Abstract

In real-time systems, in addition to the functional correctness recurrent tasks must fulfill timing constraints to ensure the correct behavior of the system. Partitioned scheduling is widely used in real-time systems, i.e., the tasks are statically assigned onto processors while ensuring that all timing constraints are met. The decision version of the problem, which is to check whether the deadline constraints of tasks can be satisfied on a given number of identical processors, has been known $NP$-complete in the strong sense. Several studies on this problem are based on approximations involving resource augmentation, i.e., speeding up individual processors. This paper studies another type of resource augmentation by allocating additional processors, a topic that has not been explored until recently. We provide polynomial-time algorithms and analysis, in which the approximation factors are dependent upon the input instances. Specifically, the factors are related to the maximum ratio of the period to the relative deadline of a task in the given task set. We also show that these algorithms unfortunately cannot achieve a constant approximation factor for general cases. Furthermore, we prove that the problem does not admit any asymptotic polynomial-time approximation scheme (APTAS) unless $P = NP$ when the task set has constrained deadlines, i.e., the relative deadline of a task is no more than the period of the task.

1 Introduction

The sporadic task model has been widely adopted to model recurring executions of tasks in real-time systems [28]. A sporadic real-time task $\tau_i$ is defined with a minimum inter-arrival time $T_i$, its timing constraint or relative deadline $D_i$, and its (worst-case) execution time $C_i$. A sporadic task represents an infinite sequence of task instances, also called jobs, that arrive with the minimum inter-arrival time constraint. That is, any two consecutive jobs of task $\tau_i$ should be temporally separated by at least $T_i$. When a job of task $\tau_i$ arrives at time $t$, the job must finish no later than its absolute deadline $t + D_i$.
According to the Liu and Layland task model [27], the minimum inter-arrival time of a task can also be interpreted as the period of the task.

To schedule real-time tasks on multiprocessor platforms, there have been three widely adopted paradigms: partitioned, global, and semi-partitioned scheduling. A comprehensive survey of multiprocessor scheduling in real-time systems can be found in [15]. In this paper, we consider partitioned scheduling, in which tasks are statically partitioned onto processors. This means that all the jobs of a task are executed on a specific processor, which reduces the online scheduling overhead since each processor can schedule the sporadic tasks assigned on it without considering the tasks on the other processors. Moreover, we consider preemptive scheduling on each processor, i.e., a job may be preempted by another job on the processor. For scheduling sporadic tasks on one processor, the (preemptive) earliest-deadline-first (EDF) policy is optimal [27] in terms of meeting timing constraints, in the sense that if the task set is schedulable then it will also be schedulable under EDF. In EDF, the job (in the ready queue) with the earliest absolute deadline has the highest priority for execution. Alternatively, another widely adopted scheduling paradigm is (preemptive) fixed-priority (FP) scheduling, where all jobs released by a sporadic task have the same priority level.

On a uniprocessor, checking the feasibility for an implicit-deadline task set is simple and well-known: the timing constraints are met by EDF if and only if the total utilization \( \sum_{i \in T} \frac{C_i}{T_i} \) is at most 100% [27]. Moreover, if every task \( \tau_i \) on the processor is with \( D_i \geq T_i \), it is not difficult to see that testing whether the total utilization is less than or equal to 100% is also a necessary and sufficient schedulability test. This can be achieved by considering a more stringent case which sets \( D_i \) to \( T_i \) for every \( \tau_i \). Hence, this special case of arbitrary-deadline task sets can be reformulated to task sets with implicit deadlines without any loss of precision. However, determining the schedulability for task sets with constrained or arbitrary deadlines in general is much harder, due to the complex interactions between the deadlines and the periods, and in particular is known to be \( \text{coNP}
}\)-hard or \( \text{coNP}
}\)-complete [17–19].

In this paper, we consider partitioned scheduling in homogeneous multiprocessor systems. Deciding if an implicit-deadline task set is schedulable on multiple processors is already \( \text{NP}
}\)-complete in the strong sense under partitioned scheduling. To cope with these \( \text{NP}
}\)-hardness issues, one natural approach is to focus on approximation algorithms, i.e., polynomial time algorithms that produce an approximate solution instead of an exact one. In our setting, this translates to designing algorithms that can find a feasible schedule using either (i) faster or (ii) additional processors. The goal, of course, is to design an algorithm that uses the least speeding up or as few additional processors as possible. In general, this approach is referred to as resource augmentation and is used extensively to analyze and compare scheduling algorithms. See for example [29] for a survey and motivation on why this is a useful measure for evaluating the quality of scheduling algorithms in practice. However, such a measure also has its potential pitfalls as recently studied and reported by Chen et al. [12]. Interestingly, it turns out that there is a huge difference regarding the approximation factors depending on whether it is possible to increase the processor speed or the number of processors. As already discussed in [11], approximation by speeding up is known as the multiprocessor partitioned scheduling problem, and by allocating more processors is known as the multiprocessor partitioned packing problem. We study the latter one in this paper.

Formally, an algorithm \( \mathcal{A} \) for the multiprocessor partitioned packing problem is said to have an approximation factor \( \rho \), if given any task set \( T \), it can find a feasible partition of \( T \) on \( \rho M^* \)
processors, where $M^*$ is the minimum (optimal) number of processors required to schedule $T$. However, it turns out that the approximation factor is not the best measure in our setting (it is not fine-grained enough). For example, it is $\mathcal{NP}$-complete to decide if an implicit-deadline task set is schedulable on 2 processors or whether 3 processors are necessary. Assuming $\mathcal{P} \neq \mathcal{NP}$, this rules out the possibility of any efficient algorithm with approximation factor better than $3/2$, as shown in [11]. (This lower bound is further lifted to 2 for sporadic tasks in Section 5.) The problem with this example is that it does not rule out the possibility of an algorithm that only needs $M^* + 1$ processors. Clearly, such an algorithm is almost as good as optimum when $M^*$ is large and would be very desirable. To get around this issue, a more refined measure is the so-called asymptotic approximation factor. An algorithm $A$ has an asymptotic approximation factor $\rho$ if we can find a schedule using at most $\rho M^* + \alpha$ processors, where $\alpha$ is a constant that does not depend on $M^*$. An algorithm is called an asymptotic polynomial-time approximation scheme (APTAS) if, given an arbitrary accuracy parameter $\epsilon > 0$ as input, it finds a schedule using $(1 + \epsilon)M^* + O(1)$ processors and its running time is polynomial assuming $\epsilon$ is a fixed constant.

For implicit-deadline task sets, the multiprocessor partitioned scheduling problem, by speeding up, is equivalent to the Makespan problem [21], and the multiprocessor partitioned packing problem, by allocating more processors, is equivalent to the bin packing problem [20]. The Makespan problem admits polynomial-time approximation schemes (PTASes), by Hochbaum and Shmoys [22], and the bin packing problem admits asymptotic polynomial-time approximation schemes (APTASes), by de la Vega and Lueker [16, 23].

When considering sporadic task sets with constrained or arbitrary deadlines, the problem becomes more complicated. When adopting speeding-up for resource augmentation, the deadline-monotonic partitioning proposed by Baruah and Fisher [3, 4] has been shown to have a $3 - \frac{1}{M}$ speed-up factor in [10], where $M$ is the given number of identical processors. The studies in [1, 2, 11] provide polynomial-time approximation schemes for some special cases when speeding-up is possible. The PTAS by Baruah [2] requires that $\frac{D_{\text{max}}}{D_{\text{min}}}$, $\frac{C_{\text{max}}}{C_{\text{min}}}$, $\frac{T_{\text{max}}}{T_{\text{min}}}$ are constants, where $D_{\text{max}}$ ($C_{\text{max}}$ and $T_{\text{max}}$, respectively) is the maximum relative deadline (worst-case execution time and period, respectively) in the task set and $D_{\text{min}}$ ($C_{\text{min}}$ and $T_{\text{min}}$, respectively) is the minimum relative deadline (worst-case execution time and period, respectively) in the task set. It was later shown in [11] that the complexity only depends on $\frac{D_{\text{max}}}{D_{\text{min}}}$. If $\frac{D_{\text{max}}}{D_{\text{min}}}$ is a constant, there exists a PTAS developed by Chen and Chakraborty [11], which admits feasible task partitioning by speeding up the processors by $(1 + \epsilon)$. The approach in [11] deals with the multiprocessor partitioned scheduling problem as a vector scheduling problem [7] by constructing (roughly) $(1/\epsilon) \log \frac{D_{\text{max}}}{D_{\text{min}}}$ dimensions and then applies the PTAS of the vector scheduling problem developed by Chekuri and Khanna [7] in a black-box manner. Bansal et al. [1] exploit the special structure of the vectors and give a faster vector scheduling algorithm that is a quasi-polynomial-time approximation scheme (qPTAS) even if $\frac{D_{\text{max}}}{D_{\text{min}}}$ is polynomially bounded.

However, augmentation by allocating additional processors, i.e., the multiprocessor partitioned packing problem, has not been explored until recently in real-time systems. Our previous work in [11] has initiated the study for minimizing the number of processors for real-time tasks. While [11] mostly focuses on approximation algorithms for resource augmentation via speeding up, it also showed that for the multiprocessor partitioned packing problem there does not exist any APTAS for arbitrary-deadline task sets, unless $\mathcal{P} = \mathcal{NP}$. However, the proof in [11] for the non-existence of APTAS only works when the input task set $T$ has exactly two types of tasks in which one type consists of tasks with relative deadline less than or equal to its period (i.e., $D_i \leq T_i$ for some $\tau_i$ in $T$)

---

1. Indeed, there are (very ingenious) algorithms known for the implicit-deadline partitioning problem that use only $M^* + O(\log^2 M^*)$ processors [25], based on the connection to the bin-packing problem.
and another type consists of tasks with relative deadline larger than its period (i.e., \( D_j > T_j \) for some \( \tau_j \in T \)). Therefore, it cannot be directly applied for constrained-deadline task sets.

