We present the full panchromatic afterglow light curve data of GW170817, including new radio data as well as archival optical and X-ray data, between 0.5 and 940 days post-merger. By compiling all archival data, and reprocessing a subset of it, we have ensured that the panchromatic dataset is uniform and therefore immune to the differences in data processing or flux determination methods used by different groups. Simple power-law fits to the uniform afterglow light curve indicate a $f_{-0.86}^{+0.04}$ rise, a $t^{-1.90}^{+0.12}$ decline, and a peak occurring at $155 \pm 4$ days. The afterglow is optically thin throughout its evolution, consistent with a single spectral index ($-0.569 \pm 0.002$) across all epochs. This gives a precise and updated estimate of the electron power-law index, $p = 2.138 \pm 0.004$. By studying the diffuse X-ray emission from the host galaxy, we place a conservative upper limit on the hot ionized ISM density, $<0.01 \text{cm}^{-3}$, consistent with previous afterglow studies. Using the late-time afterglow data we rule out any long-lived neutron star remnant having magnetic field strength between $10^{10.4}$ G and $10^{16}$ G. Our fits to the afterglow data using an analytical model that includes VLBI proper motion from Mooley et al., and a structured jet model that ignores the proper motion, indicates that the proper motion measurement needs to be considered while seeking an accurate estimate of the viewing angle.

1. INTRODUCTION

Discovered on August 17, 2017 and localized to the lenticular galaxy NGC 4993 at 40 Mpc (Coulter et al. 2017), GW170817 is the first binary neutron star merger detected in gravitational waves (Abbott et al. 2017a). Uniquely, GW170817 was also accompanied by radiation across the electromagnetic spectrum (Abbott et al. 2017b), which allowed the merger astrophysics to be studied in great detail. A low-luminosity short $\gamma$-ray burst (SGRB; Goldstein et al. 2017; Savchenko et al. 2017) was observed 1.7 seconds after the merger. The macronova/kilonova, which peaked at ultraviolet (infrared) wavelengths on timescales of a few hours (days), indicated $\sim 0.05 M_\odot$ of r-process enriched merger ejecta traveling at $0.1c-0.3c$ (e.g. Kasliwal et al. 2017; Kasen et al. 2017).

The synchrotron afterglow, first detected 9 days after the merger at X-ray wavelengths (Troja et al. 2017), 16 days post-merger in the radio (Hallinan et al. 2017), and 110 days post-merger in the optical (Lyman et al. 2018), gave key insights into the relativistic ejecta and the circum-merger environment. The delayed onset and rising light curve of the afterglow ruled out a jet and established that the panchromatic afterglow emission, as well as the $\gamma$-rays, were produced in a mildly relativistic wide-angle outflow (Mooley et al. 2018b). Such an outflow could be explained by a cocoon (e.g., Lazzati et al. 2017; Gottlieb et al. 2018) formed due to the interaction between an ultrarelativistic jet (as seen in SGRBs) and the merger dynamical/wind ejecta or due to the fast tail of the (fairly isotropic) dynamical ejecta. The afterglow emission peaked and started to decline approximately 160 days post-merger (Dobie et al. 2018; Alexander et al. 2018a; D’Avanzo et al. 2018; Nynka et al. 2018; Troja et al. 2018). While the steeply declining light curve disfavored the isotropic ejecta model, the light curve and polarization measurements remained inconclusive as to whether a putative jet successfully penetrated the merger ejecta or was completely choked by it (e.g., Margutti et al. 2018; Alexander et al. 2018a; Corsi et al. 2018; Nakar & Piran 2018; Lamb et al. 2018).

The measurement of superluminal motion of the radio source using Very Long Baseline Interferometry (VLBI) finally broke the degeneracy between the successful- and choked-jet models (Mooley et al. 2018a). The radio emitting region showed a proper motion of about 2.7 mas between 75 days and 230 days post-merger. The light curve and VLBI modeling (Mooley et al. 2018a) together indicated that the jet core was successful and narrow, having an opening angle $< 5$ degrees and observed from a viewing angle between 14–28 degrees, and energetic, with the isotropic equivalent energy being about $10^{52}$ erg (lying at the tail-end of the regular SGRB distribution; Fong et al. 2015). The implied Lorentz factor close to the light curve peak is $\Gamma \simeq 4$ (Mooley et al. 2018a). The strong constraints on the geometry of GW170817 facil-
itiated a precise measurement of the Hubble constant (Hotokezaka et al. 2019). Subsequently, independent VLBI and afterglow light curve observations (Ghirlanda et al. 2019; Mooley et al. 2018c; Troja et al. 2019; Lamb et al. 2019; Fong et al. 2019; Hajela et al. 2019) confirmed the presence of a successful jet in the late-time afterglow of GW170817.

The wealth of observational data collected for the afterglow of GW170817 makes this one of the best studied (off-axis) SGRB afterglows. However, the dataset currently available in literature lacks uniformity, i.e. it suffers from differences in data processing and flux determination methods used by different groups. Recently, Fong et al. (2019) and Hajela et al. (2019) presented the reprocessing of some of the optical and X-ray afterglow data (Hubble Space Telescope or HST F606W 600 nm data and Chandra X-ray Observatory soft X-ray data), but the majority of the data (including radio data) were still lacking uniformity. Further, various groups have modeled the afterglow data of GW170817, but these groups have used different subsets of the data. The impact of these inhomogeneities is seen (at least partially) in the significant differences in the modeling results (e.g., Resmi et al. 2018; Mooley et al. 2018a; Ghirlanda et al. 2019; Wu & MacFadyen 2019; Lamb et al. 2019, see below). Taken together, a thorough compilation of all the observational data and a uniform dataset for the afterglow of GW170817 is warranted.

