Abstract

By using the Hectospec 6.5 m Multiple Mirror Telescope and the 2.16 m telescope of the National Astronomical Observatories, of the Chinese Academy of Sciences, we obtained 188 high signal-to-noise ratio spectra of H II regions in the nearby galaxy M101, which is the largest spectroscopic sample of H II regions for this galaxy so far. These spectra cover a wide range of regions on M101, which enables us to analyze two-dimensional distributions of its physical properties. The physical parameters are derived from emission lines or stellar continua, including stellar population age, electron temperature, oxygen abundance, etc. The oxygen abundances are derived using two empirical methods based on O3N2 and R23 indicators, as well as the direct T_e method when [O III] λ4363 is available. By applying the harmonic decomposition analysis to the velocity field, we obtained a line-of-sight rotation velocity of 71 km s$^{-1}$ and a position angle of 36°. The stellar age profile shows an old stellar population in the galaxy center and a relatively young stellar population in outer regions, suggesting an old bulge and a young disk. The oxygen abundance profile exhibits a clear break at ~18 kpc, with a gradient of $-0.0364$ dex kpc$^{-1}$ in the inner region and $-0.00686$ dex kpc$^{-1}$ in the outer region. Our results agree with the “inside-out” disk growth scenario of M101.

Key words: galaxies: evolution – galaxies: fundamental parameters – galaxies: individual (M101) – galaxies: stellar content

1. Introduction

H II regions are sites of strong star formation in galaxies, which make H II regions perfect probes of star formation processes, evolution of massive stars, and the surrounding interstellar medium. Plenty of information can be obtained by analyzing the emission lines and underlying stellar continuum of their spectra. The gas-phase metallicity, defined as the number ratio of oxygen to hydrogen atoms, is one of the key properties in galaxy formation and evolution. The oxygen is synthesized in high-mass stars ($>8 M_\odot$) and then released to the interstellar medium through stellar winds or supernova explosion. The spatial distributions of the oxygen abundance in galaxies are affected by a variety of processes, such as enriched outflows (Tremonti et al. 2004), accretion (Dalcanton et al. 2004), and mergers (Kewley et al. 2006, 2010; Rupke et al. 2010; Rich et al. 2012; Torrey et al. 2012; Sánchez et al. 2014). Thus studying the metallicity and its relation with other properties would provide clues on the galaxy formation and evolution.

Research on the metallicity of H II regions has been booming in the last two decades. Zaritsky et al. (1994) and van Zee et al. (1998) found that H II regions have an average metallicity gradient of $-0.05$ dex kpc$^{-1}$, i.e., the inner regions of galaxies are more metal-rich than the outskirts. The negative gradients are found to be universal, as reviewed by many (such as Bresolin 2007; Li et al. 2013; Scarano & Lépine 2013; Sánchez et al. 2014; Ho et al. 2015; Sánchez-Menguiano et al. 2016), suggesting inner-to-out transportation of metals. Observations also show breaks in the oxygen abundance gradients in a number of galaxies (Zaritsky 1992; Roy & Walsh 1997). Pilyugin (2003) claimed that such breaks are due to the systematic error involving the excitation parameter, while others attribute it to the barrier effect of corotation, which isolates the inner and outer regions of one disk from the other due to opposite directions of gas flow (Lépine et al. 2011; Scarano & Lépine 2013). More recently, several studies focusing on gas content have found that the metallicity gradients flatten to a constant value beyond the isophotal radii $R_25$ or $2 R_e$ (Rosales-Ortega et al. 2011; Marino et al. 2012; Sánchez et al. 2012b, 2014; López-Sánchez et al. 2015; Sánchez-Menguiano et al. 2016), and several scenarios are proposed to explain the nature of this flattening, such as the bar-induced radial gas flows (Cavichia et al. 2014), minor mergers, and perturbations from satellite galaxies (Bird et al. 2012; López-Sánchez et al. 2015), the varying of star formation efficiency over large galactocentric distances (Bresolin et al. 2012; Esteban et al. 2013), and the balance between outflows and inflows with the intergalactic medium (Oppenheimer & Davé 2008; Oppenheimer et al. 2010; Davé et al. 2011, 2012).

