Quentin-en-Yvelines University, 24 km southwest of Paris. Tropospheric NO$_2$ columns above Paris and Guyancourt have shown similar values during the whole lockdown period from March to May 2020. A decade of data sets were filtered to consider air masses at both sites with similar meteorological conditions. The median NO$_2$ columns and the surface measurements of Airparif (Air Quality Observatory in Île de France) during the lockdown period in 2020 were compared to the extrapolated values estimated from a linear trend analysis for the 2011–2019 period at each station. Negative NO$_2$ trends of $-1.5 \text{ Pmolec. cm}^{-2} \text{ yr}^{-1}$ ($\sim -6.3 \% \text{ yr}^{-1}$) are observed from the columns, and trends of $-2.2 \text{ Kg m}^{-2} \text{ yr}^{-1}$ ($\sim -3.6 \% \text{ yr}^{-1}$) are observed from the surface concentration.

The negative anomaly in tropospheric columns in 2020 attributed to the lockdown (and related emission reductions) was found to be 56 % at Paris and 46 % at Guyancourt, respectively. A similar anomaly was found in the data of surface concentrations, amounting to 53 % and 28 % at the urban and suburban sites, accordingly.

1 Introduction

Megacities can be considered as being a hotspot of anthropogenic pollution due to the concentration of population and human activities. People living in urban areas are exposed to air quality levels that are often poorer than the World Health Organization (WHO) recommended limits (WHO, 2006). In 2020, the emergence of a novel coronavirus that caused the COVID-19 pandemic in many countries around the world prompted the governments of the affected states to apply restrictive regulations. Most countries implemented lockdown measures (restrictions on people’s movements) to limit the progression of the COVID-19 pandemic. As a result, urban areas have become interesting laboratories for analyzing the impact of these measures on air quality. Atmospheric concentrations of air pollutants in megacities were expected to decrease as a direct impact of the air and road traffic activity drop during the lockdown period. Observations of the TROPOspheric Monitoring Instrument (TROPOMI) instrument on board the Copernicus Sentinel 5-Precuror (S5P) satellite (Veeckind et al., 2012) were the earliest ones to be presented by the media to show the significant decrease in tropo-
Atmospheric 

The objective of this study is to quantify the effect of NO$_2$ decreases due to the lockdown by considering the long-term variability and meteorological conditions over the Île-de-France region during the last decade, using different datasets characterizing the lockdown impact at a local scale, with in situ instrumentation, and at a larger scale, including a large part of the agglomeration with tropospheric column measurements. In total, two complementary sites are used, with one in the center of Paris and the other one in the peripheral zone, to highlight the possibly heterogeneous impact of lockdown in the Île de France region. The originality of the study is to rely not only on a single reference year before the COVID-19 pandemic that could strongly bias the study but on a long, decadal data set, in order to account for NO$_2$ variability over a longer period. This allows, in addition, the calculation of long-term NO$_2$ column changes over the Paris region. Specific data filtering, using wind speed and direction, is applied in order to isolate the data which are affected by local pollution in the greater Paris area and to consider the changes in meteorological conditions for the different years.

This paper is organized as follows. Observations of tropospheric and surface amounts of NO$_2$ by ground-based and satellite measurements are presented in Sect. 2, as well as the wind data from European reanalysis. The description of the method used to discriminate specific data to calculate the NO$_2$ decrease in 2020, taking into account similar meteorological conditions, is presented in Sect. 3. The results of NO$_2$ decreases in 2020 due to the lockdown are shown in Sect. 4 for the different data sets. The results of NO$_2$ level reductions in respect to the literature findings are discussed in Sect. 5. Conclusions are finally presented in Sect. 6.

2 NO$_2$ data

Tropospheric NO$_2$ columns measured by two ground-based systems were analyzed to trace and intercompare the evolution of NO$_2$ in the urban and suburban regions of Île-de-France. The analysis was supplemented by a study of NO$_2$ column satellite measurements using the TROPOMI instrument. In addition, the in situ measurements of NO$_2$ surface concentrations from the Airparif air quality network were also considered. In this work, the 10-year period of 2011–2020, with the first year corresponding to the start of the SAOZ measurements at the suburban site of Guyancourt, was considered. Table 1 shows the ground-based stations, type of instrument and geographical coordinates, and Fig. 1 shows the location of each station in the Île-de-France region.