In this work we present a thorough compilation of the available radio, X-ray and optical data. The work includes new data not published before, and a reprocessing of some previous data sets using consistent methodology. The result is a uniform panchromatic dataset of GW170817’s afterglow. The observational data span 0.5 days to 940 days post-merger. We have made these afterglow measurements available in ASCII format on the web\(^1\), and this online dataset will be continuously updated (beyond 940 days) as new measurements become available. The new observations, data compilation and (re)processing are presented in §2. The full uniform afterglow data are presented in Table 1 and the light curve is shown in Figure 1. §3 describes power-law fits to the afterglow light curve and an analytical model to obtain jet and interstellar medium (ISM) parameters. Constraints on the density of the circum-merger environment and the nature of the merger remnant are presented in §4. In §5 we present preliminary fits to the afterglow light curve using the numerical structured jet model from Lazzati et al. (2018), a short review of all previous modeling efforts, and an examination of our modeling results in the context of previous results. We end with a summary and discussion in §6.

2. DATA COMPILATION, (RE)PROCESSING, ANALYSIS

We compiled all flux density upper limits from the literature (see references given in Table 1). Flux densities in the case of radio afterglow detections were compiled from Mooley et al. (2018c) and references therein, and optical (HST/F606W) afterglow detections reported in the Fong et al. (2019) reprocessing. Below we report on new data obtained with the Karl G. Jansky Very Large Array (VLA), MeerKAT, the Australia Telescope Compact Array (ATCA) and enhanced Multi Element Remotely Linked Interferometer Network (eMERLIN) radio telescopes between 180 and 780 days post-merger spanning frequencies between 1.2–9 GHz.

We further processed and analyzed radio data reported by Resmi et al. (2018); Margutti et al. (2018); Alexander et al. (2018a), ensuring consistent method of flux determination (as reported in Mooley et al. 2018c). Similarly, we also reprocessed X-ray and optical (HST/F814W) data to ensure a uniform data processing and flux determination technique. Our radio reprocessing substantially improves the precision of the flux density values (by up to a factor of 2 in RMS noise, i.e., 1\(\sigma\) errorbar) with respect to previously-published values. Through our reprocessing, we find discrepancies of up to 1.5\(\sigma\) in the previously-published radio flux density values. Our measurements with the reprocessed X-ray and optical data are in agreement, within 1\(\sigma\), with previously published values.

The new observations and data (re)processing methods are described below, and the full afterglow dataset spanning radio, optical and X-ray frequencies is given in Table 1. We note that, in Table 1, all flux density measurements are quoted with 1\(\sigma\) error bars and all upper limits are 3\(\sigma\). The full uniform afterglow light curve is shown in Figure 1.

2.1. VLA

VLA data of GW170817 covering the period between 2017 August 18 and 2018 Jan 8 have been reported by Alexander et al. (2017); Hallinan et al. (2017); Alexander et al. (2018b); Mooley et al. (2018b,a); Margutti et al. (2018); Alexander et al. (2018a); Mooley et al. (2018c); see Table 1. We have reprocessed some of these observations (see Table 1) using the NRAO Common Astronomy Software Applications (CASA) pipeline (Mc-

\(^1\)http://www.tauceti.caltech.edu/kunal/gw170817/
Mullin et al. 2007) and WSClean (Offringa et al. 2014) for imaging. Additionally, we observed GW170817 on 2018 Dec 18–20 and 2019 Sep 24–27 with the VLA (PI: Corsi; VLA/18B-204). The Wideband Interferometric Digital Architecture (WIDAR) correlator was used at S band (2–4 GHz). We used PKS J1248–1959 as the phase calibrator and 3C286 as the flux density and bandpass calibrator. The data were calibrated and flagged for radio frequency interference (RFI) using the CASA pipeline. We then split and imaged the target data using the CASA tasks split and clean.

2.2. ATCA

We observed GW170817 with the ATCA (PI: Dobie, Piro) at four epochs between 2018 Nov to 2019 Sep (Table 1). We determined the flux scale and bandpass response for all epochs using the ATCA primary calibrator PKS B1934–638. Observations of PKS B1245–197 were used to calibrate the complex gains. All observations used two bands of 2048 MHz centered at 5.5 and 9.0 GHz.

We reduced the visibility data using standard MIRIAD (Sault et al. 1995) routines. The calibrated visibility data from both bands were combined, averaged to 32 MHz channels, and imported to DIFMAP (Shepherd 1997). Bright field sources were modeled separately for each band using the visibility data and a combination of point-source and Gaussian components with power-law spectra. After subtracting the modeled field sources from the visibility data, GW170817 dominates the residual image. Restored naturally-weighted images for each band were generated by convolving the restoring beam and modeled components, adding the residual map and averaging to form a wide-band image. Image-based Gaussian fitting with unconstrained flux density and source position was performed in the region near GW170817.

Following our Markov chain Monte Carlo (MCMC) analysis (§3; see also Mooley et al. 2018c) we corrected all ATCA flux density values with a constant multiplicative factor of 0.8.

2.3. uGMRT

We reprocessed archival upgraded Giant Metrewave Radio Telescope (uGMRT) Band 5 (1.0–1.4 GHz) data with the CASA package. The data were initially flagged and calibrated using a custom developed pipeline in CASA. The data were further inspected for RFI and flagged using standard tasks in CASA. The target source data were then imaged with the CASA task clean. A few rounds of phase-only self-calibration and two rounds of amplitude and phase self-calibration were done. The flux density of the GW source at multiple epochs is listed in Table 1. The quoted errors are map RMS values near the source position.