For the results, from the literature and also this paper, related to the multiprocessor partitioned scheduling and packing problems, Table 1 provides a short summary.

**Our Contributions** This paper studies the multiprocessor partitioned packing problem in much more detail. On the positive side, when the ratio of the period of a constrained-deadline task to the relative deadline of the task is at most \( \lambda = \max_{\tau_i \in T} \max \left\{ \frac{T_i}{D_i}, 1 \right\} \), in Section 5, we provide a simple polynomial-time algorithm with a \( 2\lambda \)-approximation factor. In Section 4, we show that the deadline-monotonic partitioning algorithm in [3, 4] has an asymptotic \( \frac{1}{2\lambda} \)-approximation factor for the packing problem, where \( \gamma = \max_{\tau_i \in T} \min \left\{ \frac{T_i}{D_i}, 1 \right\} \). In particular, when \( \gamma \) and \( \lambda \) are not constant, adopting the worst-fit or best-fit strategy in the deadline-monotonic partitioning algorithm is shown to have an \( \Omega(N) \) approximation factor, where \( N \) is the number of tasks. In contrast, from [10], it is known that both strategies have a speed-up factor 3, when the resource augmentation is to speed up processors. We also show that speeding up processors can be much more powerful than allocating more processors. Specifically, in Section 5, we provide input instances, in which the only feasible schedule is to run each task on an individual processor but the system requires only one processor with a speed-up factor of \( (1 + \epsilon) \), where \( 0 < \epsilon < 1 \).

On the negative side, in Section 6, we show that there does not exist any asymptotic polynomial-time approximation scheme (APTAS) for the multiprocessor partitioned packing problem for task sets with constrained deadlines, unless \( P = \mathbb{NP} \). As there is already an APTAS for the implicit deadline case, this together with the result in [11] gives a complete picture of the approximability of multiprocessor partitioned packing for different types of task sets, as shown in Table 1.

### Table 1

| Task and Platform Model |
|-------------------------|
| \( T = \{ \tau_1, \tau_2, \ldots, \tau_N \} \) of \( N \) independent sporadic real-time tasks. Each of these tasks releases an infinite number of task instances, called jobs. A task \( \tau_i \) is defined by \( (C_i, T_i, D_i) \), where \( D_i \) is its relative deadline, \( T_i \) is its minimum inter-arrival time (period), and \( C_i \) is its (worst-case) execution time. For a job released at time \( t \), the next job must be released no earlier than \( t + T_i \) and it must finish \( (up to) C_i \) amount of execution before the jobs absolute deadline at \( t + D_i \). The utilization of task \( \tau_i \) is denoted by \( u_i = \frac{C_i}{T_i} \). We consider platforms with identical processors, i.e., the execution and timing property remains no matter which processor a task is assigned to. According to the relations of the relative deadlines and the minimum inter-arrival times of the tasks in \( T \), the task set can be identified to be with (1) implicit deadlines, i.e., \( D_i = T_i \) \( \forall \tau_i \), (2) constrained deadlines, i.e., \( D_i \leq T_i \) \( \forall \tau_i \), or (3) arbitrary deadlines, otherwise. The cardinality of a set \( X \) is denoted by \( |X| \).

In this paper we focus on partitioned scheduling, i.e., each task is statically assigned to a fixed processor and all jobs of the task is executed on the assigned processor. On each processor, the
jobs related to the tasks allocated to that processor are scheduled using preemptive earliest deadline first (EDF) scheduling. This means that at each point the job with the shortest absolute deadline is executed, and if a new job with a shorter absolute deadline arrives the currently executed job is preempted and the new arriving job starts executing. A task set can be feasibly scheduled by EDF (or EDF is a feasible schedule) on a processor if the timing constraints can be fulfilled by using EDF.

2.2 Problem Definition

Given a task set \( T \), a feasible task partition on \( M \) identical processors is a collection of \( M \) subsets, denoted \( T_1, T_2, \ldots, T_M \), such that
- \( T_j \cap T_{j'} = \emptyset \) for all \( j \neq j' \),
- \( \bigcup_{j=1}^{M} T_j \) is equal to the input task set \( T \), and
- set \( T_j \) can meet the timing constraints by EDF scheduling on a processor \( j \).

Definition 1. The multiprocessor partitioned packing problem: The objective is to find a feasible task partition on \( M \) identical processors with the minimum \( M \).

We assume that \( u_i \leq 100\% \) and \( \frac{C_i}{D_i} \leq 100\% \) for any task \( \tau_i \) since otherwise there cannot be a feasible partition.

2.3 Demand Bound Function

This paper focuses on the case where the arrival times of the sporadic tasks are not specified, i.e., they arrive according to their interarrival constraint and not according to a pre-defined pattern. Baruah et al. [5] have shown that in this case the worst-case pattern is to release the first job of tasks synchronously (say, at time \( 0 \) for notational brevity), and all subsequent jobs as early as possible. Therefore, as shown in [5], the demand bound function \( \text{dbf}(\tau_i, t) \) of a task \( \tau_i \) that specifies the maximum demand of task \( \tau_i \) to be released and finished within any time interval with length \( t \) is defined as

\[
\text{dbf}(\tau_i, t) = \max \left\{ 0, \left\lfloor \frac{t - D_i}{T_i} \right\rfloor + 1 \right\} \times C_i.
\]

The exact schedulability test of EDF, to verify whether EDF can feasibly schedule the given task set on a processor, is to check whether the summation of the demand bound functions of all the tasks is always less than \( t \) for all \( t \geq 0 \) [5].

3 Reduction to Bin Packing

When considering tasks with implicit deadlines, the multiprocessor partitioned packing problem is equivalent to the bin packing problem [20]. Therefore, even though the packing becomes more complicated when considering tasks with arbitrary or constrained deadlines, it is pretty straightforward to handle the problem by using existing algorithms for the bin packing problem if the maximum ratio \( \lambda \) of the period to the relative deadline among the tasks, i.e., \( \lambda = \max_{\tau_i \in T} \max \left\{ \frac{T_i}{D_i} \right\}, 1 \), is not too large.

For a given task set \( T \), we can basically transform the input instance to a related task instance \( T^\dagger \) by creating task \( \tau_i^\dagger \) based on task \( \tau_i \) in \( T \) such that
- \( T_i^\dagger = D_i, C_i^\dagger = C_i \), and \( D_i^\dagger = D_i \) when \( T_i \geq D_i \) for \( \tau_i \), and
- \( D_i^\dagger = T_i^\dagger, C_i^\dagger = C_i \) and \( T_i^\dagger = T_i \) when \( T_i < D_i \) for \( \tau_i \).
Now, we can adopt any greedy fitting algorithms (i.e., a task is assigned to “one” allocated processor that is feasible; otherwise, a new processor is allocated and the task is assigned to the newly allocated processor) for the bin packing problem by considering only the utilization of transformed tasks in $T^\dagger$ for the multiprocessor partitioned packing problem, as presented in [30, Chapter 8]. The construction of $T^\dagger$ has a time complexity of $O(N)$, and the greedy fitting algorithm has a time complexity of $O(NM)$.

**Theorem 2.** Any greedy fitting algorithm by considering $T^\dagger$ for task assignment is a $2\lambda$-approximation algorithm for the multiprocessor partitioned packing problem.

**Proof.** Clearly, as we only reduce the relative deadline and the periods, the timing parameters in $T^\dagger$ are more stringent than in $T$. Hence, a feasible task partition for $T^\dagger$ on $M$ processors also yields a corresponding feasible task partition for $T$ on $M$ processors. As $T^\dagger$ has implicit deadlines, we know that any task subset in $T^\dagger$ with total utilization no more than $100\%$ can be feasibly scheduled by EDF on a processor, and therefore the original tasks in that subset as well. For any greedy fitting algorithms that use $M$ processors, using the same proof as in [30, Chapter 8], we get $\sum_{\tau_i \in T^\dagger} C_{\tau_i} > \frac{M}{2\lambda}$.

By definition, we know that $\sum_{\tau_i \in T} C_{\tau_i} \geq \sum_{\tau_i \in T^\dagger} C_{\tau_i} > \frac{M}{2\lambda}$. Therefore, any feasible solution for $T$ uses at least $\frac{M}{2\lambda}$ processors and the approximation factor is hence proved. ▷

### 4 Deadline-Monotonic Partitioning under EDF Scheduling

This section presents the worst-case analysis of the deadline-monotonic partitioning strategy, proposed by Baruah and Fisher [3,4], for the multiprocessor partitioned packing problem. Note that the underlying scheduling algorithm is EDF but the tasks are considered in the deadline-monotonic (DM) order. Hence, in this section, we index the tasks accordingly from the shortest relative deadline to the longest, i.e., $D_i \leq D_j$ if $i < j$. Specifically, in the DM partitioning, the approximate demand bound function $db^* f(\tau_i, t)$ is used to approximate Eq. (1), where

$$db^* f(\tau_i, t) = \begin{cases} 0 & \text{if } t < D_i \\ \left(\frac{t - D_i}{C_i} + 1\right) C_i & \text{otherwise.} \end{cases}$$

(2)

