Improved Solar Operation Control for a Solar Cooling System of an IT Center

Jan Albers

Institut für Energietechnik, Technische Universität Berlin, Marchstraße 18, 10587 Berlin, Germany; jan.albers@tu-berlin.de; Tel.: +49-30-314-25-314

Abstract: In this contribution, a model predictive control algorithm is developed, which allows an increase of the solar operating hours of a solar cooling system without a negative impact on the auxiliary electricity demand, e.g., for heat rejection in a dry cooler. An improved method of the characteristic equations for single-effect H₂O/LiBr absorption chillers is used in combination with a simple dry-cooler model to describe the part load behavior of both components. The aim of the control strategy is to find a cut-in and a cut-off condition for the solar heat operation (SHO) of an absorption chiller cooling assembly (i.e., including all the supply pumps and the dry cooler) under the constraint that the specific electricity demand during SHO is lower than the electricity demand of a reference cooling technology (e.g., a compression chiller cooling assembly). Especially for the cut-in condition, the model predictive control algorithm calculates a minimum driving temperature, which has to be reached by the solar collector and storage in order to cover the cooling load with a low cooling water temperature but restricted auxiliary electricity demand. Measurements at a solar cooling system for an IT center were used for the testing and a first evaluation of the control algorithm.

Keywords: solar fraction; minimum driving temperature; model predictive control; absorption chiller; dry cooler; characteristic equation method

1. Introduction

Worldwide, an increase of the cooling demand is expected. In the building sector, the cooling demand is the most rapidly increasing effective energy demand [1]. Usually, the cold generation is realized by electrically driven compression chillers. Hence, the expected development in effective energy demand will lead to an increased power requirement as well. Acting on the assumptions of the World Energy Outlook [2], the global power requirements will increase by 60% between 2016 and 2040. Approximately 15% to 20% of this elevation will be caused by the cooling demand. Consequently, solar-assisted cooling systems (SAC systems) have a large potential to reduce the fossil fuel consumption related to non-regenerative power generation.

On the other hand, it has been shown (e.g., in [3]) that a minimum solar fraction is necessary for SAC systems in order to achieve a lower primary energy consumption than a conventional system using an electrically driven compression chiller. Henning et al. [3] illustrated that the system performance with regard to primary energy savings is improved when the COP of the thermally driven chiller increases, the solar fraction increases, and the specific electricity consumption of the auxiliary components like supply pumps and cooling tower etc. decreases.

For SAC systems with parallel backup heating, the achievable solar fraction is a question of the possible operating time with solar heat from the collector. Solar heat operation (SHO) can start earliest when the collector temperature is higher than a minimum driving temperature $t_{\text{min}}$ and has to end latest when the collector temperature drops below. Of course, additional temperature differences have to be taken into account (e.g., for a heat exchanger between the collector and storage, heat losses...
etc.). The minimum driving temperature $t_{Di}^{\text{min}}$ depends on the cooling load as well as the capacity and part load behaviour of the chiller. Moreover, it depends on the possible cooling water temperature, which is limited by the dry or wet bulb temperature. Generally speaking, $t_{Di}^{\text{min}}$ depends on the load and meteorological conditions as well as the technology used for the chiller and the reject heat device but not on the collector technology. Nevertheless, the collector technology (including storages and the connection to parallel or serial backup heating systems) has a large influence on the necessary preheating time (i.e., the period from sunrise until $t_{Di}^{\text{min}}$ is reached and solar heat operation can start) and thereby influences the overall system performance [4].

Taking the heat capacity effects of the collector and installation, as well as heat losses to the surrounding into account, Izquierdo [5] determined a solar radiation threshold $I_{\text{min}}$ as an equivalent measure to the minimum driving temperature. For a small SAC system in Madrid, two different heat rejection technologies were compared for the same meteorological conditions. In comparison to a wet cooling tower, a dry cooler revealed approximately 12 K higher cooling water temperatures. This led to about 20 K higher driving temperatures in the collector circuit and reduced the possible operating time of the SAC system from 9 to 3 h. The preheating time increased from approximately 3 to 6 h.

The influence of heat capacity effects on the preheating time was investigated by Li [6] and Kohlenbach [7] as well. While Li used a separated smaller part of a partitioned hot water storage tank to reduce the preheating time, Kohlenbach applied different temperature nodes of the storage tank for the control of the chiller before, during, and after solar heat operation. In both references, a constant (i.e., load and weather independent) start-up temperature of $t_{Di}^{\text{min}} = 75$ and 60 °C was used.

In order to shorten the preheating time, which is necessary to achieve a desired solar collector outlet temperature and thereby enable a longer solar operation of a single-effect H$_2$O/LiBr absorption chiller, Shirazi et al. [8] recommend a variable speed pump for the solar collector loop. A comparison of the simulation results to a constant flow strategy showed that the solar fraction can be increased by about 11% by the temperature control strategy. Shirazi et al. [8] concluded that the longer solar operating time of the chiller (which results from the higher collector temperature) is more important for achieving a high solar fraction than the reduced collector efficiency due to a higher collector temperature.

Comparably, Qu et al. [9] investigated a constant flow rate versus constant outlet temperature control by transient simulations of an SAC system with parabolic trough collectors and a double-effect H$_2$O/LiBr absorption chiller. They also indicated that the constant temperature control reduces the preheating time in the morning by approximately one hour and extends the operating time of the chiller driven by solar energy by approximately half an hour in the afternoon.

To make low collector temperatures applicable, Clauß et al. [10] described a control strategy similar to the one mentioned in [11] but without the constraint of an overflowing evaporator. Clauß et al. [10] used a control strategy based on the characteristic equation method that determines the required cooling water temperature for a predetermined driving temperature (e.g., from the solar collector field) in order to match a certain cooling load and to maintain the chilled water set value. In addition, using the cooling water temperature as the manipulated variable offers the possibility to save electric power and also water—if a wet cooling tower is used—provided the available driving temperature from the collector is higher than necessary to cover the load. In this case, a higher cooling water temperature can be used, which reduces the electricity demand of the reject heat device.

