The redshift evolution of the growth rate of the gravitational potential, \(dD/a/dz\), is an excellent discriminator of dark energy parameters and, in principle, more powerful than standard classical tests of cosmology. This evolution is directly observable through the integrated Sachs-Wolfe effect in cosmic microwave background (CMB) anisotropies. We consider the prospects of measuring the growth rate via a novel method employed through measurements of CMB polarization towards galaxy clusters. The potentially achievable errors on dark energy parameters are comparable and fully complementary to those expected from other upcoming tests of dark energy, making this test a highly promising tool of precision cosmology.

One of the key issues in modern cosmology is developing efficient and complementary methods to measure cosmological parameters and cosmological functions. In particular, much interest has been devoted to developing methods to constrain the properties of the mysterious dark energy component that causes the recently discovered accelerated expansion of the universe [1]. To this end, it has been pointed out that type Ia supernovae, number counts, and weak gravitational lensing are all end, it has been pointed out that type Ia supernovae, number counts, and weak gravitational lensing are all

entering into measurements that provide information since it is a function which plagues large scale temperature anisotropy measurements. To make this study practical, we consider the prospects of upcoming arcminute scale CMB polarization observations with instruments such as the South Pole Telescope (SPT) and the planned CMBPol satellite mission.

To begin, we review aspects related to the growth of large scale structure. In linear theory, all Fourier modes of the density perturbation, \(\delta(\equiv \delta\rho_M/\rho_M)\), grow at the same rate: \(\delta_k(a) = D(a)\delta_k(a = 1)\), where \(D(a)\) is the growth factor normalized to unity today and \(a = (1+z)^{-1}\) is the scale factor. In the matter-dominated era \(D(a) = a\), while in the presence of a smooth dark energy component perturbation growth slows and \(D(a)\) increases less rapidly with \(a\). In general, the growth function can be computed by solving the linear perturbation equation \(\ddot{\delta}_k + 2a(\dot{a})\dot{a}\delta_k - 4\pi G\rho_M\delta_k = 0\) where dot is the derivative with respect to physical time.

Defining the growth suppression rate (growth rate relative to that in a flat, matter-dominated universe) as \(g(a) \equiv D(a)/a\), and still allowing for a general \(w(a)\), one can write

\[
2\frac{d^2g}{d\ln a^2} + \left[5 - 3w(a)\Omega_{DE}(a)\right] \frac{dg}{d\ln a} + 3[1 - w(a)] \Omega_{DE}(a)g = 0,
\]

where \(\Omega_{DE}(a)\) is the fractional dark energy density at the scale factor \(a\). For constant \(w\), the solution is given in terms of the hypergeometric function [4], while to compute \(g(a)\) and/or \(D(a)\) for a non-constant \(w(a)\) one can either solve Eq. (1) numerically or use analytic approximations [5].

It has long been known that the growth function strongly depends on \(\Omega_M\), the fractional density in matter, and \(w\). Also, the strength of several cosmological tests, such as number counts [6], clustering measured in redshift slices [7] and weak lensing [8] comes primarily from their dependence on the growth function \(D(z)\). On the other
hand, it has been known that redshift or time derivatives of distance are more directly related to dark energy parameters; in particular, the equation of state \( w(z) \) is directly related to the first and second derivatives of distance with respect to redshift \( \dot{r}(z) \). Unfortunately, the derivatives are not directly measured but are obtained by taking numerical derivatives of noisy data, which significantly increases the error in the reconstructed \( w(z) \).

It is interesting to examine the sensitivity of the rate of change of the growth suppression factor to \( \Omega_M \) and \( w \). To do this, we first consider constant \( w \), and then a two-parameter description of time-varying \( w \). For the latter we do not choose the commonly used \( w(z) = w_0 + w' z \) [16], but rather \( w(z) = w_0 + w_a z/(1 + z) \) [17] which is bounded at high redshift and facilitates the integration of Eq. [16]. For \( w' \) aficionados, we mention that the error in \( w_a \) is roughly twice the error in \( w' \). Fig. [1] shows the error bars in the \( \Omega_M - w \) plane (top) and \( w_0 - w_a \) plane (bottom) using various classical tests assuming a fiducial model of \( \Omega_M = 0.3 \) and \( w = -1 \); we use the same fiducial model throughout the paper. The calculation uses the Fisher matrix formalism and assumes 10% measurements in a given quantity at each interval of \( \Delta z = 0.1 \) in redshift between \( z = 0.1 \) and \( z = 2 \). We show a variety of quantities, including the distance \( r(z) \), the volume element \( r^2(z)/H(z) \) and the growth factor \( D(z) \), which are the most commonly considered probes of dark energy. We also consider \( dD/d\eta \) (\( \eta \) is conformal time) and \( dg/dz \). As emphasized in Ref. [12], \( dD/d\eta \), which is measured by large-scale velocities, is mostly sensitive to \( \Omega_M \) and not \( w \). What Fig. [1] illustrates is that \( dg/dz \) is much more powerful than other probes due to the specific way the degeneracy is broken. For example, for the same relative accuracy in observations, \( dg/dz \) is about 15 times stronger than the comoving distance \( r(z) \)!