The uGMRT Band 4 (0.55–0.85 GHz) observations were processed using the SPAM pipeline (Intema et al. 2009, 2017) by splitting the wideband data in 6 frequency chunks of 50 MHz wide which are processed separately. For each observing session, instrumental calibrations are derived using the best available scan on flux calibrator 3C147 or 3C286. These calibrations are applied to the target visibility data, after which this data is split into separate files. The target files per epoch are concatenated and taken through several cycles of self-calibration, imaging, and flagging of bad data. The final two cycles include direction-dependent calibration to mitigate ionospheric effects. The pipeline yields an image and calibrated visibility dataset for each frequency chunk. In a final step, to benefit from the improved sensitivity and uv-coverage of the wideband data, the calibrated visibility data of the 6 frequency chunks per epoch are jointly imaged using WSClean (Offringa et al. 2014).

2.4. MeerKAT

GW170817 was observed with the MeerKAT telescope (Jonas & MeerKAT Team 2018; Camilo et al. 2018) at 7 epochs between 2018 Jan 18 and 2018 Sep 02 (see Table 1). The first observation was performed during the AR1 phase using 16 antennas, while remaining observations used the full 64 antenna array. All observations are centred at 1.3 GHz using 4096 channels spanning 856 MHz and an 8 s integration time. About 10% of the band is flagged due to the bandpass roll off, resulting in an effective bandwidth of 770 MHz, and a further 27% of is flagged due to RFI. At 1.3 GHz, the field of view (full width at half maximum of the primary beam) is about 1.1 degrees. The data are processed using the Containerized Automated Radio Astronomy Calibration pipeline (CARACal; Ramatsoku et al. 2020), which performs; i) automatic RFI flagging using CASA and AOFlagger (Offringa et al. 2010); ii) a standard cross-calibration (delay, bandpass and gain calibration) using a combination of CASA and MeqTrees (Noordam

2 Although we used WSClean, we noted that unresolved background radio sources in the field did not vary significantly with respect to the images generated using CASA clean (which was used for all other VLA data), thus ensuring uniformity of flux measurements for all VLA data.

3 http://www.ncra.tifr.res.in/~ishwar/pipeline.html
& Smirnov 2010). We used PKS 1934–638 as the primary calibrator and 3C286 as the secondary calibrator; and iii) a direction-dependent self-calibration (Pearson & Readhead 1984) that uses a combination of WSClean (Offringa et al. 2014), CubiCal (Kenyon et al. 2018), and PyBDSF (Mohan & Rafferty 2015). After the cross-calibration step, we found a variability of around 10% on the flux density measurements between epochs, which was corrected by bootstrapping the fluxes to a common fluxscale using 2 reference point-like sources within 2 arcminutes of the afterglow position. It is worth noting that this uncertainty is due to our calibration process, and is not a limitation of the telescope. The self-calibration includes a model of the MeerKAT primary beam that is derived from Holography measurements of the array (Asad et al. 2019).

2.5. eMERLIN

We observed GW170817 with the eMERLIN array between January and March 2018 with 11 individual runs. Each run had a duration of 5–6 hours. Observations were conducted using the the C band receiver tuned at frequencies between 4.82 and 5.33 GHz, for a total bandwidth of 512 MHz distributed in 4 spectral windows, each one divided into 512 channels. The phase reference source was J1311−2329. Flux density calibration and bandpass correction were obtained from 3C286 and OQ208, respectively. The observations were primarily at low elevations (< 20 degrees), and the flux density measurements may be affected by a small bias due to reduced gain sensitivity of the telescopes at these elevations. Nevertheless, the core of the host galaxy was detected (at 160 ± 20 µJy beam$^{-1}$) in almost all runs, with associated variability of about 12% between runs, compatible with the uncertainties. We measure the flux density of NGC 4993 to be 0.25 ± 0.01 mJy beam$^{-1}$ at 4.5 GHz with the VLA (Mooley et al. 2018a), indicating a flux density correction factor of about 0.6 for the eMERLIN measurements. The flux density of GW170817 (detected only in the first observing run, on 2018 January 14), the associated uncertainty, and 3σ upper limits reported in Table 1 include the absolute flux density error (25%) and statistical map noise error.

2.6. HST

Reduced HST images were downloaded from the MAST archive. To remove most of the stellar light we first fit a simple Sersic model to NGC 4993 using Galfit (Peng et al. 2002). This leaves significant residuals (asymmetries, dust lanes, shell/tidal features, etc.) which were removed by applying a 1σ box median filter. This was followed by astrometric correction to align the images with each other. To obtain PSF photometry at the expected position of GW170817 we have done the following: (1) we estimate an empirical PSF model (50 × 50 pixel size) by first detecting point-like sources using SExtractor (Bertin & Arnouts 1996), and constructing an average PSF from these. Sources that do not fit well to the average PSF were removed, and a final PSF was constructed using the remaining point-like sources. (2) we fit the PSF model to the data at the expected position of GW170817. Uncertainties and limiting magnitudes are estimated by randomly (> 100 times) fitting the PSF model to the background as close to the position of GW170817 as possible.4

2.7. Chandra and XMM-Newton

We list the Chandra and XMM-Newton observational data on GW170817 used here for spectral analysis in Table 2.