Unfortunately, the characteristic equation applied by Clauß et al. [10] is valid only for the 10-kW absorption chiller under investigation (i.e., type suninverse). Furthermore, the external supply flow rates in hot, cooling, and chilled water circuit must agree with the nominal flow rates, because otherwise the slope and loss parameter in the characteristic equation would change. Moreover, Clauß et al. [10] did not report on the reverse applicability of the characteristic equation method, i.e., calculating a necessary driving temperature from a given cooling water temperature in order to keep the preheating time short.

In this contribution, a model predictive control algorithm is developed, which allows an increase of the solar operating hours of an SAC system by calculating the minimum possible driving temperature under the constraint of a maximum allowed auxiliary electricity demand to ensure a short preheating
time. This new strategy utilizes an improved and more precise method of characteristic equations [12]. The computer code of the method is available in [13]. The same characteristic equation method is used to control the absorption chiller itself, irrespective of whether it is operated in a solar or conventional cooling system [14]. Since the chiller control is based on characteristic equations, it is called a CE controller. Nevertheless, the focus of this contribution is not on the absorption chiller control (which is done by the CE controller and is described, e.g., in [14,15]), but on the control of the switchover between solar and backup heat operation of the chiller in a solar cooling system. Hence, following a short description of the SAC system at the Federal Environment Agency in Dessau, Germany (which was used to test the switchover strategy), the improved characteristic equation method is explained only briefly. Afterwards, the model predictive control algorithm for the switchover strategy is derived. It combines the absorption chiller model with a simple dry-cooler model. Finally, the measured results of the strategy are shown and discussed.

2. Materials and Methods

2.1. Solar Assisted Cooling System

In Figure 1, a simplified process and instrumentation diagram of the SAC system at the Federal Environment Agency (UBA) in Dessau, Germany with five heating circuits and four cooling circuits, each combined into one symbol, is depicted. The cold demand is dominated by the cooling circuit of the IT center with an average cooling load of approximately 20–25 kW around the clock. During summertime, the absorption chiller is powered either by district heat from a central CHP plant or by solar heat from a field of vacuum heat pipe collectors (216 m² absorber area, 3 × 7.5 m³ storage volume). The idea of the relatively large storage volume and collector field with respect to the cooling load is to accumulate solar heat during daytime in order to cover the cooling load by solar heat operation of the absorption chiller during nighttime as well. The design values of the absorption chiller are provided in Table 1.

![Figure 1. Simplified process and instrumentation diagram of the SAC system at the Federal Environmental Agency (UBA) in Dessau, Germany. Only the temperature probes and flow meters that are used in the result section are labelled.](image-url)
Table 1. Design values of the absorption chiller type FM050V0.3 at the Federal Environment Agency (UBA) in Dessau, Germany.

| Variable | Description                  | Unit     | FM050V0.3 |
|----------|------------------------------|----------|-----------|
| $t_{Di}$ | Hot water inlet temperature  | °C       | 75        |
| $V_D$    | Hot water volume flow rate   | m³/h     | 6.0       |
| $Q_D$    | Driving heat flow            | kW       | 44        |
| $t_{Ai}$ | Cooling water inlet temperature | °C   | 28        |
| $V_H$    | Cooling water volume flow rate | m³/h | 18.0      |
| $Q_H$    | Reject heat flow             | kW       | 78        |
| $t_{Eo}$ | Chilled water outlet temperature | °C    | 9         |
| $V_E$    | Chilled water volume flow rate | m³/h | 5.9       |
| $Q_E$    | Cooling capacity             | kW       | 34        |
| COP      | Coefficient of performance   | -        | 0.77      |

A compression-type chiller is used for the peak load and as redundancy for the IT center. During wintertime, solar heat is used for space heating and the reject heat device (RHD) is used directly for the cold supply. In this case, neither the compression-type chiller nor the absorption chiller is running. Nominal values of the reject heat device in dry-cooler mode are provided in Table 2. A more detailed description of the seasonal solar cooling concept can be found in [16].

Table 2. Nominal values of the reject heat device in dry-cooler mode at the Federal Environment Agency (UBA) in Dessau, Germany.

| Variable | Description                  | Unit     | Dry-Cooler |
|----------|------------------------------|----------|------------|
| $t_{K_1,0}$ | Fluid inlet temperature    | °C       | 32         |
| $t_{K_0,0}$ | Fluid outlet temperature    | °C       | 29         |
| $V_{K,0}$   | Fluid volume flow rate      | m³/h     | 45.5       |
| $x$        | Mass fraction ethylene-glycol | kg/kg  | 0          |
| $t_{L_1,0}$ | Air inlet temperature       | °C       | 21         |
| $V_{L,0}$   | Air volume flow rate        | m³/h     | 45,940     |
| $Q_{L,0}$   | Reject heat flow            | kW       | 158        |
| $P_{el,DC,0}$ | Electrical power         | kW_{el}  | 13.7       |

2.2. Operating Period with High Solar Fraction

During summertime, two operating modes are possible for the absorption chiller:

- Solar heat operation (SHO); and
- Backup heat operation (BHO).

Independent of BHO or SHO, the thermally driven absorption chiller (TDC) is controlled by a model predictive controller based on an improved method of characteristic equations (the so-called CE controller). The CE controller calculates simultaneously the set values in hot and cooling water (i.e., $t_{Di}^{set}$ and $t_{Ai}^{set}$), which are necessary to cover the cooling load $Q_E^{set} = V_E \cdot p_{E,CP,E} \cdot (t_{Ei} - t_{Eo}^{set})$. The CE controller is explained in more detail in [15] and in the next section.