Recently, the integral field unit (IFU) spectrograph has become an important and powerful tool for spatial-resolved spectroscopic observations, which has greatly increased the progress of the two-dimensional research on galaxies. Many surveys, using IFU technology, have been carried out, such as...
SAURON (Bacon et al. 2001), PINGS (Rosales-Ortega et al. 2010), CALIFA (Sánchez et al. 2012a), and MaNGA (Bundy et al. 2015). According to their different observational strategies, MaNGA is mapping a large number of galaxies with limited spatial resolution (1–3 kpc) and field of view (~70 arcsec), while PIGNS provides a better spatial resolution and larger field of view but with a limited number of galaxies, and CALIFA is a compromise between the two. Sánchez et al. (2014) found a common metallicity gradient of $-0.10 \pm 0.09$ dex $R^{-1}$ for 193 CALIFA galaxies, and the metallicity gradients do not exhibit the dependence on other properties of galaxies, such as morphology, mass, and the presence or absence of bars (Sánchez-Menguiano et al. 2016). By studying 49 local field star-forming galaxies, Ho et al. (2015) proposed a local benchmark of metallicity gradients of $-0.39 \pm 0.18$ dex $R^{-1}$. More recently, Belfiore et al. (2017) analyzed 550 nearby galaxies from the MaNGA survey and confirmed that the metallicity gradient is flat for low-mass galaxies ($M_B < 10^{10}$ $M_{\odot}$), steepens for more massive galaxies until $M_B \sim 10^{10.5}$ $M_{\odot}$, and flattens lightly again for even more massive galaxies. This research provided strong constraints on the galactic chemical composition of nearby galaxies (Chiappini et al. 2001; Fu et al. 2009; Ho et al. 2015; Sánchez-Menguiano et al. 2016; Belfiore et al. 2017).

Kong et al. (2014) proposed the “Spectroscopic Observations of the H II Regions In Nearby Galaxies (H2ING)” Project, which has performed spectroscopic observations on H II regions in 20 nearby large galaxies since 2008. As the third paper of this project, we report the spectroscopic observation of H II regions in nearby galaxy M101, with the Multiple Mirror Telescope (MMT) 6.5 m telescope (Fabricant et al. 2005) and the National Astronomical Observatories, Chinese Academy of Sciences (NAOC) 2.16 m telescope (Fan et al. 2016). M101 (also known as NGC 5457, $\alpha = 14\text{h}03\text{m}12.5\text{s}$, $\delta = +54\text{d}20\text{m}56\text{s}$) is a large face-on Scd galaxy containing plenty of H II regions (Hodge et al. 1990; Kennicutt et al. 2003; Bresolin 2007; Gordon et al. 2008; Croxall et al. 2016). It has a distance of about 7.4 Mpc and an apparent scale of about 36 pc arcsec$^{-1}$, which enables us to observe its H II regions to a scale of a few hundred parsecs with our 1″5 fiber and 2″5 slit observations. A major-axis position angle of 39° and an inclination angle of 18° (Bosma et al. 1981) allow us to perform detailed studies of its stellar populations and ionized nebulae. Observations of the M101 H II regions have been carried out since the 1970s (Searle 1971; Smith 1975; McCall et al. 1985; Kennicutt & Garnett 1996; Bresolin 2007). Recently, Li et al. (2013) presented a catalog containing 79 H II regions from their observations and several previous works since 1996. Croxall et al. (2016) have enlarged the sample of H II regions by using the Large Binocular Telescope, and obtained 109 spectra of H II regions in M101. In this paper, we have obtained 188 H II regions with high signal-to-noise ratios (S/Ns) from our observations, which is the largest spectroscopic sample of H II regions for M101. With the spectra of numerous H II regions, we have derived the physical properties of H II regions, and presented a detailed study of the spatial distribution of these properties. This paper is structured as follows. In Section 2, we describe the observation, data reduction and emission line measurements. In Section 3, we present the measurements and analysis of physical properties of the H II region sample. Metallicities are derived with three methods and the gradient is also calculated and discussed. We summarize our results in Section 4.

2. Data

2.1. Observations

The H II region candidates are selected from the continuum-subtracted Hα image (Hoopes et al. 2001). Candidates are primarily selected with a preference for large regions, using SExtractor (Bertin & Arnouts 1996) with the irregular area filter with at least 25 pixels (1 pixel = 2″028). The foreground stars are excluded from the H II catalog by matching with the 2MASS all-sky Point Source Catalog (Cutri et al. 2003). Then candidates are observed with the Hectospec multi-fiber positioner and spectrograph on the 6.5 m MMT telescope and the NAOC 2.16 m telescope.