Even though the DM partitioning algorithm in [3,4] is designed for the multiprocessor partitioned scheduling problem, it can be easily adapted to deal with the multiprocessor partitioned packing problem. For completeness, we revise the algorithm in [3,4] for the multiprocessor partitioned packing problem and present the pseudo-code in Algorithm 1. As discussed in [3,4], when a task $\tau_i$ is considered, a processor $m$ among the allocated processors where both the following conditions hold

$$C_i + \sum_{\tau_j \in T_m} db^* f(\tau_j, D_i) \leq D_i$$

(3)

$$u_i + \sum_{\tau_j \in T_m} u_j \leq 1$$

(4)

is selected to assign task $\tau_i$, where $T_m$ is the set of the tasks (as a subset of $\{\tau_1, \tau_2, \ldots, \tau_{i-1}\}$), which have been assigned to processor $m$ before considering $\tau_i$. If there is no $m$ where both Eq. (3) and Eq. (4) hold, a new processor is allocated and task $\tau_i$ is assigned to the new processor. The order in which the already allocated processors are considered depends on the fitting strategy:

- **first-fit (FF) strategy**: choosing the feasible $m$ with the minimum index;
- **best-fit (BF) strategy**: choosing, among the feasible processors, $m$ with the maximum approximate demand bound at time $D_i$;
Algorithm 1 Deadline-Monotonic Partitioning

Input: set $T$ of $N$ tasks;
1: re-index (sort) tasks such that $D_i \leq D_j$ for $i < j$;
2: $M \leftarrow 1$, $T_1 \leftarrow \{\tau_1\}$;
3: for $i = 2$ to $N$ do
4:   if $\exists m \in \{1, 2, \ldots, M\}$ such that both 3 and 4 hold then
5:      choose $m \in \{1, 2, \ldots, M\}$ by preference such that both 3 and 4 hold;
6:      assign $\tau_i$ to processor $m$ with $T_m \leftarrow T_m \cup \{\tau_i\}$;
7:   else
8:      $M \leftarrow M + 1$; $T_M \leftarrow \{\tau_i\}$;
9: end if
10: end for
11: return feasible task partition $T_1, T_2, \ldots, T_M$;

= worst-fit (WF) strategy: choosing $m$ with the minimum approximate demand bound at time $D_i$.

For a given number of processors, it has been proved in [10] that the speed-up factor of the DM partitioning is at most $3$, independent from the fitting strategy. However, if the objective is to minimize the number of allocated processors, we will show that DM partitioning has an approximation factor of at least $\frac{N}{3}$ (in the worst case) when the best-fit or worst-fit strategy is adopted. We will prove this by explicitly constructing two concrete task sets with this property. Afterwards, we show that the asymptotic approximation factor of DM partitioning is at most $\frac{N}{2}$ for packing, where $\gamma = \max_{\tau_i \in T} \frac{C_{\tau_i}}{\min(T, D_i)}$.

Theorem 3. The approximation factor of the deadline-monotonic partitioning algorithm with the best-fit strategy is at least $\frac{N}{3}$ when $N \geq 8$ and the schedulability test is based on Eq. (3) and Eq. (4).

Proof. The theorem is proven by providing a task set that can be scheduled on two processors but where Algorithm 1 when applying the best-fit strategy uses $\frac{N}{3}$ processors. Under the assumption that $K \geq 4$ is an integer, $N = 2K$, and $H$ is sufficiently large, i.e., $H \gg K^K$, such a task set can be constructed as:

- Let $D_1 = 1$, $C_1 = 1/K$, and $T_1 = H$.
- For $i = 2, 4, \ldots, 2K$, let $D_i = K^{i/2}$, $C_i = K^{i/2} - 2$, and $T_i = D_i$.
- For $i = 3, 5, \ldots, 2K - 1$, let $D_i = K^{i/2}$, $C_i = K^{i/2} - K^{i/2} - 1$, and $T_i = H$.

The task set can be scheduled on two processors under EDF if all tasks with an odd index are assigned to processor 1 and all tasks with an even index are assigned to processor 2. On the other hand, the best-fit strategy assigns $\tau_i$ to processor $\left\lfloor \frac{i}{2} \right\rfloor$. The resulting solution uses $K$ processors. Details are in the Appendix.

Theorem 4. The approximation factor of the deadline-monotonic partitioning algorithm with the worst-fit strategy is at least $\frac{N}{2}$ when the schedulability test is based on Eq. (3) and Eq. (4).

Proof. The proof is very similar to the proof of Theorem 3 considering the task set:

- Let $D_1 = 1$, $C_1 = 1$, and $T_1 = H$.
- For $i = 2, 4, \ldots, 2K$, let $D_i = K^{i/2}$, $C_i = K^{i/2} - 1$, and $T_i = D_i$.
- For $i = 3, 5, \ldots, 2K - 1$, let $D_i = K^{i/2}$, $C_i = K^{i/2} - K^{i/2} - 1$, and $T_i = H$.

Odd tasks are assigned to processor 1 and even tasks to processor 2 the task set is schedulable while $\tau_i$ is assigned to processor $\left\lfloor \frac{i}{2} \right\rfloor$ using the worst-fit strategy. Details are in the Appendix.

Theorem 5. The DM partitioning algorithm is an asymptotic $\frac{2}{\gamma}$-approximation algorithm for the multiprocessor partitioned packing problem, when $\gamma = \max_{\tau_i \in T} \frac{C_{\tau_i}}{\min(T, D_i)}$ and $\gamma < 1$. 

ISAAC 2018
Proof. We consider the task $\tau_l$ which is the task that is responsible for the last processor that is allocated by Algorithm 1. The other processors are categorized into two disjoint sets $M_1$ and $M_2$, depending on whether Eq. (3) or Eq. (4) is violated when Algorithm 1 tries to assign $\tau_l$ (if both conditions are violated, the processor is in $M_1$). The two sets are considered individually and the maximum number of processors in both sets is determined based on the minimum utilization for each of the processors. Afterwards, a necessary condition for the amount of processors that is at least needed for a feasible solution is provided and the relation between the two values proves the theorem. Details can be found in the Appendix.

5 Hardness of Approximations

It has been shown in [2] that a PTAS exists for augmenting the resources by speeding up. A straightforward question is to see whether such PTASes will be helpful for bounding the lower or upper bounds for multiprocessor partitioned packing. Unfortunately, the following theorem shows that using speeding up to get a lower bound for the number of required processors is not useful.

▶ Theorem 6. There exists a set of input instances, in which the number of allocated processors is up to $N$, while the task set can be feasibly scheduled by EDF with a speed-up factor $(1 + \epsilon)$ on a processor, where $0 < \epsilon < 1$.

Proof. We provide a set of input instances, with the property described in the statement:

- Let $D_1 = 1$, $C_1 = 1$, and $T_1 = \frac{(1+\epsilon)^N}{\epsilon}$.
- For any $i = 2, 3, \ldots, N$, let $D_i = \frac{(1+\epsilon)(N-i)}{\epsilon}$, $C_i = D_i$, and $T_i = \frac{(1+\epsilon)^{N-i}}{\epsilon}$.

Since $C_i = D_i$ for any task $\tau_i$, assigning any two tasks on the same processor is infeasible without speeding up. Therefore, the only feasible processor allocation is $N$ processors and to assign each task individually on one processor. However, by speeding up the system by a factor $1 + \epsilon$, the tasks can be feasibly scheduled on one processor due to $\sum_{i=1}^{N} \frac{d_b f(\tau_i, t)}{1+\epsilon} \leq t$ for any $t > 0$. A proof is in the Appendix. Hence, the gap between these two types of resource augmentation is up to $N$.

Moreover, the following theorem shows the inapproximability for a factor 2 without adopting asymptotic approximation.

▶ Theorem 7. For any $\epsilon > 0$, there is no polynomial-time approximation algorithm with an approximation factor of $2 - \epsilon$ for the multiprocessor partitioned packing problem, unless $P = NP$.

Proof. Suppose that there exists such a polynomial-time algorithm $A$ with approximation factor $2 - \epsilon$. $A$ can be used to decide if a task set $T$ is schedulable on a uniprocessor, which would contradict the coNP-hardness [17] of this problem. Indeed, we simply run $A$ on the input instance. If $A$ returns a feasible schedule using one processor, we already have a uniprocessor schedule. On the other hand, if $A$ requires at least two processors, then we know that any optimum solution needs $\geq \left\lceil \frac{2}{2-\epsilon} \right\rceil = 2$ processors, implying that the task set $T$ is not schedulable on a uniprocessor.

6 Non-Existence of APTAS for Constrained Deadlines

We now show that there is no APTAS when considering constrained-deadline task sets, unless $P = NP$. The proof is based on an L-reduction (informally an approximation preserving reduction) from a special case of the vector packing problem, i.e., the 2D dominated vector packing problem.
We now show that the packing problem is at least as hard as the 2D-DVP problem from a complexity with strictly constrained deadlines (based on vector $v$). This becomes problematic, as one dimension in the vectors in such input instances for the two-dimensional vector packing problem (2D-DVP) problem is a special case of the two-dimensional vector packing problem, and the implication for $v$ is a special case equivalent to the traditional bin-packing problem, which admits an APTAS. We will show that the two-dimensional dominated vector packing problem can be totally ignored, and the input instance becomes a special case of the two-dimensional vector packing problem with following conditions for each vector $v_i$.

Moreover, we further assume that $v_{i,1}$ and $v_{i,2}$ are rational numbers for every $v_i \in V$. Therefore, we will provide a proper $L$-reduction in Section 6.3 to show the non-existence of APTAS for the multiprocessor partitioned packing problem for tasks with constrained deadlines.

### 6.2 2D-DVP Problem and Packing Problem

We now show that the packing problem is at least as hard as the 2D-DVP problem from a complexity point of view. For vector $v_i$ with $v_{i,2} > v_{i,1}$, we create a corresponding task $\tau_i$ with

$$D_i = 1, \quad C_i = v_{i,2}, \quad T_i = \frac{v_{i,2}}{v_{i,1}}.$$ 

Clearly, $D_i < T_i$ for such tasks. Let $H$ be a common multiple, not necessary the least, of the periods $T_i$ of the tasks constructed above. By the assumption that all the values in the 2D-DVP problem are rational numbers and $v_{i,1} > 0$ for every vector $v_i$, we know that $H$ exists and can be calculated in $O(N)$. For vector $v_i$ with $v_{i,2} = 0$, we create a corresponding implicit-deadline task $\tau_i$ with

$$T_i = D_i = H, \quad C_i = v_{i,1}.$$
The following lemma shows the related schedulability condition.