2.1 Tropospheric columns

2.1.1 SAOZ data

The NO$_2$ tropospheric columns in the Île-de-France region are measured by two ground-based SAOZ instruments (Pommereau and Goutail, 1988) that are part of French research infrastructure of ACTRIS (Aerosols, Clouds and Trace gases Research Infrastructure). The first one was installed in 2005 at the observation platform of QualAir (http://qualair.aero.jussieu.fr/, last access: January 2021) at the Sorbonne University in Paris (urban station) and the second one has been operational at the LATMOS (Laboratoire Atmosphères, Observations Spatiales) laboratory in Guyancourt (southwestern suburban station) since 2011. SAOZ is a UV-Visible spectrometer primarily designed for monitoring the stratospheric ozone and NO$_2$ during twilight observations in the frame of the NDACC (Network for the Detection of Atmospheric Composition Change; see Hendrick et al., 2011, for a description of retrieval). The long-term data series of SAOZ instruments were compared with data from most satellite missions to validate or monitor their performance. For example, SAOZ instruments participated in the validation of the latest satellite mission (Sentinel-5 Precursor) launched on October 2017 for the measurements of ozone (Garane et al., 2019) and stratospheric NO$_2$ (Verhoelst et al., 2021).

During the day, SAOZ observations are sensitive to increased tropospheric NO$_2$ amounts in polluted regions (Tack et al., 2015). Every ~2 min, the sunlight backscattered by the atmosphere in the zenith direction of SAOZ is acquired, and the DOAS (differential optical absorption spectroscopy) method (Platt and Stutz, 2008) is applied in the NO$_2$ absorption bands to obtain the respective slant column densities. The stratospheric NO$_2$ columns are removed from slant columns to retrieve the tropospheric NO$_2$ for solar zenith
angles (SZAs) lower than 80° (see Dieudonné et al., 2013, for a detailed description of the SAOZ tropospheric NO$_2$ retrieval). The SAOZ data set of tropospheric NO$_2$ measurements at Paris was used in different studies to relate the NO$_2$ concentrations at the surface with the integrated NO$_2$ column in the boundary layer (Dieudonné et al., 2013) to interpret ozone measurements (Klein et al., 2017) and the seasonal cycle of the ozone gradient (Ancellet et al., 2020).

SAOZ tropospheric NO$_2$ columns are available at the SAOZ web page (http://saoz.obs.uvsq.fr/SAOZ_tropo_Paris.html, last access: 1 January 2021 and http://saoz.obs.uvsq.fr/SAOZ_tropo_Guyancourt.html, last access: 1 January 2021). These data were averaged daily between 06:00 and 18:00 UT and between 11:00 and 14:00 UT for comparison with satellite observations.

2.1.2 TROPOMI data

Tropospheric NO$_2$ columns retrieved by TROPOspheric Monitoring Instrument (TROPOMI) aboard Sentinel 5 Precursor (S5P) satellite (Veefkind et al., 2012) launched in October 2017 were also used to discriminate air masses above SAOZ instruments benefiting from the high spatial resolution of this instrument (3.5 × 7 km$^2$ and 3.5 × 5.5 km$^2$ since August 2019). TROPOMI is a passive-sensing hyperspectral nadir-viewing imager, aboard a near-polar sun synchronous orbit satellite at an altitude of 817 km, with an overpass at 13:30 local time and practically daily global coverage.

Retrieval applied on TROPOMI data allows the distinction between tropospheric, stratospheric and total NO$_2$ columns. The algorithm was adapted from the DOMINO/TEMIS (Dutch OMI NO$_2$/Tropospheric Emission Monitoring Internet Service) approach for the ozone monitoring instrument (OMI; Boersma et al., 2007, 2011), based on the DOAS method to obtain slant column densities (SCDs) of NO$_2$ that are assimilated to the TM5-MP chemical transport model (CTM) to separate the SCD. The CTM runs using 0–12 h forecast meteorological data from the European Centre for Medium-Range Weather Forecasts (ECMWF) corresponding to the offline product. Finally, each slant column is converted to vertical column using the precalculated air mass factor (AMF) look-up tables. A detailed description can be found at the TROPOMI web page (http://www.tropomi.eu/data-products/nitrogen-dioxide, last access: January 2021).
Van Geffen et al. (2020) analyzed the uncertainties of the SCD of TROPOMI and compared them to OMI-QA4ECV data (Boersma et al., 2018). They show a very good agreement over a remote Pacific Ocean sector, with a correlation of 0.99, but values with 5% higher than the OMI-QA4ECV ones. Verhoelst et al. (2021) compared NO2 total, tropospheric and stratospheric columns with the data of ground-based instruments of Pandora, multi-axis differential optical absorption spectroscopy (MAX-DOAS) and zenith-scattered light DOAS (ZSL-DOAS or SAOZ) distributed around the world. Observations from MAX-DOAS were used for tropospheric comparisons since they are sensitive to absorbers in the lowest few kilometers of the atmosphere (Hönninger et al., 2004). A negative bias from 23% to 37% is observed in the cases of clean to slightly polluted conditions. In the case of highly polluted areas, the bias can reach 51%.

TROPOMI tropospheric NO2 columns have been widely used to estimate the reduction in NO2 amounts linked to the lockdown in 2020, which was implemented in different countries to prevent the spread of COVID-19 (e.g., Bauwens et al., 2020; Ding et al., 2020; Liu et al., 2020; Biswal et al., 2021; Koukoul et al., 2021).