For Chandra we used CIAO v4.11 (Fruscione et al. 2006) with CALDB v4.8.2 to analyze the data, initially reprocessing the data using the chandra_repro tool. The tool specextract was used to extract the X-ray spectra of GW170817 and its host galaxy NGC 4993. For GW170817, we use a circular region with radius 1″, which encompasses 90% of the PSF at 1.5 keV, centered on the source. We extract background events from a nearby source-free circular region with radius 19.2″. For groups of observations made close to each other, in order to increase signal to noise, we combine the spectral products using the CIAO tool combine_spectra for use in spectral fitting.

To measure the emission from NGC 4993, we extract events from a 50″ circular region centered on the nucleus, masking 6 point sources lying within the region (including GW170817 and the AGN associated with the galaxy). We used a circular source-free region, with radius 34″, outside the galaxy extraction region, to estimate the background. For the emission from the galaxy, since we do not expect this to change significantly over time, we combine spectral products from all Chandra observations.

We used XMMSAS v15.0.0 to analyze the XMM-Newton data and the tool evselect to extract spectral and lightcurve data. We do not use XMM-Newton obsID 0830191001 since the source is too faint with respect to the Active Galactic Nuclei (AGN) for spectral analysis. Count rates greater than 0.7 s$^{-1}$ in the range 10–12 keV.

4 We have validated our PSF photometry method by comparing the resulting lightcurve of GW170817 in the F606W filter with that published by Fong et al. (2019). The methods agree within the uncertainties.
Figure 1. Upper panel: The panchromatic (radio, optical and X-ray) afterglow light curve of GW170817, color coded according to the observing frequency, up to 940 days post-merger (all data points have 1σ errorbars as presented in Table 1; upper limits are not shown here) using the uniform dataset presented in this work. The light curve is scaled to 3 GHz using the best-fit spectral index ($-0.569$) derived from the MCMC power-law fitting (see §3). Lower panel: The averaged (using moving average; $\Delta t/t = 1/17$ where $\Delta t$ is the width of the kernel and $t$ is the time after merger) light curve (blue data points) shows a general trend consistent with power-law rise and decline. In grey are the same data points as shown in the upper panel.

on the pn detector were used to determine periods of high background data, which were excluded from our analysis. Significant background flaring resulted in only 26 and 48 ks filtered exposures for obsIDs 0811210101 and 0811212701, respectively. Source events were then extracted from a circular region with radius 5″ centered on GW170817. While this is less than 50% of the EPIC-pn encircled energy, it was necessary to use a small region in order to exclude emission from the AGN, which is only 10 arcsec from the source. We find this does not introduce any large systematic effect when comparing to Chandra results from similar epochs. Background events were extracted from nearby, source-free circular regions of 55″ in radius.

For both GW170817 and NGC 4993, the spectra were grouped with a minimum of 1 count per bin with the HEASOFT tool grppha. We used the X-ray spectral fitting package XSPEC v12.10.1 to fit the data. For GW170817 we fit the data with an absorbed power-law model ($\text{tbabs*ztbabs*powerlaw}$), where $\text{tbabs}$ is a neutral absorbing column attributed to our own Galaxy, fixed at $8.9 \times 10^{20} \text{ cm}^{-2}$ (Dickey & Lockman 1990), and
GTABBS is a neutral absorbing column intrinsic to the source, $N_{H,{\text{NGC}} 4993}$, at $z = 9.73 \times 10^{-3}$ which we initially allow to vary within the fit. We use the Cash statistic as the fit statistic, with the background subtracted, and the spectra were fitted in the 0.5–8 keV range for Chandra and the 0.2–10 keV range for XMM-Newton.

We initially allow all spectral parameters to vary across observational epochs to test for spectral variations, however we do not find any evidence for this. We therefore re-fit the spectra with the $N_{H,\text{NGC} 4993}$ and $\Gamma$ parameters tied across all epochs. We find no evidence for absorption intrinsic to the source with a 90% upper limit of $N_{H,\text{NGC} 4993} < 5 \times 10^{20} \text{cm}^{-2}$. For the power-law, the best fit photon index is $\Gamma = 1.54^{+0.19}_{-0.15}$ which is consistent with $\Gamma = 1.57$ that is inferred from the radio to X-ray spectrum (confirmed in §3). Therefore we fix $N_{H,\text{NGC} 4993} = 0$ and $\Gamma = 1.57$ in order to measure the flux from GW170817 which is presented in Table 2.

We calculate the 3σ upper limit on the count rate of GW170817 in Chandra observation 18955 from events extracted in the background region. We determine that the number of background counts expected in the source extraction region is 0.015, corresponding to a count rate of $5.7 \times 10^{-5}$ counts s$^{-1}$, which when assuming our spectral model corresponds to a 0.5–8 keV flux of $1.1 \times 10^{-15} \text{erg cm}^{-2} \text{s}^{-1}$ or a flux density at 1 keV of $8.5 \times 10^{-11} \text{Jy}$.

Overall, we detect 9604 counts between 0.5–8 keV in the source extraction region from all observations combined of which 9.4% are attributable to NGC 4993. We use a power-law model to calculate a flux, where the power-law index, $\Gamma = 0.7 \pm 0.6$, and normalization, $N = 1.8 \pm 1.0 \times 10^{-6}$, yielding a 0.5–8 keV flux of $2.0^{+1.1}_{-0.7} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1}$. Since the source counts are a small fraction of the total (source+background) counts, background subtraction introduces large uncertainties into the spectral modelling results, which should be treated with caution.