**Lemma 10.** Suppose that the set \( T_m \) of tasks assigned on a processor consists of (1) strictly constrained-deadline tasks, denoted by \( T_m^\le \), with a common relative deadline \( 1 = D \) and (2) implicit-deadline tasks, i.e., \( T_m \setminus T_m^\le \), in which the period is a common integer multiple \( H \) of the periods of the strictly constrained-deadline tasks. EDF schedule is feasible for the set \( T_m \) of tasks on a processor if and only if

\[
\sum_{\tau_i \in T_m^\le} C_i \le 1 \quad \text{and} \quad \sum_{\tau_i \in T_m} u_i \le 1.
\]

**Proof.** Only if: This is straightforward as the task set cannot meet the timing constraint when \( \sum_{\tau_i \in T_m} \frac{C_i}{T_i} \ge 1 \) or \( \sum_{\tau_i \in T_m} u_i > 1 \).

If: If \( \sum_{\tau_i \in T_m^\le} \frac{C_i}{T_i} \le 1 \) and \( \sum_{\tau_i \in T_m} u_i \le 1 \), we know that when \( t < D \), then \( \sum_{\tau_i \in T_m} dbf(\tau_i, t) = 0 \). When \( D \le t < H \), we have

\[
\sum_{\tau_i \in T_m} dbf(\tau_i, t) = \sum_{\tau_i \in T_m^\le} \left( \left\lfloor \frac{t-D}{T_i} \right\rfloor + 1 \right) \times C_i \le \sum_{\tau_i \in T_m} \left( \frac{t-D}{T_i} + 1 \right) \times C_i
\]

\[
\le \sum_{\tau_i \in T_m^\le} C_i + (t-D)u_i \le D + (t-D) = t.
\]

Moreover, with \( \sum_{\tau_i \in T_m} u_i \le 1 \), we know that when \( t = H \)

\[
\sum_{\tau_i \in T_m} dbf(\tau_i, H) = \sum_{\tau_i \in T_m^\le} \left( \left\lfloor \frac{H-D}{T_i} \right\rfloor + 1 \right) \times C_i + \sum_{\tau_i \in T_m \setminus T_m^\le} \frac{H}{T_i} C_i
\]

\[
= 1 \sum_{\tau_i \in T_m^\le} \frac{H}{T_i} C_i + \sum_{\tau_i \in T_m \setminus T_m^\le} \frac{H}{T_i} C_i = H \left( \sum_{\tau_i \in T_m} u_i \right) \le H,
\]

where \( := 1 \) comes from the fact that \( \frac{H}{T_i} \) is an integer for any \( \tau_i \in T_m^\le \) and \( T_i > D > 0 \) so that \( \left\lfloor \frac{H-D}{T_i} \right\rfloor + 1 \) is equal to \( \frac{H}{T_i} \).

For any value \( t > H \), the value of \( \sum_{\tau_i \in T_m} dbf(\tau_i, t) \) is equal to \( \sum_{\tau_i \in T_m^\le} dbf(\tau_i, t-D) + \sum_{\tau_i \in T_m} dbf(\tau_i, H) \). Therefore, we know that if \( \sum_{\tau_i \in T_m} \frac{C_i}{T_i} \le 1 \) and \( \sum_{\tau_i \in T_m} u_i \le 1 \), the task set \( T_m \) can be feasibly scheduled by EDF.

**Theorem 11.** If there does not exist any APTAS for the 2D-DVP problem, unless \( P = \overline{NP} \), there also does not exist any APTAS for the multiprocessor partitioned packing problem with constrained-deadline task sets.

**Proof.** Clearly, the reduction in this section from the 2D-DVP problem to the multiprocessor partitioned packing problem with constrained deadlines is in polynomial time.

For a task subset \( T' \) of \( T \), suppose that \( V(T') \) is the set of the corresponding vectors that are used to create the task subset \( T' \). By Lemma 10, the subset \( T_m \) of the constructed tasks can be feasibly scheduled by EDF on a processor if and only if \( \sum_{\tau_i \in T_m^\le} C_i = \sum_{\tau_i \in V(T_m)} C_i \le 1 \) and \( \sum_{\tau_i \in T_m} u_i \le 1 \).

Therefore, it is clear that the above reduction is a perfect approximation preserving reduction. That is, an algorithm with a \( \rho \) (asymptotic) approximation factor for the multiprocessor partitioned packing problem can easily lead to a \( \rho \) (asymptotic) approximation factor for the 2D-DVP problem.
6.3 Hardness of the 2D-DVP problem

Based on Theorem 11, we are going to show that there does not exist APTAS for the 2D-DVP problem, which also proves the non-existence of APTAS for the multiprocessor partitioned packing problem with constrained deadlines.

**Theorem 12.** There does not exist any APTAS for the 2D-DVP problem, unless $P = NP$.

**Proof.** This is proved by an L-reduction, following a similar strategy in [31] by constructing an L-reduction from the Maximum Bounded 3-Dimensional Matching (MAX-3-DM), which is MAX SNP-complete [24]. Details are in the Appendix, where a short comment regarding an erroneous observation in [31] is also provided.

The following theorem results from Theorems 11 and 12.

**Theorem 13.** There does not exist any APTAS for the multiprocessor partitioned packing problem for constrained-deadline task sets, unless $P = NP$.

7 Concluding Remarks

This paper studies the partitioned multiprocessor packing problem to minimize the number of processors needed for multiprocessor partitioned scheduling. Interestingly, there turns out to be a huge difference (technically) in whether one is allowed faster processors or additional processors. Our results are summarized in Table 1. For general cases, the upper bound and lower bound for the first-fit strategy in the deadline-monotonic partitioning algorithm are both open. The focus of this paper is the multiprocessor partitioned packing problem. If global scheduling is allowed, in which a job can be executed on different processors, the problem of minimizing the number of processors has been also recently studied in a more general setting by Chen et al. [13, 14] and Im et al. [23]. They do not explore any periodicity of the job arrival patterns. Among them, the state-of-the-art online competitive algorithm has an approximation factor (more precisely, competitive factor) of $O(\log\log M)$ by Im et al. [23]. These results are unfortunately not applicable for the multiprocessor partitioned packing problem since the jobs of a sporadic task may be executed on different processors.

Appendix

Proofs related to Section 4

Proof of Theorem 3. We provide a task set that can be scheduled on two processors but where Algorithm 2 when applying the best-fit strategy uses $\frac{N}{2}$ processors. Let $K \geq 4$ be an integer, $N$ is 2$K$, and $H$ is sufficiently large, i.e., $H \gg K^2$. Let $D_1 = 1$, $C_1 = 1/K$, and $T_1 = H$.

For $i = 2, 4, \ldots, 2K$, let $D_i = K^{i-1}$, $C_i = K^{i-2}$, and $T_i = D_i$.

For $i = 3, 5, \ldots, 2K - 1$, let $D_i = K^{i-1}$, $C_i = K^{i-2} - K^{i-1}$, and $T_i = H$.

Hence, in this input instance, $D_1 = D_2 = 1, D_3 = D_4 = K, \ldots, D_{2K-1} = D_{2K} = K^{K-1}$. For the simplicity of presentation, we will omit any term multiplied with $1/H$ by assuming that this is positive and arbitrarily small. When applying DM partitioning, tasks $\tau_1$ and $\tau_2$ are both assigned on processor 1. Then, we know that at time $t \geq 1$, $dbf^*(\tau_1, t) + dbf^*(\tau_2, t) \approx \frac{1}{K} + \frac{1}{K}$. Clearly, $\tau_3, \tau_5, \tau_7, \ldots, \tau_{2K-1}$ are not eligible for processor 1, because for $i = 1, 2, \ldots, K - 1$ we have

$$C_{2i+1} + dbf^*(\tau_i, D_{2i+1}) + dbf^*(\tau_{2i+1}) \approx K^i - K^{i-1} + \frac{1}{K} + \frac{K^i}{K} > K^i = D_{2i+1}. \quad (6)$$

Therefore, $\tau_3$ is assigned on processor 2. When considering $\tau_4$, both processors are feasible, and processor 2 has a higher approximate demand at time $D_4$, i.e., $dbf^*(\tau_1, D_4) + dbf^*(\tau_2, D_4) \approx \frac{1}{K} + \frac{K}{K}$ and $dbf^*(\tau_3, D_4) = C_3 = K - 1$. Therefore, $\tau_4$ is assigned on processor 2 under the best-fit strategy. Similarly, $\tau_5, \tau_7, \ldots, \tau_{2K-1}$ are not eligible for processor 2, because for $i = 2, 3, \ldots, K - 1$ we have

$$C_{2i+1} + dbf^*(\tau_i, D_{2i+1}) + dbf^*(\tau_{2i+1}) \approx K^i - K^{i-1} + C_3 + \frac{K^i}{K} > K^i = D_{2i+1}. \quad (7)$$

When considering $\tau_6$, the allocated three processors are all feasible, but processor 3 has a higher approximate demand at time $D_6$. One can formally prove that task $\tau_{2i+1}$ is assigned to processor $i + 1$ because $C_{2i+1} + dbf^*(\tau_{2i+1}, D_{2i+1}) + dbf^*(\tau_{2i+2}, D_{2i+1}) > D_{2i+1}$ for any $j = 0, 1, \ldots, i - 1$. Moreover, since $dbf^*(\tau_{2i+1}, D_{2i+1}) + dbf^*(\tau_{2i+2}, D_{2i+2}) \approx C_{2i+1} + K^i/K < K^i - K^{i-1} = dbf^*(\tau_{2i+1}, D_{2i+2})$ for any $1 \leq i \leq K - 1$ and $j = 0, 1, \ldots, i - 1$ due to the assumption $K \geq 4$, we know that processor $i + 1$ has the highest approximate demand at time $D_{2i+2}$ among the first $i + 1$ (allocated) processors. Thus, task $\tau_{2i+2}$ is assigned to processor $i + 1$ due to the best-fit strategy. Therefore, we conclude that the best-fit strategy assigns $\tau_i$ to processor $\lceil \frac{i}{2} \rceil$. The resulting solution uses $K$ processors.