In their validation paper against consolidated ground-based data, Verhoelst et al. (2021) used TROPOMI’s tropospheric columns of NO2 with a quality assurance (QA) value higher than 0.75 to remove cloudy scenes presenting cloud radience fraction higher than 0.5, snow- or ice-covered scenes and problems in the retrieval. In our study, we have decided to use a less restrictive threshold of 0.5 in order to enhance the number of days and to avoid biasing the results towards clear-day conditions. This resulted in doubling the number of data taken into account. The monthly mean NO2 tropospheric columns of TROPOMI present a similar seasonal evolution within 2σ for both QA values (not shown).

TROPOMI tropospheric NO2 columns are available at the Copernicus web page (https://s5phub.copernicus.eu, last access: March 2021).

2.2 Surface concentrations

Airparif is a network of standard in situ sensors to monitor air quality over the Île-de-France region. One of the key variables measured by Airparif is NO2. Hourly NO2 concentrations are measured at most of the stations. The concentrations are measured by chemiluminescence (Fontijn et al., 1970), where the NO2 amount is obtained after a reduction to NO on a heated molybdenum converter. This kind of in situ sensor can overestimate ambient NO2 concentrations due to interferences with the non-NO2 fraction of reactive nitrogen (NOx). As an example, for urban sites in Mexico City, Dunlea et al. (2007) found an average NO2 overestimation for this type of sensor by 22%.

The Airparif network is formed by the (1) so-called traffic stations located at the edge of major traffic axes, (2) urban background stations located in the city but not in the immediate vicinity of emission sources, (3) suburban and rural stations, and, finally, a station installed at the top of the Eiffel Tower at an altitude of 300 m.

In this study, two Airparif sites near the SAOZ of Paris were used, with one being considered as a traffic site (Quai de Célestins) and the other as urban (Paris 13th). Airparif data of Versailles, the nearest station to the SAOZ of Guyancourt, were used to represent the suburban site. Finally, two more stations at the base (Paris 7) and at the top of the Eiffel Tower were considered to compare the evolution of the NO2 concentration at different altitudes in the boundary layer. Data were obtained from Airparif web page (https://data-airparif-asso.opendata.arcgis.com/, last access: 22 January 2021). Daily average data between 06:00 and 18:00 UT are used in this study as for the SAOZ instrument.

2.3 ERA5 reanalysis

ERA5 is the latest reanalysis of the ECMWF (European Centre for Medium-Range Weather Forecasts) generated by Copernicus Climate Change Service. ERA5 is produced by the Integrated Forecast System (IFS) CY41r2 version, released in 2016, with a 10-member 4D-Var assimilation with windows of 12h each. The horizontal grid resolution is ~31 km with 137 hybrid vertical levels up to 0.01 hPa (Hersbach et al., 2020). In addition to the significant increase in the horizontal and vertical resolution of ERA5, as well as the 10-year experience of the model forecast and assimilation, new and reprocessed observational data records were considered. Further information can be found in online documents at the ECMWF web page (https://confluence.ecmwf.int/display/CKB/ERA5, last access: January 2021).

ERA5 surface winds over Europe have been validated with wind observations from 245 stations in Europe, including two stations in Île de France (Molina et al., 2021). The conclusion is that ERA5 is able to reproduce the wind speed from hourly to monthly time frequencies for any location in Europe with a Pearson’s correlation coefficient varying from 0.6 to 0.85 on an hourly scale and 0.9 to 0.95 on a 24 h scale.

In this study, wind speed and direction at 950 hPa (mid-altitude of the convective boundary layer) were extracted from the 0.25° horizontal resolution in latitude and longitude data (over the 48.75° N, 49.00° N and 2.00° E, 2.50° E region) at noon. The available quality-checked final product was considered for 1 January 2011 to 31 October 2020 and a provisional product for November–December 2020, where the latter is not really expected to differ from the final product (Hersbach et al., 2020).

3 Methodology

The evaluation of the lockdown effects on atmospheric NO2 amounts is performed by selecting air masses moving from the Parisian agglomeration to the suburban region. The objective is to consider only the days on which air masses for
both sampling sites have a long enough residence time over the Paris area and have been influenced by local pollution. In this work, the sampling filter of the air masses coming particularly from the Parisian agglomeration was determined with the purpose of evaluating the decrease in human activities linked to the lockdown in Paris at both sites. The downwind direction from Paris to Guyancourt is privileged to filter out air masses originating from the western sector, which are mainly of oceanic origin and have not yet encountered many European emissions. Combined wind speed and direction are considered in this study to identify such days. This procedure aims at selecting data sets with similar meteorological conditions for different years, thus reducing the impact of interannual weather variability. The evolution of NO$_2$ concentrations and tropospheric columns at Airparif and SAOZ stations (Table 1) are considered. The data of NO$_2$ concentration measurements by in situ instruments and NO$_2$ tropospheric column measurements by SAOZ were averaged daily between 06:00 and 18:00 UT. The measurement data are filtered using the wind speed and direction of ERA5 analysis at noon to select the weather conditions in which the Guyancourt site receives air masses that have passed the Paris agglomeration. Equation (1) represents the estimated residential time, $t$, of air masses coming from the center of Paris to Guyancourt.