### 3. ANALYTICAL MODELING

Following previous afterglow studies (Dobie et al. 2018; Alexander et al. 2018a; Mooley et al. 2018c), we fit the afterglow data\(^5\) using a smoothly-broken power law model,

\[
F(t, \nu) = 2^{1/s} \left(\frac{\nu}{3 \text{GHz}}\right)^{\beta} F_p \left[\left(\frac{t}{t_p}\right)^{-\alpha_1} + \left(\frac{t}{t_p}\right)^{-\alpha_2}\right]^{-1/s}
\]

where $\nu$ is the observing frequency, $\beta$ is the spectral index, $F_p$ is the flux density at 3 GHz at light curve peak, $t$ is the time post merger, $t_p$ is the light curve peak time, $s$ is the smoothness parameter, and $\alpha_1$ and $\alpha_2$ are the power-law rise and decay slopes, respectively. This MCMC fitting was done\(^6\) using the Python package \texttt{emcee} (Foreman-Mackey et al. 2013). We obtain best-fit values listed in Table 3. Figure 2 shows the best-fit broken power-law curve and the resulting residuals. Further analysis of the shape of the light curve is needed to see whether these plateaus are statistically significant and derive the precise angular structure of the relativistic outflow. Figure 3 shows the corner plot corresponding to the MCMC analysis.

We use a rough analytic model, described in Mooley et al. (2018c), to estimate the jet opening angle $\theta_j$ and the viewing angle $\theta_v$. The sharpness of the light curve peak, $\Delta t/t = (t_2 - t_1)/t_2$, where $t_1$ is the time around the transition from the $\nu^{0.86}$ rise to the peak and $t_2$ is the time when the light curve approaches $t^{-2}$, is directly related to the ratio $\theta_j/\theta_v$. Using the approximations $\theta_v - \theta_j \gg \theta_j$ and jet Lorentz factor $\Gamma \propto t^{-3/8}$ (Blandford & McKee 1976) we find that $\Delta t/t \approx (8/3) \theta_j/\theta_v$. Here we use the approximation that $\theta_j/\theta_v$ is much smaller than unity. From our MCMC analysis we find $0.2 \lesssim \Delta t/t \lesssim 0.4$ (68% confidence or better, depending on where $t_1$ and $t_2$ lie), indicating that $0.1\theta_v \lesssim \theta_j \lesssim 0.2\theta_v$.

Using $\Gamma \approx 4.1 \pm 0.5 \approx 1/(\theta_v - \theta_j)$ close to the peak of the light curve from the VLBI measurement (Mooley et al. 2018a), we get $\theta_j \approx 1^\circ - 4^\circ$ and $\theta_v \approx 14 - 20^\circ$.

Using the Blandford-McKee solution (Blandford & McKee 1976), we can estimate the ratio of the jet kinetic energy and the density of the circum-merger environment $E/n_{\text{ISM}}$. We have,

\[
E/n_{\text{ISM}} \approx \theta_j^2 R^3 \Gamma^2 m_p c^2 \approx 8\theta_j^2 c^3 T^8 m_p c^5 \\text{(2)}
\]

since $R = c t_{\text{lab}} = (1 - 1/2\Gamma^2) c (1 - \beta \cos(\theta_v))^{-1/2} t \approx 2\Gamma^2 c t$, where $R$ is the distance travelled (in the lab

\(^5\) We do not consider the gVLBA and eMERLIN data points while modeling since they have relatively large uncertainties in the absolute flux calibration.

\(^6\) We chose 100 walkers, 1000 steps and flat priors on all of the parameters. Since compact interferometric data may be affected by extended emission from the host galaxy, we also introduced a scale factor into the MCMC fit to explore possible offsets in the ATCA, MeerKAT and uGMRT flux densities. We recover the constant flux multiplication factor of 0.8 for the ATCA (most likely due to the compact array being sensitive to extended structure around GW170817 Mooley et al. 2018c), while the factor is consistent with unity for the MeerKAT and uGMRT data.
Figure 2. Broken power-law fit (using MCMC; best-fit shown as a black curve in the upper panel and residual shown in the lower panel) to the afterglow light curve. The corner plot for the MCMC analysis is shown in Figure 3. The light curve is scaled to 3 GHz using the best-fit spectral index (−0.569) derived from the MCMC analysis. Color coding is the same as in Figure 1. The light curve rises as $t^{0.86±0.04}$ and declines as $t^{-1.90±0.12}$. The light curve peak occurs at 155 ± 4 days post-merger. The lack of any substantial outlier data points indicates that the afterglow is optically thin throughout its evolution, with the synchrotron self-absorption frequency lying below the radio band and cooling frequency lying above the soft X-ray band. See §3 for details.