Now, consider the following task assignment, in which $\tau_i$ is assigned on processor 1 (resp., 2) if $i$ is an odd (resp. even) number. Let $T'_i$ be the set of tasks that are assigned on processor $i$. The assignment is feasible on processor 2, as all the tasks are with implicit deadlines, and the total utilization is 100%. The assignment is also feasible on processor 1 by verifying the schedulability by using $dbf$, i.e., the demand bound function without approximation! Since all tasks in $T'_i$ have the same period, we only have to verify $dbf$ at time 1, $K, K^2, K^3, \ldots, K^{K-1}$, in which $\sum_{\tau_i \in T'_i} dbf(\tau_i, K^k) = K^{k-1} - 1 + \frac{1}{K}$ for $k = 1, 2, \ldots, K - 1$.

We will now show that when $t > K^{K-1}$, the $dbf$ of $T'_i$ at time $t$ will still be no more than $t$, i.e., showing that $\sum_{\tau_i \in T'_i} dbf(\tau_i, t) \leq t, \forall t > 0$. Since the $N/2 = K$ tasks in $T'_i$ have the same period, for the simplicity of presentation, let $T$ be $H$ with $T \gg K^2$. We can divide the time interval $[0, \infty)$ into $[0, D_1), [D_1, D_3), \ldots, [D_{N-3}, D_{N-1}), [D_{N-1}, T), [T, T + D_1), [T + D_1, T + D_3), \ldots$. Suppose that $\ell$ is a non-negative integer and $j$ is an index $j \in \{1, 3, 5, \ldots, N - 1, N + 1\}$, where $t$
Packing Sporadic Real-Time Tasks on Identical Multiprocessor Systems

is in interval \([T + D_{j-2}, T + D_j]\). Here, \(D_{-1}\) is an auxiliary parameter set to 0 and \(D_{N+1}\) is an auxiliary parameter set to \(T\) for brevity.

Then, due to the parameters of task \(\tau_i\) and \(t \in [T + D_{j-2}, T + D_j]\), for task \(\tau_i \in T'_1\), we have \(dbf(\tau_i, t) = \ell(C_i + 2)\) if \(i < j\) and \(dbf(\tau_i, t) = \ell C_i\) if \(j \leq i \leq N\). As a result, when \(j \in \{5, 7, \ldots, N-1\}\) and \(t \in [T + D_{j-2}, T + D_j]\), we have

\[
\sum_{\tau_i \in T'_1} dbf(\tau_i, t) = \ell \left( \sum_{\tau_i \in T'_1} C_i + \sum_{\tau_i \in T'_1} \sum_{i < j} C_i \right) = \ell \left( \frac{1}{K} \sum_{i=1}^{K-1} K^i - K^{i-1} \right) + \frac{1}{K} \sum_{i=1}^{(j-2)/2} K^i - K^{i-1} \leq \ell T + D_{j-2}
\]

Moreover, when \(j = 1\), we have \(\sum_{\tau_i \in T'_1} dbf(\tau_i, t) = \ell (K^{K-1} - 1 + \frac{1}{K}) \leq \ell T\). When \(j = 3\), we have \(\sum_{\tau_i \in T'_1} dbf(\tau_i, t) = \ell (K^{K-1} - 1 + \frac{1}{K}) + \frac{1}{K} \leq \ell T + D_1\). When \(j = N + 1\), we have \(\sum_{\tau_i \in T'_1} dbf(\tau_i, t) = \ell (K^{K-1} - 1 + \frac{1}{K}) + K^{K-1} - 1 + \ell \frac{1}{K} \leq \ell T + D_{N-1}\). Therefore, we reach the conclusion that \(\sum_{\tau_i \in T'_1} dbf(\tau_i, t) \leq \ell T, \forall t > 0\).

Hence, there exists a feasible solution by using only 2 processors, but the DM partitioning algorithm under BF uses \(N/2\) processors.

Proof of Theorem 4 Suppose that \(K\) is an integer, \(N = 2K\), and \(H\) is sufficiently large, i.e., \(H > K\). Consider the following input task set:

- Let \(D_1 = 1, C_1 = 1,\) and \(T_1 = H\).
- For \(i = 2, 4, \ldots, 2K\), let \(D_i = K^\frac{i}{2}, C_i = K^\frac{i-1}{2},\) and \(T_i = D_i\).
- For \(i = 3, 5, \ldots, 2K - 1,\) let \(D_i = K^\frac{i}{2}, C_i = K^\frac{i}{2} - K^\frac{i-1}{2},\) and \(T_i = H\).

We know that \(D_2 = D_3 = K, D_4 = D_5 = K^2, \ldots, D_{2K-2} = D_{2K-1}\). The proof is very similar to that of Theorem 3. For the simplicity of presentation, we will omit any term multiplied with \(1/H\) by assuming that this is positive and arbitrarily small.

When applying DM partitioning, task \(\tau_1\) and \(\tau_2\) are both assigned on processor 1. One can formally prove that task \(\tau_{2i+1}\) is assigned to processor \(i + 1\) because \(C_{2i+1} + dbf^*(\tau_{2i+1}, D_{2i+1}) + dbf^*(\tau_{2i+2}, D_{2i+2}) > D_{2i+1}\) for any \(j = 0, 1, \ldots, i - 1\). Moreover, since \(dbf^*(\tau_{2j+1}, D_{2j+1}) + dbf^*(\tau_{2j+2}, D_{2j+2}) = C_{2j+1} + K^{i+1}/K > K^i - K^{i-1} \approx dbf^*(\tau_{2j+1}, D_{2j+2})\) for any \(1 \leq i \leq K - 1\) and \(j = 0, 1, \ldots, i - 1\), we know that processor \(i + 1\) has the lowest approximate demand at time \(D_{2i+2}\) among the first \(i + 1\) (allocated) processors. Therefore, task \(\tau_{2i+2}\) is assigned to processor \(i + 1\) due to the worst-fit strategy, and \(N/2\) processors are allocated.

Similarly, assigning \(\tau_i\) on processor 1 (resp., 2) if \(i\) is an odd (resp. even) number is a feasible solution using two processors.

Proof of Theorem 5 Suppose that the system allocates the last processor when considering a certain task \(\tau_i\). If \(\ell > 1\), the solution is optimal. We consider \(\ell \geq 2\). That is, when considering \(\tau_i\), for any \(m \in \{1, 2, \ldots, M\}\), either the condition in Eq. (3) or Eq. (4) is violated. Algorithm 1 hence uses \(M + 1\) processors and assigns task \(\tau_i\) to that processor.

The first \(M\) processors are categorized into two disjoint sets \(M_1\) and \(M_2\). For any \(m \in M_1\), the condition in Eq. (3) is violated. For any \(m \in M_2\), Eq. (3) holds but Eq. (4) is violated. Hence,

\[
Ct + \sum_{\tau_i \in T_m} dbf^*(\tau_i, D_t) > D_t, \quad \forall m \in M_1 \tag{8}
\]

\[
u_t + \sum_{\tau_i \in T_m} u_i > 1, \quad \forall m \in M_2. \tag{9}
\]
If $|M_1|$ is 0, by Eq. (8), we have $\sum_{\tau_i \in T} \frac{C_i}{T_i} > 1 - u_\ell \geq 1 - \gamma$, in which the asymptotic approximation factor for this case is $\frac{1}{1-\gamma} \leq \frac{2}{1-\gamma}$.

For the rest of the proof, we focus on the case that $|M_1| > 0$. Suppose that $|M_2|$ is $x|M_1|$, with $x \geq 0$ and $|M_1| > 0$. That is, $|M_1| = \frac{M}{1+x}$ and $|M_2| = \frac{Mx}{1+x}$. To prove the approximation factor, we will build the lower bound of $\sum_{\tau_i \in T} \frac{C_i}{T_i}$ and $\max_{t > 0} \sum_{\tau_i \in T} \frac{dbf(\tau_i, t)}{t}$. For notational brevity, we define the two parameters $\beta$ and $k$:

\[
\beta \equiv \frac{|M_1|C_\ell}{\sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell)} \quad (10)
\]
\[
k \equiv \frac{|M_1|D_\ell - (1 + \beta) \sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell)}{\sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell)} \quad (11)
\]
By definition, $\beta > 0$ and we also have

\[
\frac{\sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell)}{|M_1|D_\ell} = \frac{1}{1 + k + \beta} \quad (12)
\]
Moreover, since $M_1$ is not empty and $D_\ell > 0$, we also have $1 + k + \beta > 0$. By (12), we know that

\[
\max_{t > 0} \sum_{\tau_i \in T} \frac{dbf(\tau_i, t)}{t} \geq \frac{\sum_{\tau_i \in T} \frac{dbf(\tau_i, D_\ell)}{D_\ell}}{|M_1|D_\ell} \geq |M_1| \frac{\sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell)}{|M_1|D_\ell} = \frac{M}{(1 + x)(1 + k + \beta)} \quad (13)
\]