$$t = \cos \left( \text{abs} \left( \text{dir}_x - \theta_{\text{era5}} \right) \times \pi/180 \right) \times D / v_{\text{era5}}, \quad (1)$$

where $v_{\text{era5}}$ and $\theta_{\text{era5}}$ correspond to the speed and direction of the wind at 12:00 UT and 950 hPa (altitude level in the middle of the convective boundary layer), $\text{dir}_x$ is the direction between Guyancourt and Paris (290°), and $D$ is the approximate diameter of agglomeration (9.5 km) if we consider it as a circle.

Using this parameter, $t$, three types of days were distinguished, and for each class a linear fit between urban versus suburban observations was calculated, as follows:

1. air masses of the Parisian agglomeration not influencing Guyancourt or Versailles ($t < 0$)
2. air masses of the Parisian agglomeration influencing Guyancourt or Versailles ($t > 0$)
3. air masses of the Parisian agglomeration in a condition of weak wind influencing Guyancourt or Versailles, which is a subclass of the precedent one ($t > 30 \text{ min}$).

Figure 2 shows the scatterplot of SAOZ tropospheric NO$_2$ of Paris and Guyancourt (left panel) and Airparif in situ NO$_2$ of Paris’s 13th district and Versailles (right panel) for the 2011–2020 period. Case 1 is represented by light green points, case 2 by blue circles and case 3 by red dots. A linear orthogonal fit was applied for the three cases to highlight the relationship between urban and suburban stations for the different conditions of wind speed and direction. For each case, higher NO$_2$ amounts are observed at Paris, and the air masses at the surface present lower linear regression slopes than tropospheric columns. Case 1 presents the largest slopes, i.e., 2.99 ± 0.01 (2σ standard error) for SAOZ measurements and 1.36 ± 0.01 for Airparif, highlighting the importance of wind direction. In this case when Guyancourt is upwind of Paris, air masses pass over Guyancourt without having touched the agglomeration. Those air masses arriving in the center of Paris have crossed part of the agglomeration and then show larger NO$_2$ columns. Cases 2 and 3 correspond to air masses generally crossing first the Parisian agglomeration and then southwestern suburban region. They show slopes closer to unity. In the case of SAOZ, the slopes of 1.38±0.01 and 1.31±0.01 were obtained for cases 2 and 3,
and the slopes of 1.11±0.01 and 1.04±0.03 in case of Airparif, respectively. For our study, the classification of days with air masses associated with \( t > 30 \text{ min} \) will be considered because, in this case, air masses pass over both stations with weak wind, allowing for pollutant accumulation over the Paris agglomeration.

The poorer correlation observed with SAOZ data could be explained since different types of air masses could be sampled at Guyancourt in the tropospheric column, i.e., those passing through the agglomeration center and accumulating NO\(_2\) when passing from the center to the edge (leading to larger columns at Guyancourt than at Paris) and those that have crossed only the limits of the agglomeration (leading to smaller columns at Guyancourt than at Paris).

4 Results

4.1 NO\(_2\) evolution in 2020

The period preceding the lockdown represents meteorological conditions over Île-de-France mainly characterized by the high occurrence of oceanic air masses (see Fig. S3 of Petit et al., 2021) and fairly strong southwesterly winds (Fig. 3; left wind rose) preventing pollution events over this region. Changes in weather conditions 3 d after the implementation of the lockdown in 17 March 2020 (middle wind rose; Fig. 3) were mostly anticyclonic and contributed to the stagnation of pollutants in air masses advected from Paris to Guyancourt. Low wind speeds (< 6 m s\(^{-1}\)) are predominantly northeasterly in the mid-March to mid-May period. The period after the end of the lockdown (Fig. 3; right wind rose) shows winds from southwesterly and northeasterly directions in the mid-May to July period.

Figure 4 shows the evolution of tropospheric NO\(_2\) columns in Paris (red curve) and Guyancourt (blue curve) in 2020 as observed by SAOZ (top panel). Colored points correspond to the filtered data with \( t > 0 \) (open circles) and \( t > 30 \text{ min} \) (solid points). The filtered air masses at Paris and Guyancourt present similar values for most of the cases with coincident daily events of increased tropospheric NO\(_2\). Similar results are observed from in situ measurements at Airparif stations (Fig. 4; bottom panel). Vertical dashed lines are displayed in Fig. 4 to separate the four periods, i.e., before, during and after the lockdown and the last period of mixed restrictions (partial activities) after 31 October. The seasonal variability in NO\(_2\) is well pronounced in the surface observations, with a minimum in June and a maximum in winter.