In summer 2017, several tests were executed in order to extend the duration of SHO and thereby increase the solar fraction and primary energy saving of the SAC system. One of these test periods is depicted in Figure 2, where the cut-in condition for SHO was left unchanged but the cut-off condition was blocked manually in order to maximize the solar fraction.
SHO started on the first day when \( t_{Ho} > t_{set}^{Di} \) and the difference \( \Delta t_{SHO}^{on} = t_{set}^{Di} - t_{PS11} \) was smaller than 3 K for at least 5 min, which was true at approximately 10:30 (cf. Figure 1 for the sensor position and Figure 3 for their chronological progression). At first glance, this condition looks strange because the storage temperature was lower than the necessary driving temperature \( t_{min}^{Di} = t_{set}^{Di} \) to cover the cooling load (i.e., the storage was still not hot enough). However, the temperature \( t_{PS0} \approx t_{Di} \) available for the chiller is a mixture of \( t_{Ho} \) and \( t_{PS11} \) (cf. Figure 1). Hence, the existing cut-in condition for SHO mentioned above (i.e., without the switchover strategy explained later on) is a compromise of \( t_{Ho} > t_{set}^{Di} \), which was true at 10:00 a.m., and \( t_{PS11} > t_{set}^{Di} \), which was true at 11:50 a.m. When the cut-in condition became true, the flap near the solar heat storages was opened by the control signal \( C_{PS} \) and the flaps near to the district heating heat exchanger \( C_{DH} \) were closed. Afterwards, the discharge pump P35 was switched on and the measured discharge flow rate \( V_{PS} > 0 \) was used to supply the absorption chiller with solar heat. The other curves in Figure 3 will be explained later.
The examined solar heat operation period was ongoing over more than three days (cf. \( V_{PS} \) in Figure 2b). Despite the volatile solar irradiation and the resulting volatile driving temperature \( t_{Di} \) for the chiller, it was possible to control the evaporator outlet temperature \( t_{Ho} \) with a deviation to the set value \( t_{Ho}^{\text{set}} \) of less than \( \pm 0.5 \) K (cf. Figure 2c) by means of the CE controller.

Although the flow rates of the absorption chiller were not automatically controlled, they were not constant (cf. Figure 2b). The variation of \( V_{Di} \) is an unwanted effect of hydraulic interdependencies between the discharge pump, heating circuits, and absorption chiller. Therefore, flow rates higher than the design value occurred. In contrast, the cooling water flow rate \( V_{Ho} \) was adjusted manually (on the third day in order to avoid the humidifier activation, which was not successful, and afterwards to cover the load and keep the solar heat operation ongoing).

During normal operation (i.e., outside the test period for the high solar fraction), SHO is stopped when \( t_{Ho} < t_{Di}^{\text{set}} \) and the difference \( \Delta t_{SHO}^{\text{eff}} = t_{Di}^{\text{set}} - t_{PS11} < 0 \) K becomes true. Since this cut-off condition was deactivated during the test period, the desorber inlet temperature \( t_{Di} \) varied between approximately 85 and 50 °C and the cooling water inlet temperature to the absorber \( t_{Ai} \) between 36 and 18 °C, respectively. To achieve these low cooling water temperatures in the reject heat device, the technical possibility to pre-cool the incoming ambient air by spraying water into the air flow (adiabatic evaporative pre-cooling) was allowed, although this operation mode is normally blocked due to high operating costs and hygienic aspects. By means of two short operating periods of the humidifier on the third day (cf. control signal \( C_{Hu} \) of the humidifier in Figure 2a), a termination of SHO could be avoided.

However, independent of the adiabatic pre-cooling possibility, high air flow rates in the reject heat device were necessary when the storage temperatures were still low (e.g., in the morning) and/or ambient air temperature was high (cf. control signal \( C_{DC} \) for the ventilators in Figure 2a). Thus, the specific electricity demand \( w \) of the solar thermally driven absorption chiller cooling assembly (ACCA) including the electricity demand of the thermally driven chiller (TDC), the supply pumps (Pu) and reject heat device (RHD):

\[
w_{\text{ACCA}} = \frac{P_{\text{el,ACCA}}}{Q_E} = \frac{P_{\text{el,TDC}} + P_{\text{el,Pu}} + P_{\text{el,RHD}} + P_{\text{aux,el,RHD}}}{Q_E} \tag{1}
\]

became higher than the specific electricity demand \( w_{\text{CCCA}} \) of an electrically driven compression chiller cooling assembly (CCCA) also including the chiller itself, supply pumps, and the reject heat device. In this case, no primary energy saving was possible anymore and the solar heat operation should have been stopped. In Figure 2d, the instantaneous measured values of \( w_{\text{ACCA}} \) during the test period are compared to an averaged measured value \( w_{\text{CCCA}} \) of the air-cooled compression-type chiller (which was not in operation during the test period). During the first two nights, the continuous solar heat operation with low driving temperatures and consequently low cooling water temperatures led to...
values of $w_{ACCA}$ that are lower than $w_{CCCA}$. Due to an increasing ambient air temperature, this does not apply for the whole third day. Consequently, to avoid values $w_{ACCA} > w_{CCCA}$, an improved cut-off condition for SHO must take the specific electricity demand of the conventional or reference cooling assembly into account (in addition to the available solar driving temperature in the storage $t_{PS1}$ and the minimum driving temperature $t_{Di}^{\text{min}} = t_{Di}^{\text{set}}$, which is necessary to cover the load under given weather conditions).

The ongoing of SHO on the fourth day, with low solar irradiation but relatively high ambient air temperature, was used to define the boundary. During the whole day, the storage temperature did not increase above 50 °C. Therefore, a tremendous effort of electricity and water was necessary to reach cooling water temperatures lower than 20 °C in order to cover the load. However, for all this, the possible cooling capacity was lower than the demand. Thus, in the evening, the evaporator outlet temperature did not match the set value anymore (cf. Figure 2c). At midnight of the fifth day, the solar heat operation (SHO) was stopped manually and the chiller was operated by district heating (BHO).