Based on (6), we know that

\[
|M_1|C_\ell + \sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell) > |M_1|D_\ell \quad \Rightarrow \quad D_\ell \leq D_\ell
\]
\[
\Rightarrow \sum_{m \in M_1} \sum_{\tau_i \in T_m} \frac{D_\ell}{T_i} C_i > |M_1|D_\ell - |M_1|C_\ell - \sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell) \quad \Rightarrow \sum_{m \in M_1} \sum_{\tau_i \in T_m} \frac{D_\ell}{T_i} C_i > k \sum_{m \in M_1} \sum_{\tau_i \in T_m} dbf(\tau_i, D_\ell) \quad (10) \quad (11)
\]
\[
\Rightarrow \sum_{\tau_i \in T} \frac{C_i}{T_i} > \sum_{m \in M_1} \sum_{\tau_i \in T_m} \frac{D_\ell}{T_i} C_i \geq k \sum_{m \in M_1} \sum_{\tau_i \in T_m} \frac{dbf(\tau_i, D_\ell)}{D_\ell} \geq \frac{Mk}{(1 + x)(1 + k + \beta)} \quad (13)
\]

By Eq. (9), Eq. (14), and with $\gamma \geq \frac{C_i}{\min\{T_i, D_\ell\}} \geq u_\ell$, we get

\[
\sum_{\tau_i \in T} \frac{C_i}{T_i} \geq \sum_{m \in M_2} \sum_{\tau_i \in T_m} u_i + \sum_{m \in M_1} \sum_{\tau_i \in T_m} u_i > (1 - u_\ell)|M_2| + \frac{Mk}{(1 + x)(1 + k + \beta)} \geq M \left( \frac{x}{1 + x}(1 - \gamma) + \frac{k}{(1 + x)(1 + k + \beta)} \right) \quad (15)
\]
Any feasible solution to pack the tasks in $T$ needs at least $\sum_{\tau_i \in T} \frac{C_i}{T_i}$ or $\max_{t > 0} \sum_{\tau_i \in T} \frac{dbf(\tau_i, t)}{t}$.
processors. Thus, for the lower bound of the number of required processors, by Eq. \((13)\) and Eq. \((15)\),

\[
\max \left\{ \max_{t \geq 0} \sum_{\tau_i \in T} \frac{dbf(\tau_i, t)}{t}, \sum_{\tau_i \in T} C_i \right\} \geq M \times \frac{1}{1 + x} \times \max \left\{ \frac{1}{1 + k + \beta}, x(1 - \gamma) + \frac{k}{1 + k + \beta} \right\} \geq 1 \quad \text{\(M \times \frac{1 - \gamma}{2} \geq 2\)}
\]

where \(\geq 1\) is because: 1) \(\frac{1}{1 + x} \) is a constant with respect to \(x\) and \(x(1 - \gamma) + \frac{k}{1 + k + \beta}\) is an increasing function with respect to \(x\), 2) their only intersection happens when \(x = \frac{(1 - \gamma)(1 + k + \beta) + 1}{1 + k + \beta}\), and 3) hence

\[
\left\{ \frac{M}{1 + x} \times \max \left\{ \frac{1}{1 + k + \beta}, x(1 - \gamma) + \frac{k}{1 + k + \beta} \right\} \right\} \geq \frac{M}{1 + x} \times \max \left\{ \frac{1}{1 + k + \beta}, 1 \right\} \geq \frac{M}{1 + x} \times \frac{1 + k + \beta}{1 + k + \beta} = M \times \frac{1}{T + 1 + k + \beta}.
\]

The inequality \(\geq 2\) is from the fact that \(\frac{1}{T + 1 + k + \beta}\) is equal to \(C_t / D_t\) by definition and is more than no more than \(\max_{\tau_i \in T} \min(C_i, D_i)\), defined as \(\gamma\), i.e., \(\frac{\beta}{T + 1 + k + \beta} \leq \gamma\), which implies that \(\beta - \gamma(1 + k + \beta) \leq 0\).

Hence, there must be at least \(\frac{1}{1 - \gamma} M\) processors in any feasible solution. Thus, the DM partitioning is an asymptotic \(\frac{1}{1 - \gamma}\)-approximation algorithm for the multiprocessor partitioning packing problem. \(\square\)

**Proofs related to Section 5**

**Proof of Theorem 6** of the property \(\sum_{i=1}^{N} \frac{dbf(\tau_i, t)}{1 + \epsilon} \leq t, \forall t > 0\). Since the \(N\) constructed tasks in the proof of Theorem 6 have the same period, for the simplicity of presentation, let \(T = \frac{(1 + \epsilon)^{N-2}}{\epsilon}\). We can divide the time interval \([0, \infty)\) into \([0, D_1), [D_1, D_2), \ldots, [D_{N-1}, D_N = T), [T + 0, T + D_1), [T + D_1, T + D_2), \ldots\). Suppose that \(\ell\) is a non-negative integer and \(j\) is an index \(j \in \{1, 2, 3, \ldots, N\}\), where \(t\) is in interval \([\ell T + D_{j-1}, \ell T + D_j)\). Here, \(D_0\) is an auxiliary parameter set to 0 for brevity.

Then, due to the parameters of task \(\tau_i\) and \(t \in [\ell T + D_{j-1}, \ell T + D_j)\), we have \(dbf(\tau_i, t) = (\ell + 1)C_i\) if \(i < j\) and \(dbf(\tau_i, t) = \ell C_i\) if \(j \leq i \leq N\). As a result, when \(j \in \{3, 4, \ldots, N\}\) and \(t \in [\ell T + D_{j-1}, \ell T + D_j)\), we have

\[
\sum_{i=1}^{N} \frac{dbf(\tau_i, t)}{1 + \epsilon} = \left( \ell \sum_{i=1}^{N} \frac{C_i}{1 + \epsilon} \right) + \sum_{i=2}^{j-1} \frac{C_i}{1 + \epsilon} = \frac{\ell}{1 + \epsilon} \left( 1 + \sum_{i=1}^{N} C_i \right) + \frac{1}{1 + \epsilon} \left( 1 + \sum_{i=2}^{j-1} C_i \right)
\]

\[
= \frac{\ell}{1 + \epsilon} \left( 1 + \sum_{i=2}^{N} \frac{1}{1 + \epsilon} \left( 1 + \epsilon \right)^{-2} \right) + \frac{1}{1 + \epsilon} \left( 1 + \sum_{i=2}^{j-1} \frac{1}{1 + \epsilon} \left( 1 + \epsilon \right)^{-2} \right)
\]

\[
= \frac{\ell}{1 + \epsilon} \left( \frac{(1 + \epsilon)^{N-2} - 1}{\epsilon^{-1}} \right) + \frac{1}{1 + \epsilon} \left( \frac{(1 + \epsilon)^{j-2} - 1}{\epsilon^{-1}} \right)
\]

\[
= \frac{\ell}{1 + \epsilon} \left( \frac{(1 + \epsilon)^{N-2}}{\epsilon^{N-1}} \right) + \frac{1}{1 + \epsilon} \left( \frac{(1 + \epsilon)^{j-2}}{\epsilon^{j-2}} \right)
\]

\[
= \ell T + D_{j-1} \leq t
\]

where \(= 1\) is due to the geometric sequence \(C_2, C_3, \ldots, C_N\).

Similarly, when \(j = 1\), we have \(\sum_{i=1}^{N} \frac{dbf(\tau_i, t)}{1 + \epsilon} = \ell T \leq t\) and when \(j = 2\) we have \(\sum_{i=1}^{N} \frac{dbf(\tau_i, t)}{1 + \epsilon} = \ell T + 1 \leq t\). Therefore, we reach the conclusion that \(\sum_{i=1}^{N} \frac{dbf(\tau_i, t)}{1 + \epsilon} \leq t, \forall t > 0\). \(\square\)
Comments on the Error in [31] regarding non-existence of an APTAS for the two-dimensional vector packing problem

We also find that the proof for the non-existence of an APTAS for the two-dimensional vector packing problem is erroneous in [31]. By using the same terminologies in [31], here we explain this below. The error comes from a mistake in Observation 4 in [31] for the feasibility to pack any arbitrary three vectors into a unit-bin. The correct observation is that 3 vectors can only be arbitrarily packed into a unit-bin if at most two are from \( T \). By putting 3 vectors generated from \( T \) in one unit-bin, the sum in the first dimension will exceed 1. Therefore, for the only-if part in the proof of Lemma 5 in [31], it may require more than \( \frac{3q + |T|}{4} \) unit-bins for packing the remaining \( 3q + |T| - 4\alpha \) vectors in \( U \). As a result, the vectors should be created more carefully as we will show in Section 6.3. By scaling the first dimension by a factor \( \frac{4}{3} \) in vectors in \( V \) and excluding the dummy vectors corresponding \( W \) from \( V \) in Section 6.3, it can be shown that the statement in Lemma 5 in [31] can hold, and the hardness property for the two-dimensional vector packing problem can be proved.

Proofs related to Section 6.3

Our proof strategy is shown in Figure 1. The first step of our L-reduction follows a similar strategy in [31] by constructing an L-reduction from the Maximum Bounded 3-Dimensional Matching (MAX-3-DM), which is MAX SNP-complete [24]. The MAX-3-DM problem is defined as follows: We are given three sets \( X = \{x_1, \ldots, x_q\} \), \( Y = \{y_1, \ldots, y_q\} \), \( Z = \{z_1, \ldots, z_q\} \) and a subset \( S \subseteq X \times Y \times Z \) so that each element in \( X, Y, Z \) occurs in one, two, or three triples in \( S \), i.e., \( q \leq |S| \leq 3q \). The goal is to find a maximum cardinality subset \( S' \) of \( S \) such that no two triples in \( S' \) agree in any coordinate.

We denote the input instance for the MAX-3-DM problem by \( I \) and the optimal solution is with cardinality \( \text{OPT}(I) \). In our proof, we will use Observation 1 and Observation 2 from Woeginger in [31], restated here in Lemma 14 and Lemma 15.