The usable field of the MMT 6.5 m telescope is 1° in diameter, and the instrument deployed three hundred 1″5-diameter fibers on the field, corresponding to ~54 pc at the distance of M101. We used Hectospecs 270 gpm grating that provided a dispersion of 1.2 Å pixel$^{-1}$ and a resolution of ~5 Å. The spectral wavelength coverage is from 3650 to 9200 Å. The Hectospec fiber assignment software xfitfib9 allows the user to assign rankings to targets. If we ignored the spatial positions of our targets, fiber collisions would prevent many objects in the center portion of the center of M101 from being observed. We therefore assigned priority to H II regions based on their Hα fluxes. We observed two fields on the night of 2012 February 10 with 3600 s exposure times and one field on 2013 March 15 with 5400 s exposure times. Weather conditions are clear on both nights, and seeings are about 1″2, 0″8 and 0″6 for each field, respectively.

The NAOC 2.16 m telescope worked with an OMR (Optomechanics Research Inc.) spectrograph providing a dispersion of 4.8 Å pixel$^{-1}$ and a resolution of 10 Å. The observed spectra cover the wavelength range of 3500–8100 Å. Slits of 2″5 are placed manually to cover as many candidates as possible and to avoid those observed by MMT. Observations are carried out over nine nights between 2012 and 2014 with 20 slits, and exposure times varied between 3600 and 5400 s depending on weather conditions. Typical seeing is ~2″5, corresponding to a spatial resolution of ~300 pc.

2.2. Data Reduction

2.2.1. MMT Spectra

We obtained over 300 spectra from MMT observations, and these spectra are reduced in a uniform manner with the publicly available HSRED10 software. The frames are first debiased and flat-fielded. Individual spectra are then extracted and wavelength calibrated. Sky subtraction is achieved with Hectospec by averaging spectra from “blank sky” fibers from the same exposures. Three spectra of the same target are reduced and combined into one final spectrum. Standard stars are obtained intermittently and are used to calibrate spectra using the IRAF ONEDSPEC package. These relative flux corrections are carefully applied to ensure that the relative line flux ratios are accurate. We have checked the spectra through visual inspection to exclude spectra with problematic continuum.

9 https://www.cfa.harvard.edu/mmti/hectospec/xfitfib5/
10 http://mmt.org/rcool/hsred/index.html
shape, or missing Hα and Hβ emission lines. Finally, we obtained a sample of 164 H II region spectra for analysis. The 164 spectra have a median S/N of 35 at 5000Å, and over 50 spectra have S/Ns higher than 60.

2.2.2. NAOC 2.16 m Spectra

The spectroscopic data from NAOC 2.16 m observations are reduced following standard procedures using the IRAF software package. The CCD reduction includes bias and flatfield corrections, as well as cosmic-ray removal. Wavelength calibration is performed based on helium/argon lamps exposed at both the beginning and the end of each slit during the observation. Flux calibration is performed based on observations of the KPNO spectral standard stars (Massey et al. 1988) observed at the end of each slit observation. The atmospheric extinction is corrected by using the mean extinction coefficients measured for Xinglong by the Beijing–Arizona–Taiwan–Connecticut multicolor sky survey (H. J. Yan 1995, private communication). Similar to MMT spectra, those with problematic continuum shape or missing Hα and Hβ emission lines are excluded. Finally, we extracted 41 spectra, among which 17 spectra are also observed by the MMT 6.5 m telescope. Considering the higher S/Ns and better resolution of MMT spectra, we use MMT spectra for these 17 candidates, and NAOC observations provide 24 additional spectra.

Finally, we have 188 spectra in total (164 from MMT 6.5 m and 24 from NAOC 2.16 m). Locations of these H II regions are shown in Figure 1 and their coordinates are listed in Table 1. Velocities are measured using the SAO xcsao package with IRAF (see Figure 2). We have carefully checked the velocities and corrected a few bad results manually. Spectra are corrected for Galactic reddening (Schlegel et al. 1998) and then shifted to rest frame for further measurements.