### 2.3. CE Method and CE Controller

The control strategy described in Section 3.2 to start the solar heat operation (SHO) of an SAC system as early as possible and to operate it in SHO mode as long as possible under the constraint of a maximum electricity demand $w_{ACCA} < w_{CCCA}$ necessitates a calculation procedure for the part load behavior of an absorption chiller. For this purpose, the characteristic equation method was applied.

In contrast to the characteristic equation method used by Clauß et al. [10], the method in this contribution is general for H₂O/LiBr single-effect chillers [12]. By means of a revised heat transfer calculation in the absorber and desorber as compared to the established method (cf. [17]), the variation of thermodynamic losses under part load conditions can be accounted for in an explicit calculation procedure. According to the improved method, the cooling capacity $Q_E$ of an absorption chiller is a linear function of a characteristic temperature difference $\Delta \Delta t_{1}^{*}$:

$$\Delta \Delta t_{1}^{*} = t_{Di} - (1 - K_1) - t_{Ai} - (1 - K_2) + t_{Ei} - (1 - K_3),$$

$$Q_E = K_4 \cdot \Delta \Delta t_{1}^{*},$$

$$Q_D = K_5 \cdot \Delta \Delta t_{1}^{*} + K_6 \cdot \Delta \Delta t_{\text{min},i}^{*},$$

$$\Delta \Delta t_{\text{min},i}^{*} = K_1 \cdot t_{Di} - K_2 \cdot t_{Ai} + t_{Ei} - (K_3 - 1).$$

The characteristic temperature difference $\Delta \Delta t_{1}^{*}$ combines the inlet temperatures $t_{Xi}$ (where $X = D, E, C, A$ holds for the main heat exchangers, desorber, evaporator, condenser, and absorber). The coefficients $K_1$ to $K_3$ in Equation (2) account for the phase equilibrium data of the respective working pair (i.e., H₂O/LiBr) in combination with the external and internal heat capacity flow rates $W_X$ and heat transfer capabilities $Y_X = U_X \cdot A_X$. Hence, the characteristic temperature difference $\Delta \Delta t_{1}^{*}$ also includes all the information of the load-dependent and load-independent losses. The capacity of the chiller (i.e., its ‘thermal size’) is described by slope parameters $K_4$ and $K_5$, respectively. Finally, the coefficient $K_6$ scales the minimum driving heat $Q_{D,\text{min}} = K_6 \cdot \Delta \Delta t_{\text{min},i}^{*}$, which results mainly from the limited internal heat recovery in the solution heat exchanger. The minimum driving heat $Q_{D,\text{min}}$ is also not constant. It can be calculated with a second characteristic temperature difference $\Delta \Delta t_{\text{min},i}^{*}$, which is also a function of the independent external inlet temperatures $t_{Xi}$ and coefficients $K_1$ to $K_3$ [12]. The determining equations for all coefficients $K_N$ with $N = 1 \ldots 6$ can be found in [13] or [18]. For the absorption chiller at UBA, the values are depicted in Table 3 at the design conditions specified in Table 1.
Table 3. Characteristic coefficients of the absorption chiller at the Federal Environment Agency (UBA) in Dessau, Germany.

| Effective Coefficients (Dimensionless) | Slope Parameters (in kW/K) | Conversion Factor |
|---------------------------------------|-----------------------------|-------------------|
| $K_1$                                 | $-1.02$                     | $-0.09$           | $1.20$                           | $1.45$ | $0.15$ | $1.23$ |

Moreover, for control purposes, the external evaporator outlet temperature $t_{Eo}$ is of interest rather than $t_{Ei}$. Instead of $\Delta t^*$, a modified characteristic temperature difference $\Delta t_{\text{min}}^*$ can be derived analytically, which combines the hot and cooling water inlet temperature and chilled water outlet temperature:

$$\Delta t_{\text{min}}^* = (t_{Di} - t_{Ai}) - \Delta t^*.$$  (6)

Since the same coefficients $K_1$ to $K_3$ (with their respective physical meaning) are applied, a well-defined conversion factor $K_{Eo} = \left(1 - (K_1 - K_2) \cdot K_4 / W_E\right)^{-1}$ is available to transform Equations (3) and (4) into Equations (7) and (8) for use with $\Delta t_{\text{min}}^*$ instead of $\Delta t^*$.

$$Q_E = K_4' \cdot \Delta t_*',$$  (7)

$$Q_D = K_5' \cdot \Delta t_* + K_6' \cdot \Delta t_{\text{min}}^*.$$  (8)

In addition, for serial cooling water flow from the absorber to the condenser, the two characteristic temperature differences $\Delta t^*$ and $\Delta t_{\text{min}}^*$ are linked by the external thrust $t_{Di} - t_{Ai}$ [12]:

$$\Delta t_{\text{min}}^* = (t_{Di} - t_{Ai}) - \Delta t^*.$$  (9)

Thus, with $K_5'' = K_{Eo}'(K_5 - K_6)$, the characteristic equation for the driving heat can be rewritten as:

$$Q_D = K_5'' \cdot \Delta t_* + K_6' \cdot t_{Di}.$$  (10)

A comparison of the measured and calculated values for the cooling capacity (i.e., $Q_E$ and $Q_E^C$) and driving heat (i.e., $Q_D$ and $Q_D^C$) is depicted in Figure 4a for the operating period discussed in Section 2.2. The same values are plotted as a function of $\Delta t^*$ in Figure 4b. Due to the variations in the hot and cooling water flow rate (cf. $V_D$ and $V_H$ in Figure 2b), the slope parameters $K_4'$ and $K_5''$ are not constant. Thus, neither the calculated values nor the measured values of the cooling capacity are displayed as a straight line. For the driving heat, a straight line was not to be expected at all (even at constant flow rates), because the temperature thrust $t_{Di} - t_{AI}$ will cause a scatter around the straight line given by $K_5''$ and $\Delta t^*$. An additional reason for the differences and scatter results from the dynamic operating conditions of the measurements in contrast to the calculated values, which assume steady state conditions by definition in the method. Nevertheless, the agreement of the measured and calculated values seems to be satisfying.
which can be rewritten by expanding the fraction with \( V_{L,0} \) as:

\[
P_{el,DC} = \frac{\Delta P_{L,0} V_{L,0}}{\eta_{DC,tot} (V_{L,0})^2 V_{L,0}} \left( V_{L} \right)^3 + P_{aux_{el,DC}} = P_{el,DC,0} (C_{DC})^3 + P_{aux_{el,DC}}.
\]

where \( C_{DC} = V_L / V_{L,0} \) is the normalised flow rate or the control signal of the dry cooler, respectively, and \( P_{el,DC,0} \) is the electrical power under nominal conditions.