Table 2 shows different periods in 2020 related to restrictions imposed by French government to limit COVID-19 propagation. During period 1 (before the lockdown) only two particular events with high NO\(_2\) values above both stations are detected at the same time (\( t > 0 \text{ min} \)) by SAOZ instruments (19–25 January and 5–6 February). These events are also highlighted in the Airparif data. Only 1 d with \( t > 30 \text{ min} \) is observed on 5 February. The frequent occurrence of oceanic air masses with high precipitation and wind speed leads to the advection of clean air masses above the Île-de-France region before the lockdown period (Viatte et al., 2021) and low NO\(_2\) values are observed, which are lower than observed during period 2 (lockdown) for the suburban stations (Guyancourt and Versailles). A NO\(_2\) peak is observed on 17 March, coincident to the start of the lockdown period, which could be linked to the massive departure of Parisian inhabitants. A change in weather conditions at the beginning of period 2, with low northeasterly wind speeds, promote the accumulation of polluted air masses over Île-de-France. Most of the days are characterized by a residential time of \( t > 30 \text{ min} \). Despite this situation, levels of tropospheric NO\(_2\) remain low; this certainly illustrates the decrease in emissions during the lockdown period. Period 3 (after the lockdown) started on 11 May 2020, and NO\(_2\) values remained low until the second week of July (the beginning of the school holidays), with NO\(_2\) enhancement events comparable to period 2. Since then, higher NO\(_2\) values of pollution events are observed by SAOZ and Airparif instruments, which show slight differences between the urban and suburban stations for days with \( t > 30 \text{ min} \). A less restrictive lock-
down (open schools and less restrictive movement of people) was set up during period 4.

4.2 Comparison to previous years

4.2.1 Tropospheric NO$_2$ columns

TROPOMI tropospheric NO$_2$ measurements in 2020 were widely used to show a decrease in NO$_2$ amounts in different countries, which was attributed to policies restricting human activities by comparing the lockdown and pre-lockdown period or the same period in 2019 (e.g., Ding et al., 2020; Prunet et al., 2020; Siddiqui et al., 2020; Koukouli et al., 2021). SAOZ measurements between 11:00 and 14:00 UT were averaged to match overpass time of TROPOMI above the stations. TROPOMI data were previously filtered for the QA $>$ 0.5 (see Sect. 2.1.2) and a radius of 5 km around SAOZ stations. Figure 5 shows the evolution of the monthly mean and two standard errors ($2\sigma$) of tropospheric NO$_2$ columns above Paris and Guyancourt stations since January 2019, as observed by SAOZ and TROPOMI (left panels). The standard error corresponds to the standard deviation of the mean divided by the root number of considered days. Similar intermonthly evolution is observed by both instruments, with a generally good agreement within $\pm 2\sigma$ and a correlation of 0.80 at Paris and 0.70 at Guyancourt. TROPOMI presents generally lower NO$_2$ values than SAOZ but within the $2\sigma$ uncertainty level. This is not the case in May 2020 (month 17 in Fig. 5) during which TROPOMI NO$_2$ amounts are significantly larger at the $2\sigma$ level than at SAOZ. Monthly mean values present a seasonal variation, reaching values above 10 Pmolec. cm$^{-2}$ in winter in Paris, while they vary between 4 and 7 Pmolec. cm$^{-2}$ in Guyancourt. The first months of 2020 present lower values compared to 2019, mostly due to weather conditions, while the March–May NO$_2$ decrease (month 15–17) is coincident with the lockdown period. A histogram of the differences between TROPOMI and SAOZ is also shown in Fig. 5 (right panels). A mean and median difference of $-0.2$ and $+0.12$ Pmolec. cm$^{-2}$, respectively, is obtained at the Paris station and of $-0.6$ and $-0.7$ Pmolec. cm$^{-2}$, respectively, at Guyancourt. It corresponds to a median relative difference of 2% at the Paris station and $-22\%$ at Guyancourt. The dispersion of the difference represented by the half of the 68% interpercentile (IP68/2) is 2.9 and 1.6 Pmolec. cm$^{-2}$, respectively, at Paris and Guyancourt.