2.3. Spectral Fitting

To measure the emission lines of each individual spectra, the underlying stellar continuum must be subtracted. We perform a modeling of stellar continuum using the advanced ICA algorithm, mean field approach to Bayesian independent component analysis (MF-ICA), which is comparatively precise and efficient (Højen-Sørensen et al. 2001, 2002). The MF-ICA approach extracts 12 independent components (ICs) from BC03 11 (Bruzual & Charlot 2003). The 12 ICs contain the full information of the BC03 library and excellently recover the library, which spans a stellar age range from $1.0 \times 10^8$ to $2.0 \times 10^{10}$ year, and an initial chemical composition metallicity from 0.0001 to 0.1. The star formation histories are parameterized in terms of an underlying continuous model superimposed with random bursts on it (Kauffmann et al. 2003). The intrinsic starlight reddening is modeled by the extinction law of Charlot & Fall (2000). The velocity dispersion is set to vary between 50 and 450 km s$^{-1}$. MF-ICA provides reliable modeling of stellar continuum and estimates physical parameters accurately with a large improvement in efficiency. More detailed information about the MF-ICA algorithm is described in Hu et al. (2016). Figure 3 shows two typical fitting results. For each spectrum, emission lines [O II] $\lambda\lambda 3727, H\beta + [O III] \lambda\lambda 4959, 5007, H\alpha + [N II] \lambda\lambda 6548, 6583$, and [S II] $\lambda\lambda 6717, 6731$ are enlarged in four small panels below the spectrum.

2.4. Line Flux Measurement

After subtracting the stellar continuum, we perform the nonlinear least-squares fit to emission lines using the MPFIT package implemented in IDL (Markwardt 2009). Each emission line is modeled with one Gaussian profile, and we constrain the ratios $[N II] / H\alpha$, $[O III] / H\beta$, and $[O III] / [N II]$ to their theoretical values given by quantum mechanics. The emission line fluxes are measured by integration of the flux based on the fitted profiles.

The interstellar reddening is corrected by comparing the observed Hα/Hβ Balmer decrement to the theoretical value, since the intrinsic value of Hα/Hβ is not very sensitive to the physical conditions of the gas. Assuming $H\alpha/H\beta = 2.86$ and $R_V = 3.1$ with the Cardelli et al. (1989) extinction curve under the case-B recombination, the extinction in the $V$ band is given by

$$A_V = 6.77 \log \frac{F(H\alpha)}{F(H\beta)} \frac{1}{2.86}. \quad (1)$$

negative color excesses are all set to zero. The reddening-corrected line flux measurements are listed in Table 1, with values normalized to $H\beta$ flux. All spectra have strong Hα and Hβ emission lines, and 14 of them have $[O III] \lambda 4363$ emission line.

In Figure 4, we examine the excitation properties of our sample by plotting $[O III] \lambda 5007/H\beta$ versus $[N II] \lambda 6583/H\alpha$ diagnostic diagrams (BPT, Baldwin et al. 1981). The color-code indicates the deprojected distance to the galaxy center. We plot the boundaries between different photoionization sources (star-forming regions and active galactic nuclei) by Kewley et al. (2001) and Kauffmann et al. (2003). As shown in Figure 4, almost all targets in our

Note. Line fluxes are normalized to Hβ line, after correcting for reddening. Hβ λ4861 is the measured Hβ flux in units of \(10^{-17} \text{erg s}^{-1} \text{cm}^{-2}\), corrected for extinction.
sample are located in the pure star-forming region with only five exceptions. Furthermore, the H II regions show a radially changing sequence on the BPT diagram: the inner regions have higher \( \text{N II}\ \lambda 6583/\text{H}\alpha \) and lower \( \text{O III}\ \lambda \lambda 5007/\text{H}\beta \) than outer regions, suggesting a negative gradient of metallicity. This is consistent with the results from Sánchez et al. (2015) in which the inner H II regions of the galaxies appear to have higher \( \text{N II}\ \lambda 6583/\text{H}\alpha \) and lower \( \text{O III}\ \lambda 5007/\text{H}\beta \) than outer regions, using over 5000 H II regions from 306 galaxies.

More detailed information will be discussed in Section 3.3.

2.5. Oxygen Abundance Determination

2.5.1. The Direct Method

The direct method to derive oxygen abundance is to measure the ratio of a higher excitation line to a lower excitation line, in which case \( \text{O III}\ \lambda 4363/\text{O III}\ \lambda \lambda 4959, 5007 \) is the most commonly used. This ratio together with a model of two excitation zone structure for the H II regions provides an estimation of the electron temperature of the gas, and then the electron temperatures are converted to oxygen abundances with corrections for an unseen stage of ionization.
Table 2
Gas Conditions and Oxygen Abundance Measurements

| ID | $T\text{[O III]}$ (K) | $n_e$ (cm$^{-3}$) | log $u$ (log cm s$^{-1}$) | O3N2 | $12 + \log(O/H)$ | $T_e$ |
|----|---------------------|-----------------|-----------------|------|-----------------|------|

To calculate the total oxygen abundances, we make the usual assumption: O/H = (O$^+$ + O$^{2+}$)/H$^+$. Electron temperatures are derived based on the emission line intensity ratio [O III] $\lambda 4363$/[O III] $\lambda 4959$, 5007, and electron densities ($n_e$) are derived based on the intensity ratio [S II] $\lambda 6717$/[S II] $\lambda 6731$. Among the spectra of H II regions, 14 of them have [O III] $\lambda 4363$ detections with well-defined line profiles and the S/Ns larger than 3. The electron temperatures of them for the O$^{2+}$-emitting region ($T$[O III]) are derived with the PYNEB package (Luridiana et al. 2015). PYNEB is a python package for analyzing emission lines, which includes the Fortran code FIVEL (De Robertis et al. 1987) and the IRAF nebular package (Shaw & Dufour 1995).