3. Results—Model Predictive Control

The model predictive control strategy for an extended solar heat operation of the SAC system combines the absorption chiller model (i.e., the improved characteristic equation method) with a part load model for the reject heat device. Since the combination of absorption chillers with dry coolers has become increasingly more common and the humidifier at the Federal Environment Agency in Dessau is normally blocked, a dry-cooler model is sufficient. After the description of the dry-cooler model, the control strategy is derived.

3.1. Dry-Cooler Model

In Figure 5, the nomenclature for the dry-cooler model is depicted. A control signal \( C_{DC} \) is used to adjust the air flow rate \( V_L \) by changing the rotational speed of the ventilators or their motors, respectively. The necessary electrical power of the dry-cooler \( P_{el,DC} \) for a certain air flow rate \( V_L \) is proportional to the pressure drop and total efficiency \( \eta_{DC,tot} \), including all mechanical and electrical losses of the motor-ventilator assembly. In addition, a constant auxiliary power consumption \( P_{aux} \) can be considered (e.g., for a control unit). Assuming a quadratic development of the air-side pressure drop \( \Delta P_L \) with respect to the pressure drop under nominal conditions (i.e., \( \Delta P_{L,0} (V_L / V_{L,0})^2 \)), this leads to:

\[
P_{el,DC} = \frac{\Delta P_{L} V_{L}}{\eta_{DC,tot}} + P_{aux_{el,DC}} = \frac{\Delta P_{L,0}}{\eta_{DC,tot} (V_{L,0})^2} \left( V_{L} \right)^3 + P_{aux_{el,DC}} = f_{fric} \left( V_{L} \right)^3 + P_{aux_{el,DC}}.
\]

Figure 4. Comparison of the measured and calculated values for the absorption chiller and dry-cooler model as a function of time (a) and for the absorption chiller as a function of the inlet characteristic temperature difference (b).
The unknown air flow rate $V_L$, which causes the electrical power, $P_{el,DC}$ for a certain load condition, results from the reject heat flow of the absorption chiller from the absorber and condenser, $Q_L = Q_A + Q_C$. It is equivalent to the negative sum of the evaporator and desorber heat flow:

$$Q_L = (Q_A + Q_C) = -(Q_E + Q_D) = V_L \cdot \rho_L \cdot c_{p,L} \cdot (t_{ki} - t_{lo}). \quad (13)$$

To determine $V_L$ (and thereby $P_{el,DC}$), the required air outlet temperature $t_{lo}$ in Equation (13) can be calculated from the dimensionless temperature glide, $P_L$ of the air stream, assuming a counter flow heat exchanger (i.e., neglecting all cross-counter flow effects):

$$P_L = \frac{t_{lo} - t_{li}}{t_{ki} - t_{li}} = \frac{1 - \exp((R_L - 1) \cdot NTU_L)}{1 - R_L \cdot \exp((R_L - 1) \cdot NTU_L)}. \quad (14)$$

The required cooling water inlet temperature of the dry-cooler $t_{ki}$ on the left-hand side of Equation (14) is equal to the condenser outlet temperature, $t_{co}$ of the absorption chiller. It follows from the inlet temperature $t_{ai}$ plus the temperature increase in the cooling water flow of the absorption chiller due to the total reject heat flow $Q_E + Q_D = -(Q_A + Q_C)$. Since the cooling water valve is used only for safety reasons, it is normally fully open. Consequently, for serial cooling water flow, the flow rates in the absorber and condenser and in the dry-cooler are the same, i.e., $W_A = W_C = W_K = V_K \cdot \rho_K \cdot c_{p,K}$:

$$t_{ki} = t_{co} = t_{ai} + \frac{Q_E + Q_D}{W_A}. \quad (15)$$

Combining Equations (14) and (15) results in:

$$t_{lo} = P_L \cdot (t_{co} - t_{li}) + t_{li} = P_L \left( t_{ai} + \frac{Q_E + Q_D}{W_A} - t_{li} \right) + t_{li}. \quad (16)$$

and subsequently inserting Equation (16) into Equation (13) with the ambient air temperature as the air inlet temperature $t_{li} = t_{amb}$ leads to:

$$V_L = \frac{W_A}{\rho_L \cdot c_{p,L} \cdot P_L \cdot (Q_E + Q_D + W_A \cdot (t_{ai} - t_{amb})}. \quad (17)$$

However, Equation (17) determines $V_L$ only implicitly, because $P_L$ is a function of $V_L$ since the dimensionless heat transfer capability $NTU_L$ and heat capacity flow rate ratio $R_L$ in Equation (14) depend on $V_L$:

$$NTU_L = \frac{V_L}{W_L} = \frac{U_L \cdot A_L}{\rho_L \cdot c_{p,L} \cdot V_L} \quad R_L = \frac{W_L}{W_A} = \frac{\rho_L \cdot c_{p,L} \cdot V_L}{W_A}. \quad (18)$$
In order to solve Equation (17) explicitly for $V_L$, an approximation $P'_L$ for the dimensionless temperature glide, $P_L$, is used from [12], appendix O:

$$P_L \approx P'_L = \left(1 + \frac{W_L}{W_{L,0}} \left(\frac{1}{P_{L,0}} - 1\right)\right)^{-1}. \quad (19)$$