Because of the large uncertainty due to the background subtraction, we cannot separate the diffuse emission of the hot ionized ISM from that arising from un-
resolved point sources based on their spectral shapes. Therefore, we use the 2σ upper limit on the X-ray flux to estimate an limit on the number density of the hot ionized ISM in NGC 4993. To obtain the density at the location of the merger from the diffuse emission in the circular region with radius 34″, we use an isothermal beta model (Cavaliere & Fusco-Femiano 1978) to describe the global structure of the hot ionized gas. This model is characterized by the density at the galactic center, the core radius, \( r_c \), the power-law index of the density profile, \( \beta_{ISO} \), and temperature \( T \). For early-type galaxies with a diffuse X-ray luminosity of \( \lesssim 10^{40} \text{erg s}^{-1} \), the model parameters are typically in the range of \( 0.1 \lesssim T \lesssim 1 \text{keV} \), \( r_c \lesssim 10 \text{kpc} \), and \( 0.25 \lesssim \beta_{ISO} \lesssim 1 \) (Babyk et al. 2018). Given the density structure and the X-ray emissivity calculated with APEC, we compute the total X-ray flux arising from the hot ionized ISM in the circular region. Assuming \( \beta_{ISO} = 0.5 \) and the solar metallicity, we obtain a 2σ upper limit on the ISM density at the merger, \( \lesssim 10^{-2} \text{cm}^{-3} \), as shown in Figure 4. Note that our method provides a good estimate of the mean density of the hot-ionized ISM but it does not necessarily provide a precise estimate of the density at the merger location. However, our estimate is consistent with the result of Hajela et al. (2019) — \( n \lesssim 9.6 \times 10^{-3} \text{cm}^{-3} \) — in which they analyze the X-ray data in a small annular region of the inner part of NGC 4993. The consistency of these two independent analyses supports \( n \lesssim 10^{-2} \text{cm}^{-3} \). Furthermore, this estimate is consistent with that estimated from the afterglow light curve and superluminal motion modelings (e.g., Mooley et al. 2018a) and from searches for neutral gas \( (n < 0.04 \text{cm}^{-3}; \text{Hallinan et al. } 2017) \).

4.2. The merger remnant

While GW170817 is believed to have collapsed to a black hole after a short-lived hypermassive neutron star phase, the exact nature of the remnant remains observationally unknown (e.g. Kasen et al. 2017; Yu et al. 2018; Pooley et al. 2018). Here we derive constraints on the magnetic field strength \( (B) \) of any long-lived neutron
star remnant that may have resulted from GW170817. The afterglow flux density measurements up to 940 days post-merger indicate that the late-time afterglow is consistent with a decelerating jet ($t^{-p}$ decline). The full uniform afterglow light curve is shown in Figure 1. We consider an upper limit (measured flux density + 2σ uncertainty) of 3.6×10^{-10} Jy on the X-ray flux density, corresponding to a luminosity of 2×10^{38} erg s^{-1} for any pulsar wind component. Pulsar (magnetic dipole) spin-down luminosity is given by (Spitkovsky 2006; Hotokezaka et al. 2017; Metzger 2017),

$$L_{sd} \simeq 2.3 \times 10^{43} \text{ergs}^{-1} \left(\frac{B}{10^{12} \text{G}}\right)^2 \left(\frac{P}{1 \text{ ms}}\right)^{-4} \left(1 + \frac{t}{t_{sd}}\right)^2$$

where,

$$t_{sd} \simeq 31 \text{ yr} \left(\frac{B}{10^{12} \text{G}}\right)^{-2} \left(\frac{P}{1 \text{ ms}}\right)^2$$

Assuming the spin period at the time of merger is $P \simeq 1$ ms and that a fraction $f \simeq 10^{-2}$ of the spin-down power is converted into X-ray radiation, we obtain\(^7\), $B \lesssim 10^{10.4}$ G.

The sensitive late-time afterglow measurement is therefore more constraining than the previous constraints (Pooley et al. 2018; Margutti et al. 2018) on the magnetic field strength. The upper limit of $10^{10.4}$ G is at odds with simulations\(^8\) (Zrake & MacFadyen 2013; Kiuchi et al. 2014; Giacomazzo et al. 2015) that predict $B \sim 10^{15} – 10^{16}$ G. If the simulations accurately represent the dipole magnetic field strength, then it is likely that the merger remnant in GW170817 is a black hole.

However, we note that we are not able to rule out magnetars with $B \gtrsim 10^{16}$ G since for such objects the spin down luminosity would decrease rapidly within the first ~100 days (this is a very conservative timescale over which the merger ejecta would become optically thin towards any emission arising from spin-down), below the afterglow luminosity measured for GW170817 (see Figure 7 of Margutti et al. 2018 for example).

5. NUMERICAL MODELING

We have presented the uniform afterglow light curve to the astronomical community with the hope that these data will be used for extensive modeling in the future. In this section we provide a preliminary\(^9\) update on the jet and ISM parameters obtained using the numerical model from Lazzati et al. (2018) (§5.1). In §5.2 we review and contrast with previous modeling efforts.

5.1. Structured Jet Model

We modeled the data with a forward shock afterglow model based on the semi-analytic code used in Lazzati et al. (2018). The model has 5 free parameters: the viewing angle $\theta_v$, the microphysical parameters $\epsilon_e$ (the fraction of shock energy given to electrons) and $\epsilon_B$ (the fraction of shock energy given to tangled magnetic field), the electrons population distribution index $p$, and the external medium density $n_{\text{ISM}}$, which was assumed to be constant. The total kinetic energy of the fireball and its initial Lorentz factor, both dependent on the viewing angle, were taken from an hydrodynamic numerical simulation, previously described in Lazzati et al. (2017). Specifically, the energy of the blast wave, set by the numerical simulation, is $6 \times 10^{49}$ erg. The fit was performed with a dedicated implementation of a Markov-Chain Monte Carlo scheme, assuming flat priors for all free parameters except the interstellar medium density, which was assumed to be small ($n_{\text{ISM}} \leq 0.01 \text{ cm}^{-3}$; see §4 and Hallinan et al. 2017). The best fit parameters are given in Table 3. The fit to the light curve and corresponding corner plot are shown in Figure 5.

We caution that the quoted uncertainties in the best fit results are purely statistical and do not reflect the po-

---

\(^7\) This lower limit on the magnetic field strength is sensitive to $f$ and $P$. If $f = 10^{-3}$ or $P = 2$ ms then we get $B \lesssim 10^{11}$ G.