We adopted the transition probabilities of Wiese et al. (1996) and Storey & Zeippen (2000) for O$^{2+}$, Podobedova et al. (2009) for S$^+$, the collision strengths of Aggarwal & Keenan (1999) for O$^{2+}$, Tayal & Zatsarinny (2010) for S$^+$. Electron temperatures and electron densities are calculated simultaneously to obtain self-consistent estimates by PYNEB. Then the electron temperatures of [O II] ($T$[O II]) are obtained with applying the relation from Garnett (1992): $T$[O II] = 0.7 $\times$ [O III] + 3000 K. With giving $T$[O II], $T$[O III], and $n_e$, metallicities are finally calculated from the line intensities of [O II] $\lambda 3727$ and [O III] $\lambda\lambda 4959, 5007$ with PYNEB.

Errors are estimated with a Monte Carlo algorithm by repeating the calculation 2000 times. In each calculation, the input flux of each emission line is generated from a Gaussian distribution with the mean value equaling the measured emission line flux and the standard deviation equaling its error. We use the median value of 2000 results as the final value, and half of the 16%–84% range of this distribution as the corresponding error. The electron temperatures and densities are listed in Table 2.

Although the direct method is considered to be one of the most reliable methods to derive gas-phase oxygen abundances, the [O III] $\lambda 4363$ line is weak, especially in meta-rich environments. Since most of our H II regions do not have [O III] $\lambda 4363$ detections, we applied two strong-line methods to determine the oxygen abundance.

2.5.2. The O3N2 Index

The O3N2 index, defined as $O3N2 = \log \left(\frac{[O III] \lambda 5007/H\beta}{[N II] \lambda 6583/H\alpha}\right)$, was first introduced by Alloin et al. (1979). It is widely used to diagnose oxygen abundances in the literature. The four lines involved in the index are easily detected, and the close wavelength between the two pairs of lines make the index nearly free from extinction. By using 137 extragalactic H II regions, Pettini & Pagel (2004) empirically calibrated the O3N2 versus oxygen abundance determined by the $T_e$ method and photoionization models. More recently, Marino et al. (2013) provide a new calibration with $T_e$ based metallicities of 603 H II regions, which is adopted here:

$$12 + \log(O/H) = 8.533 - 0.214 \times O3N2,$$

However, O3N2 calibrations do not consider the variations of the ionization parameter ($q$), which may cause systematic errors. More will be discussed in the next subsection.
2.5.3. The KK04 Method

Kobulnicky & Kewley (2004, hereafter KK04) adopted the stellar evolution and photoionization from Kewley & Dopita (2002) to produce a modified R23 calibration. The R23 index, defined as \( R_{23} = \left( \frac{\lambda 3727}{\lambda 3037} \right) + \left( \frac{\lambda 4959}{\lambda 4363} + \lambda 5007 \right) / \lambda 3389 \), is sensitive to the ionization parameter of the gas, which is defined as the ratio between the number of hydrogen ionizing photons passing through a unit area per second and the hydrogen density of the gas. The ionization parameter is typically derived based on the line ratio \( O_{32} = \left( \frac{\lambda 3727}{\lambda 5007} \right) / \lambda 3727 \), and it is also sensitive to oxygen abundance; therefore, KK04 applied an iterative process to derive a consistent ionization parameter and oxygen abundance. First, we determined whether the H II regions lie on the upper or lower R23 branch with ratio N2O2 = [N II] \( \lambda 6583/[O II] \lambda 3727 \), then we calculated an initial ionization parameter by assuming a starting oxygen abundance of 8.0 for lower branch and 9.0 for upper branch. The initial ionization parameter is used to calculate an initial oxygen abundance. These processes are iterated until oxygen abundance converges. Errors are generated with the same Monte Carlo algorithm used in direct \( T_e \) method, i.e., repeating the calculation 2000 times.