In this equation, $W_{L,0} = \rho_L c_{p,\text{L}} V_{L,0}$ holds for the air side capacity flow rate at the nominal condition (Index 0) and $P_{L,0}$ is calculated with $W_{L,0}$ (i.e., also at the nominal condition). Thus, at the normalized flow velocity $C_{\text{DC}} = W_L / W_{L,0} = 1$, the approximation $P'_L$ equals $P_{L,0}$ (i.e., the exact value). For $C_{\text{DC}} = 0$, Equation (19) converges to the same limit value $P'_L = 1$ as $P_L$ in Equation (14). Between $C_{\text{DC}} = 0$ and $C_{\text{DC}} = 1$, the exponential dependency is considered by a reciprocal approach.

Inserting approximation Equation (19) into Equation (17) leads to an approximated but explicit equation for the air volume flow rate $V'_L \approx V_L$ or the normalized flow velocity $C'_{\text{DC}} = V'_L / V_{L,0}$ when constant property data can be assumed:

$$C'_{\text{DC}} = \frac{(Q_E + Q_D) P_{L,0}}{b_{L,0}(Q_E + Q_D) + a_{L,0}(t_{\text{Ai}} - t_{\text{amb}})}. \quad (20)$$

With $P_{L,0}$ determined, e.g., from manufacturers’ data under nominal conditions or from measurements at a single reference point, and the coefficients:

$$a_{L,0} = V_{L,0} P_{L,0} \rho_L c_{p,\text{L}}, \quad (21)$$

$$b_{L,0} = a_{L,0} / W_A + P_{L,0} - 1 \quad (22)$$

the approximated electrical power $P'_{\text{el,DC}} \approx P_{\text{el,DC}}$ under the part load condition can be calculated:

$$P'_{\text{el,DC}} = P_{\text{el,DC,0}} \left(C'_{\text{DC}}\right)^3 + P_{\text{el,DC,aux}}. \quad (23)$$

A comparison between the measured and approximated values for the electrical power (i.e., $P_{\text{el,DC}}$ and $P'_{\text{el,DC}}$) is depicted in Figure 4a for the operating period discussed in Section 2.2. without the humidification of ambient air.

### 3.2. Switchover Control Strategy

The aim of the following control strategy is to find a cut-in and a cut-off condition for the solar heat operation (SHO) of an absorption chiller cooling assembly (ACCA) under the constraint that the specific electricity demand during SHO is lower than the electricity demand of a reference cooling technology (e.g., a compression chiller cooling assembly, CCCA).

The specific electricity demand of the ACCA is dominated by the electricity demand of the dry cooler. Thus, a simplified cut-in condition for SHO is to allow a maximum control signal $C_{\text{on,SHO}}$ which results in an approximated specific electricity demand $w_{\text{ACCA}}$ lower or equal than the specific electricity demand of the compression chiller cooling assembly, i.e.:

$$w_{\text{ACCA}} \approx \frac{P_{\text{el,DC,0}} \left(C_{\text{on,SHO}}\right)^3 + P_{\text{el,DC,aux}}}{Q_E^{\text{net}}} \leq w_{\text{CCCA}}. \quad (24)$$
Solving for the maximum allowed $c_{\text{DC}}^{\text{on,SHO}}$ leads to the boundary value:

$$c_{\text{DC}}^{\text{on,SHO}} = \frac{w_{\text{CCA}} \cdot Q_E^{\text{set}} - P_{\text{el,DC,aux}}}{P_{\text{el,DC,0}}}. \tag{25}$$

This depends on the reference cooling technology ($w_{\text{CCA}}$), load condition ($Q_E^{\text{set}}$), and electrical values of the reject heat technology of the SAC system ($P_{\text{el,DC,0}}, P_{\text{el,DC,aux}}$). In addition, the control signal of the air flow rate $C_{\text{DC}} = C_{\text{DC}}^{\text{on,SHO}}$ for the same cooling load $Q_E = Q_E^{\text{set}}$ and the necessary driving heat flow according to the characteristic Equation (8) is determined by Equation (20), hence:

$$C_{\text{DC}}^{\text{on,SHO}} = \frac{Q_E^{\text{set}} + K_E \cdot (K_5 - K_6) \cdot \Delta \Delta t' + K_6 \cdot (t_{\text{DI}} - t_{\text{AI}})}{b_{L,0} \cdot (Q_E^{\text{set}} + K_E \cdot (K_5 - K_6) \cdot \Delta \Delta t' + K_6 \cdot (t_{\text{DI}} - t_{\text{AI}}) + a_{L,0} \cdot (t_{\text{AI}} - t_{\text{amb}})} \cdot P_{L,0}. \tag{26}$$

In this equation, only the supply temperatures $t_{\text{DI}}$ and $t_{\text{AI}}$ are unknown, because $C_{\text{DC}}^{\text{on,SHO}}$ is fixed by the load and technology parameters according to Equation (25). On the right-hand side, $t_{\text{EO}} = t_{\text{EO}}^{\text{set}}$ in $\Delta \Delta t'$ and $t_{\text{amb}}$ are fixed by the load and weather condition and the coefficients $a_{L,0}, b_{L,0},$ and $K_N$ describe the thermal part load behaviour of the dry-cooler and absorption chiller.