\( \text{Lemma 14 (Observation 1 from Woeginger in [31]). The cardinality } \text{OPT}(I) \text{ of an optimal solution for any input instance } I \text{ of the MAX-3-DM problem is at least } \frac{7}{4}. \)

For an input instance of the MAX-3-DM problem, let

\[
\begin{align*}
x_i' &= ir + 1, & 1 \leq i \leq q, \\
y_i' &= i^2 + 2, & 1 \leq i \leq q, \\
z_i' &= i^3 + 4, & 1 \leq i \leq q.
\end{align*}
\]
where \( r = 32q \). For a triple \((x_i, y_j, z_k)\) in \( S \), we define
\[
s'_i = r^4 - kr^3 - jr^2 - ir + 8.
\]

Let \( Q \) be the set of the above \( 3q + |S| \) integers, \( x'_i, y'_j, z'_k, s'_i \). Moreover, let \( b = r^4 + 15 \). Resulting from this, we get:

\[\textbf{Lemma 15 (Observation 2 from Woeginger in [31]).} \text{ Four integers in } Q \text{ sum up to the value } b \text{ if and only if (1) one of them corresponds to some element } x_i \in X, \text{ one of them corresponds to some element } y_j \in Y, \text{ one of them corresponds to some element } z_k \in Z, \text{ and one of them corresponds to some triple } s_i \in S, \text{ and if (2) } s_i = (x_i, y_j, z_k) \text{ holds for these four elements.} \]

\[\textbf{Proof.} \text{ This property is the same as the Observation 2 in [31]. We provide a more comprehensive proof here.}

The if part is due to the definition of \( s'_i \). The only-if part comes from the working modulo \( r \), modulo \( r^2 \), modulo \( r^3 \), and modulo \( r^4 \), a slightly updated and changed version of an argument from [20], page 98, detailed as follows:

- We denote the four integers in \( Q \) sum up to \( b = r^4 + 15 \) as \( q_1, q_2, q_3, q_4 \), i.e., \( \sum_{h=1}^{4} q_h = r^4 + 15 \).
- By the definition of \( x'_i, y'_j, z'_k, s'_i \), we know that \( (q_h \text{ modulo } r) \) is either 1, 2, 4, or 8 for \( h \in [1, 2, 3, 4] \). Moreover, \( 15 = (b \text{ modulo } r) = (\sum_{h=1}^{4} q_h \text{ modulo } r) \), wherever the last equality is due to the fact that \( r = 32q \geq 32 \) and \( (q_h \text{ modulo } r) \leq 8 \). We can now enumerate all the combinations of the 4 values \( q_1, q_2, q_3, q_4 \). The only possibility to achieve \( 15 = \sum_{h=1}^{4} (q_h \text{ modulo } r) \) is that each of the four integers \( q_1, q_2, q_3, q_4 \) exactly corresponds to one element in \( X, Y, Z, \) and \( S \), respectively. This proves the first part of the proof.

- Therefore, without loss of generality, we consider that \( q_1 = x'_i, q_2 = y'_j, q_3 = z'_k, \) and \( q_4 = s'_i \) defined by a triple \((x_i, y_j, z_k, s_i)\) in \( S \). To prove the second part of the lemma, we need to show that \( i^* \) equals to \( i, j^* \) equals to \( j, \) and \( k^* \) equals to \( k \).

- We consider the modulo \( r^2 \). We have \( (b \text{ modulo } r^2) = 15, (q_1 \text{ modulo } r^2) = x'_i, (q_2 \text{ modulo } r^2) = 2, (q_3 \text{ modulo } r^2) = 4, \) and \( (q_4 \text{ modulo } r^2) = r^2 - i^*r + 8 \). Therefore, \( (x'_i + 2 + 4 + r^2 - i^*r + 8) \text{ modulo } r^2 = 15 \), which implies \( (x'_i + 2 + 4 + r^2 - i^*r + 8) \text{ modulo } r^2 = 0 \). Since \( 1 \leq i^* \leq q, 1 \leq i \leq q, \) and \( r = 32q \), we know that \( i^* \neq i \) results in \( (r^2 - i^*r + 8) \text{ modulo } r^2 \neq 0 \). Therefore, \( i^* \) must be equal to \( i \).

- The modulo \( r^3 \) with the same step above ensures that \( j^* \) is equal to \( j \).

- The modulo \( r^4 \) with the same step above ensures that \( k^* \) is equal to \( k \).

We therefore reach the conclusion of the lemma. \[\]

The integers in \( Q \) are defined as the same as in [31]. However, the constructed (reduced) two-dimensional vectors have to be carefully designed to be a feasible input instance for the 2D-DVP problem, whereas the hardness remains. Therefore, the rest of the proof is different from [31]. For illustrating the proof strategy, Fig. 1 provides a short summary. The reduced input instance for the 2D-DVP problem is to first create \( 3q + |S| \) two-dimensional vectors as follows:

\[
\begin{align*}
v_i &= (0.18 + \frac{3x'_i}{4 \cdot 5b}, 0.26 - \frac{y'_j}{5b}), & 1 \leq i \leq q, \tag{16a} \\
v_{i+q} &= (0.18 + \frac{3y'_j}{4 \cdot 5b}, 0.26 - \frac{y'_j}{5b}), & 1 \leq i \leq q, \tag{16b} \\
v_{i+2q} &= (0.18 + \frac{3z'_k}{4 \cdot 5b}, 0.26 - \frac{z'_k}{5b}), & 1 \leq i \leq q, \tag{16c} \\
v_{i+3q} &= (0.06 + \frac{3s'_i}{4 \cdot 5b}, 0.42 - \frac{s'_i}{5b}), & 1 \leq i \leq |S|. \tag{16d}
\end{align*}
\]

\( (q_4 \text{ modulo } r^2) = r^2 - i^*r + 8 \) is due to the fact \(-i^*r + 8 < 0 \) since \( i^* > 0 \) and \( r = 32q \geq 1 \).
For the simplicity of presentation, we say that a vector \( v_i \) corresponds to set \( X, Y, Z \), or \( S \) if the vector is constructed according to an element in the corresponding set. Moreover, we create additional \(|S|\) vectors that are invariant. Accordingly, we say that these vectors are corresponding to a dummy vector set \( W \), where \(|W| = |S|\):

\[
v_{i+3q+|S|} = (0.25, 0), \quad 1 \leq i \leq |W|.
\]

We use \( V \) to denote the set of the reduced vectors that are constructed above. The following lemma shows that the above construction makes the vectors corresponding to \( X, Y, \) and \( Z \) almost similar to each other and different from the vectors corresponding to \( S \).

▶ **Lemma 16.** For a vector \( v_i \) in \( V \),

1. \( 0.18 < v_{i,1} < 0.185 \) and \( 0.25374 < v_{i,2} < 0.26 \) if \( v_i \) corresponds to \( X, Y, \) or \( Z \);

2. \( 0.205 < v_{i,1} < 0.21 \) and \( 0.22 < v_{i,2} < 0.2265 \) if \( v_i \) corresponds to \( S \).

**Proof.** By definitions with \( q \geq 1 \), we know that

\[
0 < x_i' < \frac{q \cdot 32q + 1}{5 \times (32q)^4} < 0.0000063, \quad (17)
\]

\[
0 < y_i' < \frac{q \cdot (32q)^2 + 2}{5 \times (32q)^4} < 0.0002, \quad (18)
\]

\[
0 < z_i' < \frac{q \cdot (32q)^3 + 4}{5 \times (32q)^4} < 0.00626. \quad (19)
\]

Moreover, we have

\[
0.2 > s_i' = \frac{(32q)^4 - q \cdot (32q)^3 - q \cdot (32q)^2 - q \cdot 32q + 8}{5 \times ((32q)^4 + 15)} > 0.1935. \quad (20)
\]

Therefore, by taking the above inequalities and the definition of vectors in \( V \), the statement in the lemma is simple arithmetic. ▶

▶ **Lemma 17.** The constructed input instance above from an input instance of the MAX-3-DM problem is a feasible input of the 2D-DVP problem

**Proof.** By construction \( v_{i,1} > 0 \) for any constructed \( v_i \). Based on Lemma 16 we know that \( v_{i,2} > v_{i,1} \) holds for a vector \( v_i \) corresponding to set \( X, Y, Z \), or \( S \), whereas for a vector \( v_i \) corresponding to set \( W \) we know that \( v_{i,2} = 0 \). Moreover, since \( x_i', y_i', z_i', s_i', b \) are positive integers, we also know that \( v_{i,1} \) and \( v_{i,2} \) are rational numbers by our constructions. Hence, \( V \) is a feasible input instance for the 2D-DVP problem. ▶

Now, we can show the hardness due to the vector set \( V \). The following lemmas (Lemma 18 to Lemma 21) are based on numerical properties of the construction of \( V \), considering to pack 6 vectors, 5 vectors, and 4 vectors into a bin.

▶ **Lemma 18.** Any six vectors in \( V \) cannot be feasibly packed into a bin.

**Proof.** The first dimension is at least 0.18 for each vector. ▶

▶ **Lemma 19.** If five vectors in \( V \) can be feasibly packed into a bin, then the following three properties hold:

1. at most one vector corresponds to \( W \),
2. at most three vectors correspond to \( X, Y, \) or \( Z, \) and
3. at most one vector corresponds to \( S. \)

**Proof.** This follows from the numerical properties in Lemma 16.

**Property 1:** Suppose two vectors are from \( W. \) The other three vectors cannot exceed 0.5 in the first dimension. However, as any vector \( v_i \) corresponding to \( X, Y, Z, \) or \( S \) has \( v_{i,1} > 0.18, \) we reach a contradiction. For 3, 4, and 5 vectors in \( W, \) the proof is identical.