The results of three calibrations, electron temperatures \( T [\text{O III}] \), electron densities \( n_e \), and ionization parameter \( q \) are listed in Table 2. To test the reliability of the oxygen abundance, we compare the three calibrations in Figure 5. In Figure 5, we plot O3N2 calibrations and \( T_e \) calibrations versus KK04 calibrations, with different colors indicating different ionization parameters (see Figure 5 for details). As shown in this figure, good linear correlations are seen with systematic offsets as a whole. O3N2 calibration is systematically \( \sim 0.4 \text{ dex} \) lower than KK04 calibration, and it flattens when KK04 calibration is lower than 8.5 due to the limited range of the O3N2 index. \( T_e \) calibrations agree well with O3N2 calibrations if we ignore the values near the lower limit of the O3N2 calibration. The systematic biases of different methods are expected, which are investigated by Kewley & Ellison (2008) in detail. The systemic 0.4 dex bias could be caused by temperature fluctuations or gradients within high-metallicity H II regions. In the presence of temperature fluctuations or gradients, [O III] is emitted predominantly in high-temperature zones, where O2+ is present only in small amounts. Thus the high electron temperatures estimated from the [O III] \( \lambda 4363 \) line do not reflect the true electron temperature in the H II region, leading to a systematic lower estimation of metallicity by as much as 0.4 dex (Stasińska 2002, 2005; Kewley & Ellison 2008). Moreover, the scattering between O3N2 calibrations and KK04 calibrations is not random. It correlates with ionization parameter \( q \); samples with lower \( \log(q) \) tend to have larger measured metallicity. Considering the discussion above, we use KK04 calibrations in the following analysis.

3. Results

3.1. Velocity Field

M101 is a giant and nearly face-on spiral galaxy (Sandage & Tamman 1974; Bosma et al. 1981). The velocity field of M101 has been studied based on the kinematics of HI gas (Bosma et al. 1981) and Hα-data (Comte et al. 1979). In this paper, the H II regions cover a wide range of regions on M101, which enables us to acquire the velocity map for M101. The left panel of Figure 2 shows the line-of-sight velocities of H II regions in M101, which are good tracers of gas movements. The velocities are measured using the SAO xcsao package with IRAF.

As seen in this panel, a rotating disk is clearly shown. We then apply the harmonic decomposition method (Krajnović et al. 2006) to model the velocity field. This method has been widely used to analyze the gas and stellar kinematics in both late-type (Franx et al. 1994; Wong et al. 2004) and early-type galaxies (Emsellem et al. 2007; Krajnović et al. 2008). This method is able to decompose the line-of-sight velocity map into a series of Fourier components, which are kinematic components with different azimuthal symmetry. In this work, we broadly expand the Fourier terms to the third order:

\[
V(a, \psi) = A_0(a) + \sum_{n=1}^{3} A_n(a) \sin(n\psi) + B_n(a) \cos(n\psi),
\]

where \( \psi \) is the eccentric anomaly, and \( a \) is the length of the semimajor axis of the elliptical ring. Using this model, we obtained the kinematic position angle of 36°, the inclination of 26°, the systemic velocity of 242 km s\(^{-1}\) and the line-of-sight rotation velocity of 71 km s\(^{-1}\), corresponding to a maximum rotation velocity of 168 km s\(^{-1}\). These values agree well with the previous modeling of the velocity field from Comte et al. (1979), who found the position angle of 35°, the inclination of 27°, and the systemic velocity of 238 km s\(^{-1}\). However, the inclination measured in this work is slightly larger than the result from Bosma et al. (1981), who found an inclination of 18° based on the HI velocity map. This discrepancy may be due to the larger HI disks than optical disk and interactions with close companions in the outskirts (Bosma et al. 1981; Waller et al. 1997; Mihos et al. 2012). The modeled velocity map is shown in the right panel of Figure 2 with the same color-coding of the left panel.

3.2. Stellar Population Ages

The light-weighted mean stellar age is a good tracer to the star formation history. Low stellar age indicates the young stellar population and recent strong star formation activities in the galaxy, while high stellar age means old stellar populations with few recent star formation activities. The equivalent width (EW) of the Hα emission line is sensitive to the ratio of present to past star formation rates; therefore, it is expected to be correlated with stellar age, and with the higher values of the younger populations.