The cooling water inlet temperature $t_{\text{AI}}$ in Equation (26) can be eliminated by the rearranged characteristic Equation (7) in combination with the characteristic temperature in Equation (6), i.e.:

$$t_{\text{AI}} = \frac{1}{1 - K_2} \left( (1 - K_1) \cdot t_{\text{DI}} + (1 - K_3) \cdot t_{\text{EO}} - Q_E^{\text{set}} \right) / K_4. \tag{27}$$

After inserting Equation (27) into Equation (26), it can be solved for the driving temperature $t_{\text{DI}} = t_{\text{DI}}^{\text{on,SHO}}$, which is necessary for a cooling load $Q_E^{\text{set}}$ at a chilled water temperature of $t_{\text{EO}}^{\text{set}}$ and a maximum allowed control signal for the dry cooler $C_{\text{DC}}^{\text{on,SHO}}$ in order to keep the specific electricity demand $w_{\text{ACCA}}$ below $w_{\text{max}} = w_{\text{CCA}}$ when the absorption chiller is operated with solar heat:

$$t_{\text{DI}}^{\text{on,SHO}} = \frac{1}{K_{\text{SHO}}^a} \left( (K_{\text{SHO}}^b - (K_{\text{SHO}}^c + K_{\text{SHO}}^d) \cdot Q_E^{\text{set}} / K_4 - K_{\text{SHO}}^c \cdot (1 - K_3) \cdot t_{\text{EO}}^{\text{set}} + (C_{\text{DC}}^{\text{on,SHO}} \cdot a_{L,0}) \cdot t_{\text{amb}} \right), \tag{28}$$

where:

$$K_{\text{SHO}}^a = C_{\text{DC}}^{\text{on,SHO}} \cdot b_{L,0} - P_{L,0}, \tag{29}$$

$$K_{\text{SHO}}^b = C_{\text{DC}}^{\text{on,SHO}} \cdot a_{L,0} - K_6 \cdot K_{\text{SHO}}^a. \tag{30}$$

$$K_{\text{SHO}}^c = (1 - K_1) / (1 - K_2) \cdot (C_{\text{DC}}^{\text{on,SHO}} \cdot a_{L,0} - K_6 \cdot K_{\text{SHO}}^a + K_6 \cdot K_{\text{SHO}}^c). \tag{31}$$

Finally, the operating limits of the absorption chiller have to be considered. For example, to avoid crystallization of the H$_2$O/LiBr solution, a minimum cooling water temperature $t_{\text{AI}}^{\text{min}}$ is allowed. Hence, from the rearranged characteristic Equation (7) follows a minimum driving temperature for the load case $Q_E = Q_E^{\text{set}}$, $t_{\text{EO}} = t_{\text{EO}}^{\text{set}}$:

$$t_{\text{DI}}^{\text{min,SHO}} = \frac{1}{1 - K_2} \left( (1 - K_2) \cdot t_{\text{AI}}^{\text{min}} - (1 - K_3) \cdot t_{\text{EO}}^{\text{set}} + Q_E^{\text{set}} / K_4 \right). \tag{32}$$

Consequently, the necessary driving temperature to start the solar heat operation is the maximum of the aforementioned temperatures:

$$t_{\text{DI}}^{\text{on,SHO}} = \max \left( t_{\text{DI}}^{\text{min,SHO}}, t_{\text{DI}}^{\text{on,SHO}} \right). \tag{33}$$
The cut-in condition for solar heat operation (i.e., SHO\textsuperscript{on}) becomes true when the highest storage temperature \( t_{PS11} \) and the outlet temperature of the solar heat exchanger \( t_{ho} \) are both higher than the necessary cut-in temperature for solar operation \( t_{on,SHO} \):

\[
\text{SHO}^\text{on} = (t_{PS11} > t_{on,SHO} \text{ and } t_{ho} > t_{on,SHO}).
\]

The cut-off condition for SHO consists of three aspects: Solar heat operation should be stopped when the highest temperature in the solar heat storage \( t_{PS11} \) has decreased below the necessary driving temperature \( t_{on,DC} \) to cover the load or the necessary driving temperature \( t_{on,SHO} \) for SHO, and simultaneously, the electricity demand becomes too high or the load cannot be matched anymore. Thus, the cut-off condition reads:

\[
\text{SHO}^\text{off} = \left( \max\left( t_{on,DC} - t_{PS11}, \Delta t_2 \right) > t_{on,SHO} \right) \text{ and } \left( C_{DC} > C_{DC}^{SHO} \text{ or } t_{en} - t_{on} > \Delta t_0 \right).
\]

Typical values for the thresholds \( \Delta t_2 \) and \( \Delta t_0 \) are 2 and 0.2 K, respectively.

4. Discussion

The model predictive switchover strategy for extended solar heat operation (SHO) with improved cut-in and cut-off conditions has been implemented into the industrial programmable logic controller (PLC) of the single-stage H\textsubscript{2}O/LiBr-absorption chiller of type FM050v0.3 operated at the Federal Environment Agency (UBA) since 2011. Nowadays, this chiller is marketed as type “Bee” [19]. Via a Profi-Bus-connection, the information for the control signals of the flaps \( C_{DH} \) and \( SHO \) are both higher than the

\[
\Delta t_0 \text{ff,SHO} \text{ or } t_{en} - t_{on} > \Delta t_0 \text{ff,SHO}.
\]

Typical values for the thresholds \( \Delta t_2 \) and \( \Delta t_0 \) are 2 and 0.2 K, respectively.

during the delay period, the timer would have been reset to zero and restarted when \( \text{SHO}^{\text{on}} = 1 \) had become true again. Thereby, a cut-in delay was realized.

**Figure 6.** Solar heat operation over 21 h with the improved control strategy: (a) global horizontal irradiation, \( q_{gh} \), temperatures in hot water circuit and control signals from RHD; (b) flow rates and cooling capacity; (c) ambient air temperature and temperatures in the chilled and cooling water circuit; (d) specific electricity demand.