**Property 2:** As the second dimension for any vector corresponding to \( X, Y, \) or \( Z \) is larger than 0.25, if there are more than three vectors of these vectors, the second dimension will be more than 1.

**Property 3:** Suppose that there are \( \ell \in \{2, 3, 4, 5\} \) vectors from \( S \) for contradiction. By property 1, we only have to consider whether a vector from \( W \) is one of the five vectors or not. Therefore, there are two sub-cases. (Sub-case 1:) If all the other \( 5 - \ell \) vectors are corresponding to \( X, Y, Z, \) (i.e., none of them corresponds to \( W \)), the sum in the second dimension is more than 0.25374 \times (5 - \ell) + 0.22 \times \ell > 1.10. (Sub-case 2:) If one vector corresponds to \( W, \) and other \( 4 - \ell \) vectors correspond to \( X, Y, \) or \( Z, \) then the sum in the first dimension is more than 0.18 \times (4 - \ell) + 0.205 \times \ell + 0.25 \geq 1.02 \) for \( \ell = 2, 3, 4. \) Therefore, the third property holds. \( \blacktriangleleft \)

**Lemma 20.** Five vectors in \( V \) can be feasibly packed into a bin if and only if (1) one of them corresponds to some element \( x_i \in X, \) one of them corresponds to some element \( y_j \in Y, \) one of them corresponds to some element \( z_k \in Z, \) one of them corresponds to some element in \( W, \) and one of them corresponds to some triple \( s_t \in S, \) and (2) \( s_t = (x_i, y_j, z_k) \) holds for the elements from \( X, Y, Z, S. \)

**Proof.** The if-part is based on the definition. We focus on the only-if part. Based on Lemma 19, to feasibly pack 5 vectors, denoted here as \( V', \) three of them correspond to \( X, Y, Z, \) one corresponds to \( S, \) and one corresponds to \( W. \) We know that \( \sum_{v_i \in V'} v_{i,1} \leq 1 \) and \( \sum_{v_i \in V'} v_{i,2} \leq 1. \) Let \( \sigma \) be the sum of the four integers in \( Q \) that are used to construct the vectors from \( X, Y, Z, S \) in \( V'. \)

As a result, we know that \( \sum_{v_i \in V'} v_{i,1} = 0.85 + \frac{3\sigma}{4}, \) which implies \( \sigma \leq b. \) Similarly, we have \( \sum_{v_i \in V'} v_{i,2} = 1.2 - \frac{\sigma}{25}, \) which implies \( \sigma \geq b. \) Hence, \( \sigma = b \) must hold. Therefore, the observation in Lemma 15 yields the only-if part. \( \blacktriangleleft \)

**Lemma 21.** Four vectors in \( V \) can be feasibly packed into a bin if 1) exactly three of them correspond to elements in \( X \cup Y \cup Z \) and one of them corresponds to an element in \( W, \) or 2) four of them correspond to elements in \( S \cup W. \)

**Proof.** These properties are based on the numerical inequalities in Lemma 16. Let the \( V' \) be the set of the four vectors. For the first case, we have \( \sum_{v_i \in V'} v_{i,1} < 0.185 \times 3 + 0.25 = 0.805 \leq 1 \) and \( \sum_{v_i \in V'} v_{i,2} < 0.26 \times 3 + 0 = 0.78 \leq 1. \) For the second case, we have \( \sum_{v_i \in V'} v_{i,1} \leq 0.21 \times (4 - \ell) + 0.25 \times \ell \leq 1 \) and \( \sum_{v_i \in V'} v_{i,2} \leq 0.2265 \times (4 - \ell) + 0 \leq 1, \) where \( \ell \) is the number of vectors in \( V' \) that corresponds to \( W \) and \( 0 \leq \ell \leq 4. \) \( \blacktriangleleft \)

Based on the above lemmas, the following lemma provides a connection between the feasible solutions of the MAX-3-DM problem and the multiprocessor partitioned packing problem.

**Lemma 22.** Let \( \eta > 0 \) be an integer such that \( \frac{3\eta + 2|S| - \eta}{4} \) is an integer. There exists a feasible solution for the input instance \( I \) of the MAX-3-DM problem that contains at least \( \eta \) triples if and only if there exists a feasible packing for reduced input instance \( V \) of the 2D-DVP problem that uses at most \( \frac{3\eta + 2|S| - \eta}{4} \) bins.

**Proof.** **only-if:** Let \( S' \) with \( |S'| = \eta \) be the feasible solution of the MAX-3-DM problem. Based on Lemma 20, we know that we can feasibly pack \( 5\eta \) vectors among the \( 3\eta + 2|S| \) vectors in \( V \) by using \( \eta \) bins, in which \( \eta \) vectors corresponding to \( W, \) \( \eta \) vectors corresponding to \( S, \) and \( 3\eta \) vectors
corresponding to \( X, Y, \) and \( Z \) are chosen. Note that by definition \( \eta \) is at most \( q \). For the remaining \( 3(q - \eta) \) vectors corresponding to \( X, Y, \) or \( Z \), we can group three of them by using \( (q - \eta) \) bins. For each of these \( (q - \eta) \) bins, based on Lemma 21 and the fact that \( |W| = |S| \geq q \), we can additionally assign one remaining vector corresponding to \( W \) such that these four vectors (one corresponding to \( W \), and three corresponding to \( X, Y, \) or \( Z \)) can be feasibly packed in one bin. Again, based on Lemma 21 for the remaining \( (|S| - \eta) \) vectors corresponding to \( S \) and \( (|W| - q = |S| - q) \) vectors corresponding to \( W \), we can feasibly pack any four of them in a bin. Therefore, the above packing is feasible and requires exactly

\[
\frac{3q + 2|S| - 5\eta}{4} + \eta = \frac{3q + 2|S| - \eta}{4}
\]

bins, which is valid since \( \frac{3q + 2|S| - \eta}{4} \) is assumed to be an integer.

**Proof of Theorem 12.** Consider any input instance \( I \) for the MAX-3-DM problem. Suppose that there exists an APTAS, called Algorithm \( A \), for the 2D-DVP problem for contradiction. We will show that this will contradict the MAX SNP-completeness of the MAX-3-DM problem [24]. That is, unless \( P = \mathcal{N}ackslash P \), there does not exist any polynomial time approximation algorithm \( A' \) for the MAX-3-DM problem with

\[
A'(I) \geq (1 - \epsilon)OPT(I),
\]

for an arbitrarily small real \( \epsilon > 0 \), where \( A'(I) \) is the number of triples in the solution derived from \( A' \). We also define \( \delta \) as \( \frac{\epsilon}{6q} \). Suppose that Algorithm \( A \) has an asymptotic guarantee to provide the following asymptotic approximation factor

\[
A(V) \leq (1 + \delta)OPT(V) + \alpha^*, \tag{22}
\]

where \( A(V) \) is the number of bins derived from Algorithm \( A \) for input instance \( V \), \( OPT(V) \) is the optimal solution of the 2D-DVP problem for input instance \( V \), and \( \alpha^* \) is a constant. By definition, \( A(V) \) is a positive integer.

If the maximum cardinality of a feasible \( S' \) is small, the input instance \( I \) can be solved by checking all possible subsets of \( S \) with constant-bounded cardinalities. That is, if there does not exist any feasible solution \( S' \subseteq S \) with \( |S'| = \frac{3q + 2|S| - \eta}{4} \), checking all possible subsets \( S' \) of \( S \) with cardinality up to \( \frac{3q + 2|S| - \eta}{4} \) only takes polynomial time. Thus, if \( OPT(I) < \frac{3q + 2|S| - \eta}{4} \), the optimal solution of input instance \( I \) can be determined in polynomial time.

Now, we move to the remaining case that

\[
OPT(I) \geq \frac{4}{\delta}(1 + \delta + \alpha^*). \tag{23}
\]

The L-reduction by constructing \( V \) for the 2D-DVP problem from the input instance \( I \) of the MAX-3-DM problem can be done in polynomial time. Then, based on a result from Algorithm \( A \) to solve the input instance \( V \), we determine an integer \( \eta \) with

\[
\eta = 3q + 2|S| - 4A(V). \tag{24}
\]

Equivalent to (24), we know
\[ A(V) = \frac{3q + 2|S| - \eta}{4}. \]  
(25)

Due to Lemma \ref{lemma:eta}, we also know that in the feasible solution derived from Algorithm \( A \), there must be at least \( \eta \) bins with exactly five vectors in \( V \). We can construct a feasible solution \( S' \) for the input instance \( I \) of the MAX-3-DM problem with cardinality equal to \( \eta \), i.e., \(|S'| = \eta \geq \text{OPT}(I)\). According to the proof for the only-if part of Lemma \ref{lemma:eta}, the construction of \( S' \) takes only polynomial time.

We re-organizing \( \frac{3q + 2|S| - \eta}{4} \leq (1 + \delta)\text{OPT}(I) + \alpha^* \) in Eq. (27):

\[
\text{OPT}(I) \leq (1 + \delta) \left( \frac{3q + 2|S| - \text{OPT}(I)}{4} + 1 \right) + \alpha^* \]

(27)

Now, we reach the approximation factor of the feasible solution \( S' \) for the input instance \( I \) of the MAX-3-DM problem, in which

\[
(1 - \epsilon)\text{OPT}(I) \leq \eta = |S'|. \]

(29)

Hence, the MAX-3-DM problem, which is MAX-SNP-complete, can be solved in polynomial time with any approximation factor \( 1 - \epsilon \) for any fixed \( \epsilon \) with \( 0 < \epsilon < 1 \). Therefore, this concludes that \( \mathcal{P} = \mathcal{NP} \), which contradicts the assumption \( \mathcal{P} \neq \mathcal{NP} \).