From the MF-ICA fits, we have estimated the stellar population age by computing the light-weighted mean age of different stellar population components. The left panel of Figure 6 shows the two-dimensional distribution of the mean stellar age. As shown in this figure, the stellar ages of the inner region are generally older than the outskirts in M101. We also present the EW(Hα) of each H II region in the right panel of Figure 6. The results in both of the panels are broadly consistent, with the older stellar population in the inner regions and the younger stellar population in outer regions. This negative stellar age gradient in M101 agrees with the “inside-out” disk growth scenario (Bezanson et al. 2009; Pérez et al. 2013; Tacchella et al. 2015).
The Astrophysical Journal, 854:68 (11pp), 2018 February 10

Hu et al.

for $R > 18$ kpc. The gradient of the inner regions is $-0.0364$ dex kpc$^{-1}$, which is slightly steeper than the results from Bresolin (2007), Li et al. (2013), and Pilyugin et al. (2014; $-0.0278$, $-0.0268$ and $-0.0293$ dex kpc$^{-1}$). However, the metallicity gradient becomes flat at the radius greater than 20 kpc. To compare with the characteristic gradient provided by Ho et al. (2015) ($-0.39 \pm 0.18$ dex $R_{25}^{-1}$), we convert the derived gradient to the same scale. For inner regions, the gradient is $-1.18 \pm 0.017$ dex $R_{25}^{-1}$, which is steeper than characteristic gradients. However, the gradient of the outer region is $-0.221 \pm 0.038$ dex $R_{25}^{-1}$, which is flatter.

Rosales-Ortega et al. (2012) found that gas metallicity increases with stellar mass surface density, which plays a role in determining the mass–metallicity relation and radial metallicity gradients in spirals. This has been confirmed by several researches (e.g., Sánchez et al. 2013; Barrera-Ballesteros et al. 2016). Chemical evolution models with the most important parameters varying smoothly with radius can easily reproduce negative gradients, which show that the maxima of both neutral and molecular gas move from the center to the outskirts through the disk as the galaxy evolves. Thus the star formation is strong in the central regions at early times and spread outward through disks as the gas is efficiently consumed. This shapes present galaxies with high-metallicity, low specific star formation rate in the center and negative radial metallicity gradients that flatten with time. This is known as the “inside-out” disk growth.

Several studies have found that metallicity gradients flatten to a constant value beyond the isophotal radii $R_{25}$ or $2R_e$ (Rosales-Ortega et al. 2011; Marino et al. 2012; Sánchez et al. 2012b, 2014; Lópe-Sánchez et al. 2015; Sánchez-Menguiano et al. 2016). The mechanism of this gradient flattening is under debate. One possible mechanism is a slow radial dependence of the star formation efficiency across large galactocentric distances (Bresolin et al. 2012; Esteban et al. 2013). Cosmological simulations that introduce a balance between outflows and inflows with the intergalactic medium may also contribute to shaping the metal content (Oppenheimer & Davé 2008; Oppenheimer et al. 2010; Davé et al. 2011, 2012). Interactions with satellite galaxies are suggested to enhance the metallicity in the outer regions of galaxies, which may also flatten the metallicity gradient (Bird et al. 2012; Lópe-Sánchez et al. 2015). The real scenario is likely to be the mixture of several mechanisms. We note that the turning point of the gradient in M101 is at $\sim$18 kpc, which is much smaller than $R_{25}$ ($\sim$31 kpc). An alternative explanation is proposed by Lépine et al. (2011), who state that the break in the gradient is the “pumping out” effect of corotation, which produces gas flows in opposite directions on the two sides of the radius. The corotation radius of M101 is 16.7 kpc (Scannapieco & Lépine 2013), which is very close to the break radius we find in this work. This suggests that the radial break of metallicity in M101 is probably caused by the result of corotation.

There are seven outliers far below the fit line with oxygen abundances lower than 8.2. These H II regions are located to the east of M101. M101 is not the isolated galaxy, and two close companions (NGC 5474 in the east and NGC 5477 in the southeast) are found. Kewley et al. (2006) presented some evidence that galaxy pairs have systematically lower oxygen abundance than field galaxies, and mergers may also flatten the oxygen abundance gradient. More recently, Sánchez et al.

3.3. Radial Abundance Gradient

The measurements of the radial abundance gradient from H II regions are first carried out by Searle (1971) and Smith (1975), after that series of works showed up (McCall et al. 1985; Kennicutt & Garnett 1996; Bresolin 2007; Sánchez et al. 2012a, 2014; Lin et al. 2013; Pilyugin et al. 2014; Sánchez-Menguiano et al. 2016, 2017; Belfiore et al. 2017).