TROPOMI and SAOZ data selected for days with $t>30$ min were averaged between 11:00 and 14:00 UT for the period of the 2020 lockdown in France (17 March to 10 May), and median values were computed from the SAOZ and TROPOMI data for the 2011–2020 annual range (Fig. 6). TROPOMI NO$_2$ decrease in 2020 compared to 2019 is 35±12% for Paris and 22±27% for Guyancourt. Bauwens et al. (2020) found a decrease of 28% during the first 21 d of lockdown over a 50 km region, centered over Paris, using TROPOMI and OMI data compared to same period in 2019. A larger tropospheric NO$_2$ decrease of about 47% is found from SAOZ observations between 2019 and 2020 at both studied stations (see Fig. 6).
Table 2. The four periods in 2020 shown in Fig. 4 and the related restrictions imposed by the French government to limit the COVID-19 propagation.

| Periods in 2020 | Restrictions |
|-----------------|--------------|
| P1 1 Jan to 16 Mar | None |
| P2 17 Mar to 10 May | First lockdown, where nonessential stores, schools, cultural establishments, etc. are closed. Only travel <1 km and with a certificate are authorized. Home office/remote work is strongly suggested. |
| P3 11 May to 29 Oct | Gradual lifting of restrictions, where schools and nonessential stores are opened with physical distancing and masks. Travel is possible without a certificate. A curfew was imposed in mid-October. Home office/remote work is still recommended. |
| P4 31 Oct to 15 Dec | Second lockdown, where schools opened but universities still closed. Some activities are allowed, including some nonessential stores opened with strong restrictions. Some restrictions, such as travel of <1 km maximum, are relaxed at the end of November. |

Figure 5. Monthly mean tropospheric NO\(_2\) and 2σ standard error above Paris (a) and Guyancourt (c) measured by ground-based SAOZ instrument (colored lines) and TROPOMI satellite instrument (black lines). Histogram of TROPOMI-SAOZ differences at Paris (b) and Guyancourt (d). Vertical lines represent the median, mean and dispersion by the half of the 68 % interpercentile range (IP68/2).

an even larger decrease in NO\(_2\) values, varying from 52 % to 86 %, during the lockdown in a 120 km region around Paris using yearly 2019–2020 TROPOMI data and the city-scale NO\(_2\) plume mass method.

It should be noted that the SAOZ data sets have shown a long-term negative trend since 2011. Font et al. (2019) have used in situ data to study the impact of policy initiatives in different megacities. They have shown a mean NO\(_2\) decrease in roadside (background) sites of −2.9 (1.7) % yr\(^{-1}\) in Île-de-France for the 2010–2016 period, linked to the introduction of the Euro V regulations for heavy-duty vehicles in October 2009; other policies were implemented thereafter (e.g., Euro VI regulations in 2014). The trend of tropospheric NO\(_2\) amounts needs to be considered to better quantify the effects of lockdown on air pollution, which cannot rely on the comparison with a single reference year as was done in many other studies (e.g., Bauwens et al., 2020; Prunet et al., 2020).

To better account for traffic-related pollution events in the daily averaged NO\(_2\) columns, the full daytime data of tropospheric NO\(_2\) measurements by SAOZ (SZA < 80°) of the
The year 2020 presents the lowest values of NO\textsubscript{2} used as a reference for comparison, slightly higher declines the tropospheric median column of NO\textsubscript{2} (5.4 Pmolec. cm\textsuperscript{-2}) finding significant negative trends of 5 % yr\textsuperscript{-1} from the synergistic use of OMI NO\textsubscript{2} columns. Curier et al. (2014) computed the annual median NO\textsubscript{2} concentration at Airparif stations, since 2011 (Table 1), were computed from daily available hourly data during the lockdown period, filtered for the wind speed and direction as it has been done for the tropospheric NO\textsubscript{2} column (t > 30 min). Figure 8 presents the interannual variability in the NO\textsubscript{2} concentration at the five Airparif sta-
tions. In addition, the calculated robust fit for the decadal evolution at each station is shown. The background or urban stations (Paris 7 and 13) present similar interannual variability, with higher values at Paris’s seventh district. The station of Quai de Célestins, in close proximity to local traffic, shows much higher values which are significantly different from those at other urban sites. The suburban station of Versailles presents similar values to Paris’s 13th district at ±1σ. The observation station located at the Eiffel Tower at 300 m height near Paris’s seventh district station shows the lowest values.

The five Airparif stations present negative trends from −3 to −1.3 µg m⁻³ yr⁻¹, equivalent to −4.6 % yr⁻¹ to 2.4 % yr⁻¹ (Table 4). Font et al. (2019) found a similar negative trend, varying from −3.4 % yr⁻¹ to −2.4 % yr⁻¹, for roadside stations in Paris for the 2010–2016 period. These trends appear to be less negative than those obtained from column measurements. Possible reasons for this are an increase in the NO₂ to NOₓ emission ratio and a limitation of the available amount of O₃ for the NO to NO₂ conversion.

Both factors affect the surface concentration than the boundary layer column more strongly, which could lead then to the different trend estimates.

Incomplete NO to NO₂ conversion is, for example, suggested by NO₂ and ozone concentrations of the same order of magnitude at Paris’s urban background sites (Fig. 38 in Airparif, 2020). In such a situation, the NO₂ trends are both impacted by the NOₓ emission and ozone trends. Figure 38 in Airparif (2020) cited above shows a strongly increasing ozone average urban background over Paris, e.g., 35 to 43 µg m⁻³, respectively, for the 2007–2009 and 2017–2019 periods. This positive ozone trend buffers, to some extent, the negative NOₓ emission trend.