\(^8\) We assume here that the small-scale magnetic fields, found in simulations, are comparable in strength to the global dipolar field.

\(^9\) The model currently excludes VLBI constraints, and assumes constant jet opening angle and blast-wave energy.
Potentially large systematic uncertainties associated with the numerical simulation itself. We have modeled the jet dynamics and merger ejecta interaction as a purely hydrodynamical system using FLASH (Fryxell et al. 2000), which does not have magnetohydrodynamic capabilities for relativistic flows. This can affect the final polar distribution of both the kinetic energy of the merger and the Lorentz factor of the outflow. Additionally, the FLASH simulation uses a set of initial conditions that do not necessarily reproduce the actual conditions at the base of the jet (Lazzati et al. 2017). Finally, it should be noted that the constraint on the proper motion of the radio transient (Mooley et al. 2018a) are not included in the fit.

5.2. Review of and comparison with previous models

It is now widely accepted that GW170817 produced a relativistic jet with substantial angular structure. Multiple studies, using different hydrodynamic and semi-analytic models, have modeled the afterglow of GW170817 to obtain the properties of the structured jet. The parameter constraints derived by these studies are tabulated in Table 4. Generally, all studies obtain small jet opening angles, \( \lesssim 6^\circ \), and viewing angles between 15–35\(^\circ\). Very few studies (Mooley et al. 2018a; Hotokezaka et al. 2019; Ghirlanda et al. 2019) fit the VLBI proper motion constraint. Estimates for the isotropic equivalent energy and circummerger density range from \( 10^{51.5}–10^{53} \) erg and \( 10^{-1.5}–10^{-4.5} \) cm\(^{-3}\), respectively. The circummerger density is correlated with \( \epsilon_B \), which is estimated to be between \( 10^{-1.5}–10^{-5} \). The parameters we obtain using the structure jet model are generally in agreement with the literature, although our estimate of \( \theta_v = 35.2^\circ \pm 0.6^\circ \) is the largest to-date.

Resmi et al. (2018); Hotokezaka et al. (2019); Troja et al. (2019); Ghirlanda et al. (2019); Lamb et al. (2019); Ryan et al. (2019) use semi-analytical techniques, using power-law and/or Gaussian angular profiles for the jet. Lamb et al. (2019) also use a two-component model that includes a top-hat jet and Gaussian cocoon. Only Hotokezaka et al. (2019); Ghirlanda et al. (2019) include VLBI constraints (but these studies also neglect sideways/lateral expansion of the jet). This may be the reason why they obtain low viewing angles, \( \sim 16^\circ \). The other semi-analytical studies obtain median viewing angle estimates between 20\(^\circ\)–27\(^\circ\).

Wu & MacFadyen (2019); Hajela et al. (2019) fit a “boosted fireball” model, a family of models parameterized by two parameters viz. internal energy and boost constraint into account.

10 Our code is currently being updated to take the proper motion constraint into account.
Lorentz factor (which also define the angular structure of the structured jet), to the afterglow light curve. This technique uses a template bank constructed from 3D hydrodynamical simulations together with analytic scaling relations. Lazzati et al. (2018) use input data (jet energy and opening angle, chosen to mimic a typical SGRB) from a 3D/2D hydrodynamical simulation. Sideways expansion is neglected. This work also utilizes the Lazzati et al. (2018) scheme. All of these studies obtain median viewing angles larger than 30°. Mooley et al. (2018a) carry out a dozen hydrodynamical simulations using various setups to determine the parameters that can fit the afterglow light curve and proper motion data. They obtain a median viewing angle of about 20°, which is much smaller than that obtained by Lazzati et al. (2018); Wu & MacFadyen (2019); Hajela et al. (2019), likely due to the VLBI proper motion being taken into account.

Looking at the substantial differences in all these modeling results, we therefore highlight that a combined analysis of the VLBI proper motion measured by Mooley et al. (2018a) and of the full uniform light curve presented here is crucial for obtaining an accurate estimate of the viewing angle and other parameters (jet and ISM) of GW170817.

6. SUMMARY & DISCUSSION

By compiling and reprocessing archival data at radio, optical and X-ray wavelengths, and reporting new radio data, we have presented a uniform dataset of the afterglow of GW170817 between 0.5–940 days post-merger. These afterglow measurements are available in ASCII format (continuously updated as new data get published) on the web. The afterglow light curve (Figure 1) shows a power-law rise, $F_{\nu} \propto t^{0.86}$ and a power-law decline $F_{\nu} \propto t^{-1.90}$, consistent with expectations for a laterally expanding relativistic jet core (dominating the late-time afterglow emission) surrounded by low-Lorentz factor material (dominating the early-time afterglow emission). A more detailed investigation of the shape of the afterglow light curve may provide important insights into the angular structure of the relativistic outflow from GW170817, and possibly the properties of the ejecta and jet at the time of jet launch.

Our uniform panchromatic dataset of the afterglow implies a spectral index of $\beta = -0.569 \pm 0.002$, leading to an extremely precise estimate of the electron power-law index, $p = 2.138 \pm 0.004$. The single unchanging spectral index across all epochs implies that the synchrotron self-absorption frequency is below the radio band and the cooling frequency is above the soft X-ray band throughout the evolution of the afterglow. The rate of decline of the afterglow light curve appears to be consistent with $t^{-p}$ (within 2σ), indicating that sound-speed expansion may provide a sufficiently accurate description of the jet lateral expansion. We do not find any evidence for steepening beyond $t^{-p}$ post-peak, as found by some hydrodynamical simulations (e.g. van Eerten & MacFadyen 2013).