There are 173 out of 188 H II regions whose oxygen abundances are computed by the KK04 calibration. The distribution of oxygen abundance (left panel) and its radial gradient (right panel) are presented in Figure 7. Some other works are also shown with different symbols. As the figure shows, the oxygen abundances from the KK04 calibration are 0.5 dex higher than Bresolin (2007) and Kennicutt et al. (2003), because their calibrations are based on the $\alpha$ method. However, the metallicity gradients are consistent based on different calibrations and works. In addition, our result also shows a break in the gradient at around 18 kpc radius, so we use two linear least-squares fits:

$$12 + \log(O/H) = 9.24 - 0.0364 \times R \quad (4)$$

for $R < 18$ kpc, and

$$12 + \log(O/H) = 8.64 - 0.00686 \times R \quad (5)$$

for $R > 18$ kpc.
found that the metallicity gradients are independent of morphology, incidence of bars, absolute magnitude, and mass, and that the only clear correlation is between merger stage and metallicity gradient, where merger progresses flatten the slope of gradients (see also Kewley et al. 2010; Rupke et al. 2010; Rich et al. 2012; Torrey et al. 2012). M101 might be interacting with NGC 474 and NGC 5477, as suggested by Waller et al. (1997) and Mihos et al. (2012, 2013), who analyzed deep neutral hydrogen observation and deep optical images and concluded that M101 is in an ongoing interaction with lower mass companions. These interactions may dilute the oxygen abundance of these H II regions in gas mixing processes, making the seven outliers relatively meta-poor.

4. Summary

We have investigated the distributions of physical properties of H II regions in the nearby galaxy M101 using spectra obtained from the 6.5 m MMT telescope and the NAOC 2.16 m telescope during 2012–2014. We present the observations, data reductions, and measurements of emission lines. This is the largest spectroscopic sample of H II regions in M101 by now.

We estimated the stellar population ages by fitting the continuum with the MF-ICA approach, and the stellar age profile shows an older stellar population in the inner regions and a younger in the outer regions. There is a younger component at the center of the galaxy, which indicates that recent star formation occurred at the center. This might be caused by gas falling into the center due to the nonaxisymmetric gravity of the bar.

We calculated the electron temperatures $T_{\text{[O III]}}$, electron densities $n_e$, and measured oxygen abundances with three methods. O3N2 calibrations are consistent with direct $T_e$ calibrations when we ignore the limitation effect of O3N2 calibration, and both calibrations are systemically $\sim 0.4$ dex.
lower than the KK04 calibration, due to temperature fluctuations or gradients within high-metallicity H II regions. O3N2 calibrations do not consider ionization parameters, which may cause systemic errors.

The oxygen abundance profile shows a negative gradient with a clear break at 20 kpc radius. The gradient is $-0.0364 \text{ dex kpc}^{-1}$ in the inner region and $-0.00686 \text{ dex kpc}^{-1}$ in the outer region. This is likely to be the mixture of several mechanisms, such as radial dependence of SFE over large galactocentric distances, a balance between outflows and inflows with the intergalactic medium and interactions with satellite galaxies. Since the break radius is comparable to the corotation radius (16.7 kpc), the break in the gradient could be the “pumping out” effect of corotation. If this is the case, gas flows play an important role in chemical evolutions of galaxies and should not be regarded as minor effects in evolution models. There are several low metallicities may be the result of interactions with close companions.

Both stellar population age distribution and oxygen abundance gradient support the “inside-out” disk growth scenario: the early gas infall or collapse made the inner region more metal-rich and older, while the outer disk is enriched more slowly and younger. In order to learn more about the formation and evolution of nearby galaxies, we intend to combine the spectra of H II regions with multi-wavelength photometry data (especially UV to IR) to investigate the nature of dispersions of the IRX-β relation. Due to the relatively simple star formation history and structure of H II regions, it would be helpful to find a second parameter to reduce the scatter of IRX-β relation. This will help us to further understand the interaction between dust and the interstellar radiation field, as well as the formation and evolution of nearby galaxies.

This work uses data obtained through the Telescope Access Program (TAP), which is funded by the National Astronomical Observatories of China, the Chinese Academy of Sciences (the Strategic Priority Research Program, “The Emergence of Cosmological Structures” Grant No. XDB09000000), and the Special Fund for Astronomy from the Ministry of Finance. This work is supported by the National Basic Research Program of China (973 Program) (2015CB857004), the National Natural Science Foundation of China (NSFC, Nos. 11320101002, 11421303, and 11433005), and the Youth Innovation Fund by University of Science and Technology of China (No. WK2030220019).