**Figure 7.** Start-up of solar heat operation with the improved control strategy.
Due to the lower driving temperature $t_{Di} \approx 67^\circ \text{C}$ (which is a mixed temperature of $t_{Ho} \approx 70^\circ \text{C}$ from the solar heat exchanger and $t_{PS11} \approx 65^\circ \text{C}$ from the storage), the set value for the cooling water $t_{ Ai}^{set}$ was decreased by the CE controller for a while in order to match the cooling load and chilled water set value, $t_{Eo} \approx t_{ Ai}^{set}$. Therefore, the controller of the dry-cooler increased the control signal $C_{DC}$ to adjust $t_{Ho}$ to $t_{ Ai}^{set}$ (cf. Figure 6a). Shortly after 11 a.m., $C_{DC}$ also increased above the cut-off value $C_{DC}^{min,SHO} = 0.5$ and the cut-off condition $SHO^{off}$ according to Equation (35) became true. Thus, for a definite result, $SHO^{on}$ and $SHO^{off}$ have to be used as set and reset inputs in a bistable function block.

With the rising ambient air temperature until 04:00 p.m., the necessary driving temperature $t_{on,SHO} = t_{Di}^{on,SHO}$ also increases according to Equation (28). Since the available temperature from the solar collector and storage is high enough, SHO is ongoing. At nighttime, the available storage temperature $t_{PS11}$ falls below $t_{on,SHO}$. Nevertheless, the second part of the cut-off condition in Equation (35) is not true. Due to the low ambient air temperature, a low cooling water temperature is also available to counterbalance the low driving temperature. Thereby, the chilled water set value is still matched without an increase of the specific electricity demand $w_{ACCA}$ (cf. Figure 6d). From approximately 06:30 a.m. of the second day on, the cooling water temperature $t_{Ai}$ is limited by the boundary value $t_{min}^{AI} = 19^\circ \text{C}$ (cf. Figure 8). With a continuously decreasing driving temperature $t_{Di} \approx t_{PS11}$ below $50^\circ \text{C}$, the evaporator outlet temperature $t_{Eo}$ starts to increase and the cooling load is not matched anymore. Consequently, SHO has to be stopped approximately at 07:30 a.m.

The rapid increase of $t_{on,SHO} = t_{Di}^{on,SHO}$ at approximately 7:45 a.m. is an effect of a switching action in one of the heating circuits, which causes a much lower hot water flow rate $V_D$ for some minutes. For flow rates close to zero, the slope coefficients $K_1$ and $K_2^*$ (i.e., the possible capacity of the chiller or its 'thermal size') become very small and consequently the necessary driving temperature $t_{on,SHO}^{high}$ high. Unfortunately, this interference happened in parallel or at the end of the cut-off delay for SHO. Nevertheless, it did not switch off the solar heat operation (although it looks like it) and did not have any effect on the end of SHO at all. The cut-off condition (cf. Equation (35) or $SHO^{off}$ in Figure 8) was true since 07:10 a.m. With the cut-off delay time of 20 min, SHO was stopped at 07:30 a.m. A very few minutes later (i.e., after communication between PLC and the building management system), the discharge pump P35 was switched off and the flow rate $V_{PS}$ reached zero. Now, SHO also stopped hydraulically. Incidentally, at the same moment, $V_D$ increased after the short interruption.

The potential of the improved control strategy was illustrated by a theoretical application during the test period in 2017 (cf. Figure 2), when the cooling load was low during the preheating time in the morning of the first day (cf. Figure 3). Under these operating conditions, the cut-in condition $SHO^{on}$ would have become true before 10:00 a.m. and a necessary solar driving temperature below $65^\circ \text{C}$ at the outlet of the solar heat exchanger $t_{Ho}$ would have been sufficient to start SHO.
5. Conclusions

For solar cooling systems with an absorption chiller cooling assembly (i.e., including all the supply pumps and the heat rejection device), the possible operating time with solar heat is a key parameter to achieve high solar fractions and thereby high primary energy savings. Hence, for SAC systems, the solar heat operation (SHO) of the absorption chiller should be started as early as possible and should be continued as long as possible in order to reduce the backup heating demand, thereby reducing the main source of the primary energy demand. On the other hand, when the SHO mode is activated too early and/or stopped too late, the available driving temperature from solar collector is low. Consequently, a lower cooling water temperature is necessary to cover the cooling load. It depends on the part load behavior of the chiller and can be calculated by the characteristic equation method. The lower cooling water temperature causes a higher electricity demand in the reject heat device. These theoretical interdependencies were exemplified during a test period with continuous solar heat operation over more than three days at the SAC system of the Federal Environment Agency in Dessau, Germany. It was shown that the resulting electricity demand during solar heat operation might exceed the demand of the reference technology (e.g., a compression chiller cooling assembly) and no primary energy savings are possible anymore.

In order to extend the solar heat operation period on the one hand, and to ensure a specific electricity demand below a boundary value on the other hand, a model predictive switchover strategy was developed. The combination of an improved characteristic equation method for the part load behavior of absorption chillers with a simple dry-cooler model was used to find a suitable cut-in and cut-off condition for the solar heat operation. The two conditions depend on a minimum solar driving temperature, which has to be reached by the solar collector and storage before solar heat operation is enabled. The minimum driving temperature depends on technical coefficients describing the part load characteristics of the dry cooler and absorption chiller, and also on the load and weather conditions.

Measurements at a solar cooling system for an IT center with a cooling demand of approximately 20–30 kW around the clock showed that solar heat operation could be started with approximately 67 °C and was possible down to 49 °C. The duration of solar heat operation was 21 h in comparison to 13 h of sunshine duration, and the mean specific electricity demand during the whole SHO period was approximately 25% below the average specific electricity demand of the reference cooling technology.

Although the model predictive switchover strategy utilizes the same method of characteristic equations as the control algorithm of the relevant absorption chiller in the investigated SAC system, it is generally possible to apply the switchover strategy independent of the chiller control. In contrast to the state of the art, where constant (or at least load and weather independent) cut-in temperatures for solar heat operation are used, the new switchover strategy incorporates the actual load and weather condition as well as the part load capability of the absorption chiller and reject heat device. Thus, the new switchover strategy provides the cut-in temperature as a quality of the whole absorption chiller cooling assembly supplied by solar energy.