Likewise, we do not find any evidence for flattening of the light curve during the decline phase. Specifically, we do not see any component declining as $t^{-1}$, even during the most recent radio observing epoch (767 days post-merger), that may be expected for a cocoon. Interpolating a $t^{-1}$ power law backwards in time from our 3 GHz detection 767 days post-merger, we find that any cocoon contribution to the afterglow is negligible beyond ~90 days post-merger, i.e. the jet core has likely dominated the afterglow beyond 90 days post-merger. Even at 900 days post-merger, the lack of any flattening in the light curve indicates that the jet is still in the relativistic phase, $\Gamma \beta \gtrsim 1$. This also implies that the counter-jet and the late-time dynamical ejecta afterglow have not made their appearance yet.

In our reprocessing of the X-ray data, we do not find any evidence for significant flaring or synchrotron cooling, which argues against the presence of any long-lived magnetized neutron star remnant in GW170817 (see also Lyman et al. 2018; Piro et al. 2019; Hajela et al. 2019). By analyzing the Chandra data we also study the diffuse X-ray emission of NGC 4993. The X-ray luminosity in 0.5–8 keV is estimated about 2 × 10$^{39}$ erg s$^{-1}$, somewhat lower than the X-ray luminosity of early-type galaxies (Babyk et al. 2018) given the total mass of NGC 4993 of ~10$^{12}$M$\odot$ (Pan et al. 2017). We estimate the hot ionized ISM density from the observed X-ray flux to be $\lesssim 0.01$ cm$^{-3}$. This result is consistent with that obtained from an independent analysis done by Hajela et al. (2019) as well as that estimated from the afterglow modelings of GW170817. Comparing the late-time X-ray luminosity with the pulsar spin-down luminosity, we rule out the phase space of 10$^{10.4}$ – 10$^{16}$ G for the magnetic field strength of any possible long-lived neutron star remnant in GW170817.

We fit both analytic and hydrodynamical models to the non-thermal afterglow to estimate the physical, geometrical and microphysical parameters associated with the jet. These parameters are tabulated in Table 3. We find that the ratio of the jet energy to the ISM density, $E/n_{\text{ISM}}$, to be $O(52)$–$O(53)$. The jet opening angle is a few degrees for all the models. The best-fit viewing an-

**Facility:** VLA, ATCA, uGMRT, MeerKAT, eMERLIN, HST, Chandra, XMM-Newton

**Software:** MIRIAD (Sault et al. 1995), CASA (McMullin et al. 2007), emcee (Foreman-Mackey et al. 2013), corner (Foreman-Mackey 2016), CARACal (Ramatowski et al. 2020), AOFlagger (Offringa et al. 2010), WSClean (Offringa et al. 2014), CubiCal (Kenyon et al. 2018), MeqTrees (Noordam & Smirnov 2010)

The wide range of viewing angles \( \theta_v \), seemingly inconsistent within uncertainties (see Table 4) obtained using different modeling techniques (used here and in previous studies), can be explained through the fitting of the VLBI proper motion measurement (Mooley et al. 2018a) and the systematic uncertainties (which may not be quantifiable) associated with the models/simulations. Fitting of the VLBI proper motion is especially important since the viewing angle cannot be estimated accurately by the light curve alone. As long as \( \theta_j < \theta v \ll 1 \), the light curve depends only on the ratio \( \theta v/\theta_j \) and not on \( \theta_v \) or \( \theta_j \) alone. Once the proper motion measurement is taken into account, it breaks the degeneracy and \( \theta v \) can be constrained (Mooley et al. 2018a,c; Nakar & Piran 2019; Nakar & Piran 2020). We highlight the importance of considering these limitations when drawing any physical conclusions or comparing the modeling results obtained using different techniques.

Given the upper limit on the ISM density, \( \lesssim 0.01 \text{ cm}^{-3} \) (§4), we predict that the radio emission arising from the dynamical ejecta (kilonova ejecta) can be detected in the future (Nakar & Piran 2011), depending on the actual ISM density and the velocity distribution of the ejecta. The latter is quite sensitive to the neutron equation of state (EOS; e.g., Hotokezaka et al. 2018; Radice et al. 2018). For example, a soft EOS predicts radio remnant with a flux density at \( \sim 10 \mu \text{Jy} \) level on a time scale of 10 yr, if the ISM density is \( \sim 10^{-3} \text{ cm}^{-3} \) (Radice et al. 2018). Detecting a long-lasting radio remnant will offer an opportunity to constrain the neutron star EOS from the light curve.

| Parameter       | Value | Units |
|-----------------|-------|-------|
| $F_{\nu, p}$    | 100 ± 3 | µJy   |
| $t_p$           | 155 ± 4 | days |
| $\alpha_1$      | 0.86 ± 0.04 |     |
| $\alpha_2$      | $-1.96_{-0.12}^{+0.11}$ |     |
| $\log_{10}(s)$  | 0.56_{-0.11}^{+0.13} |     |
| $\beta$         | $-0.569 ± 0.002$ |     |
| $\chi^2$/dof   | 68/96 |       |
| $p$             | 2.138 ± 0.004 |     |
| $E/n_{\text{ISM}}$ | $\simeq 1.5 \times 10^{53}$ | erg cm$^3$ |
| $\theta_\nu$    | $\simeq 14$ | degrees |
| $\theta_1$      | $\simeq 1 - 4$ | degrees |

Table 3. Parameters estimated from modeling the afterglow light curve.