However, while this reasoning would qualitatively explain the differences in trends between column and in situ measurements, it fails to explain differences in trends between different in situ sites in the sense that larger NO₂ values would lead to smaller negative trends. This is not observed; on the contrary, the NO₂ trend is more negative at base of the Eiffel Tower than at altitude when NOₓ becomes lower. Thus, the exact explanation of the differences in trends at different sites and heights still needs more investigation. In 2020, significant decreases, compared to the extrapolated value using the above-calculated linear trends, are observed at all stations and reach similar median values, which are slightly higher for the traffic station and slightly lower for Eiffel Tower observation station. The relative values of NO₂ reductions are shown in Table 4. Comparable values at 1σ are observed for traffic and urban stations in Paris, with lower values at Paris’s 13th district, where the standard error is higher. Nevertheless, the reduction in NO₂ concentrations observed in absolute values is more important at traffic stations (such as CELES – Quai de Célestins) compared to the urban station (such as Paris’s seventh district). The observation station installed at the Eiffel Tower at 300 m height presents a 53 % reduction that is identical to the station at Paris’s seventh district, which is located at the base of the tower. The suburban station of Versailles presents the lowest reduction of 28.5 %, which is significantly different to other stations at 1σ, except for Paris’s 13th district. It should be noted that both stations show an almost twice as large standard deviation of 14 %. The reasons for these lower values are not clear. It can be speculated that, at this suburban site, the relative contribution of residential heating to

Table 3. NO\textsubscript{2} sources is stronger than at Paris sites, and probably, these sources increased during the lockdown period due to the presence of people in their homes (Menut et al., 2020).

Collivignarelli et al. (2021) compared the NO\textsubscript{2} concentration observed by the traffic and urban stations of Airparif during the lockdown in 2020 to the same period in previous years (2017–2019). They found a decrease of 15\% for the urban stations and 33\% for traffic stations. However, when considering similar meteorological conditions with respect to rainfall, temperature and wind speed, the authors found a reduction of 51.5\% corresponding to traffic stations and approximately 45\% for background ones, similar to values obtained in this study.

5 Discussion

Various studies have been conducted to assess the impact of recent lockdowns on air quality in many countries around the world due to COVID-19 pandemic. In a number of works, the observed NO\textsubscript{2} contents were compared with the respective levels for the same period of previous years using ground-based and/or satellite measurements. Shi and Brasseur (2020) found a decrease in NO\textsubscript{2} concentrations in China by 50\%, compared to 2019 during the same period of the lockdown, and by 60\% compared to 2018, highlighting the interannual variability of NO\textsubscript{2} reductions that could depend on meteorological conditions or long-term variability. Other authors compared NO\textsubscript{2} amounts before and during the lockdown. For example, Siddiqui et al. (2020) observed a 46\% reduction in NO\textsubscript{2} tropospheric columns in India using satellite data, Liu et al. (2020) estimated a 48\% reduction in China before and during the Lunar New Year, which is 21\% more than in previous years 2015–2019 (given that a NO\textsubscript{2} reduction has been observed over the past years even without COVID), and Bauwens et al. (2020) deduced a 20\%–38\% reduction in western Europe. Many studies have considered specific techniques to limit the effect of meteorological conditions in their data. In the case of Paris, a 45\%–52\% reduction in NO\textsubscript{2} concentration was estimated by Collivignarelli et al. (2021), using equivalent temperature and wind speed days, and ~ 50\% was estimated by Barré et al. (2021), using a gradient boosting machine learning (GBML) technique. In the case of tropospheric NO\textsubscript{2} columns measured by satellite instruments, Prunet et al. (2020) estimated a 2-week-averaged reduction of NO\textsubscript{2} varying between 52\% and 86\%, using the city-scale NO\textsubscript{2} plume mass method for 16 March–26 April. In the present study, the long-term evolution was considered from 1 decade of measurements combined with air masses filtering based on slow wind speed and long residence time. The calculated reductions in the tropospheric NO\textsubscript{2} column and surface concentration are comparable in magnitude to the results of previous studies in western Europe, i.e., 46\%–56\% and 28\%–54\%, respectively.

Menut et al. (2020) compared the results of two special model calculations performed for the March 2020 lockdown period in western Europe. They used the Weather Research and Forecasting (WRF)-CHIMERE model for the following two simulations: one using a business-as-usual (BAU) scenario with classical emissions and the other one using a realistic scenario taking into account an estimate of the effect of lockdown measures on NO\textsubscript{2} in 2020. The authors found a maximum reduction of 43\% in the average NO\textsubscript{2} concentration over France. This simulation was based on a reduction in emissions of about 80\% in the transport sector and 40\% reduction in the industrial sector, but there was an increase in residential emissions during the second half of March, reducing emissions of NO\textsubscript{X} probably by more than 50\% (taking into account the distribution of NO\textsubscript{X} emissions as given by Citepa (https://www.citepa.org/fr/2020-nox/, last access: April 2021). Thus, NO\textsubscript{2} concentration reductions are slightly lower than NO\textsubscript{X} emissions changes in these simulations, probably due to an increase in the NO\textsubscript{2}/NO ratio for lower NO\textsubscript{X} concentrations. This suggests that, at least when spatially averaged, NO\textsubscript{X} emission reductions due to the lockdown are similar to those of NO\textsubscript{2} surface concentrations.

6 Conclusions

To assess the impact of France’s policy decision to limit the spread of the SARS-CoV-2 virus by establishing a restrictive lockdown between 17 March and 10 May 2020, NO\textsubscript{2} surface concentrations and tropospheric columns over Île-de-France were analyzed, more specifically in Paris and suburban areas in the southwest of the agglomeration. Possible factors that
can influence NO$_2$ changes, other than NO$_x$ emissions reduction due to the lockdown, were considered. The data sets were partitioned to select the conditions of light winds moving air masses from Paris to a suburban area in the southwest. In addition, the known long-term reduction in NO$_2$ is also considered using the measurements in the previous decade. The tropospheric NO$_2$ reduction obtained from the SAOZ data is about 50% (56% at the Paris site and 46% at the southwestern suburban site). These values are close to the literature data found for Europe within the estimated error bars (Barré et al., 2021; Prunet et al., 2020). This work highlights the ability of satellite TROPOMI measurements to distinguish between the tropospheric columns of urban and suburban sites, showing higher mean values at an urban station compared to a suburban one. The latter is also confirmed by the ground-based SAOZ measurement data. The agreement between the evolution of NO$_2$ in the troposphere observed at urban and suburban sites improves when selecting similar meteorological conditions. Surface NO$_2$ concentrations inside Paris are highly influenced by local pollution, and differences between the data of traffic and background urban sites are observed as expected. Surface concentrations were reduced by $\sim 50$% at all stations (similar to $\pm 1\sigma$), except for the site in Paris’s 13th district at Choisy Park that shows a lower reduction. The suburban station of Versailles presents NO$_2$ concentrations similar to Paris’s 13th district, and the reduction in 2020 was $10\%$ lower, within the error bars.

The reductions at Paris sites during the lockdown are important, whether or not a filter was used to remove the effect of different meteorological conditions. On the contrary, selecting data according to air mass residence time over the agglomeration strongly changes the estimates of NO$_2$ reductions at the suburban sites. As expected, if filtering is not applied, lower NO$_2$ reductions are found for suburban sites, since the data sets include also measurements that are less affected by the agglomeration and closer to background conditions. If the long-term evolution is not considered, the computed reductions highly depend on the year of reference. In this study, a negative tropospheric NO$_2$ trend of $-1.5$ Pmolec. cm$^{-2}$ yr$^{-1}$ (equivalent to $\sim 6.3\%$ yr$^{-1}$) is observed. Surface NO$_2$ concentrations also show negative trends, with a mean value of $-2.2$ µg m$^{-3}$ yr$^{-1}$ ($\sim 3.6\%$ yr$^{-1}$).

In conclusion, the negative trend estimated during the last decade indicates the long-term benefits of the environmental measures taken to reduce NO$_x$ emissions. The magnitude of the NO$_2$ supplementary reduction in 2020, which we calculate to be around $50\%$, is consistent with the reduction in emissions associated with the lockdown in France, as suggested in a recent modeling study (Menut, 2020).

**Data availability.** The data used in this study are publicly available. Tropospheric NO$_2$ data can be accessed from SAOZ instruments at http://saoz.obs.uvsq.fr (SAOZ, 2021) and from the TROPOMI satellite instrument at https://s5phpub.copernicus.eu (European Space Agency, 2021). Data under the ODbl license and NO$_2$ concentration data are available at https://data-airparif-asso.opendata.arcgis.com/ (Airparif, 2021). Wind speed and direction data from ERA5 can be found at https://confluence.ecmwf.int/display/CKB/ERA5 (ECMWF, 2021). The data of Airparif can be obtained directly by searching for the year (yyyy) and station name in the first column of Table 1 (https://data-airparif-asso.opendata.arcgis.com/datasets/YYYY-station/explore). An example for Quai des Célestins or CELES (Table 1) and the year 2020 is available at https://data-airparif-asso.opendata.arcgis.com/datasets/2020-celes/explore.

**Author contributions.** AP, FG and MP contributed to the processing, analysis and availability of the SAOZ data. AB and DI processed the TROPOMI data. AH provided ERA5 data for the area above Paris. MB developed the filter method to account for meteorological conditions. AP and SGB performed the statistical analysis. AP wrote the paper, with the assistance from all authors.

**Competing interests.** The contact author has declared that neither they nor their co-authors have any competing interests.