Of course, this comparison is not necessarily fair, since enormous amount of work has gone into developing methods to determine distances, which are now expected to be measurable to an accuracy of about 1% (per interval of 0.1 in redshift) by SNAP [13], making them the most direct probes of the cosmological expansion history, while not much attention has been devoted to the more esoteric quantity \( dg/dz \). In the remainder of this paper we show that there indeed exists a very promising cosmological test which is sensitive to \( dg/dz \).

The above discussion indicates that it would be ideal to have a cosmological probe of the evolution of growth suppression, \( dg/dz \). It turns out that just such a probe exists in a universe that is not matter-dominated at late times. The dark energy domination causes the time-variation of the gravitational potential, which in turn contributes to CMB anisotropies through the ISW effect [3]. The resulting temperature fluctuation is given by

\[
\Delta T^{\text{ISW}}(\hat{n}) = -2 \int_0^{r_{\text{rec}}} dr' \frac{d\Phi(r')}{dr'} ,
\]

where \( r_{\text{rec}} \) is the radial comoving distance to last scattering with \( z_{\text{rec}} = 1100 \). From Poisson’s equation, \( \nabla^2 \Phi = 3/2 H_0^2 \Omega_M (\delta/a) \), it follows that the gravitational potential \( \Phi \) is proportional to the growth suppression \( g \). The ISW effect therefore gives a direct measure of the integral of \( dg/dr \) (or \( dg/dz \)) computed over some effective time (or redshift) interval.

While the ISW effect determined at the present time can be used as a probe of dark energy [14], its contribution to CMB temperature fluctuations is dwarfed by the primordial anisotropy contribution at last scattering. Though the cross-correlation between the large scale structure and CMB anisotropies fluctuation has been considered as a method to extract the ISW contribution [15], such correlations are affected by the dominant noise contribution related to primary anisotropies [16].

There is another way of extracting information captured in the ISW effect: through the measurement of
CMB polarization towards galaxy clusters. The polarization signal is generated by rescattering of the temperature quadrupole seen by free electrons in the cluster frame. Provided that the optical depth to scattering in individual clusters is determined a priori by other methods, such as the Sunyaev-Zel’dovich (SZ) effect, one can measure the quadrupole at the cluster location with a reduction in cosmic variance. Note that the quadrupole measured from a cluster at high redshift is not the same quadrupole as one observes today due to the difference in the projected length scales. Since the ISW effect contributes a significant fraction of the quadrupolar anisotropy at late times, cluster polarization provides an indirect probe of dark energy. Because clusters can be selected over a wide range in redshift, the polarization signal can be measured as a function of redshift and inverted to reconstruct the evolution of the ISW quadrupole.

The anisotropy quadrupole, $C_2(z)$, has two contributions: one at the surface of last scattering due to the Sachs-Wolfe (SW) effect, $C_{2}^{SW}(z)$, and another at late times due to the ISW effect, $C_{2}^{ISW}(z)$. We write these two contributions to the power spectrum, projected to a redshift $z$, respectively as

$$C_{2}^{SW}(z) = \frac{4\pi}{9} \int_{0}^{\infty} \frac{dk}{k} \Delta_{\phi,\phi}(k, r_{\text{rec}}) j_{2}^2[k(r_{\text{rec}} - r)]$$

$$C_{2}^{ISW}(z) = 16\pi \int_{0}^{\infty} \frac{dk}{k} \Delta_{\phi,\phi}(k, r_{\text{rec}}) \times$$

$$\times \left[ \int r_{\text{rec}} \frac{dr'}{g(z')} \frac{1}{g(z)} \frac{d}{dr} g(z) j_2(k(r' - r)) \right]^2.$$

Here $r$ is the radial comoving distance out to redshift $z$ and $\Delta_{\phi,\phi}(k, r_{\text{rec}}) = k^3 P_{\phi}(k, r_{\text{rec}})/2\pi^2$ is the logarithmic power spectrum of fluctuations in the potential field at the last scattering surface. We will concentrate on the dark energy properties, whose effects are dominant at low redshifts, and assume that the parameters that define the power spectrum, such as the normalization, spectral tilt, and physical matter and baryon densities $\Omega_{\text{m}} h^2$ and $\Omega_{\text{b}} h^2$, are known to the accuracy expected from the Planck mission with polarization information. Given these priors, the SW contribution is then known to a few percent accuracy. Also note that, conveniently, only the large scales in the power spectrum contribute to the ISW effect, so that we do not need to consider thorny issues related to small-scale non-linear structures and additional parameters such as the neutrino mass.

The galaxy cluster polarization signal arises from the rescattering of the quadrupole which receives a contribution from $C_{2}^{ISW}(z)$ at low redshifts. Ref. 17 discussed how well this quadrupole can be measured as a function of redshift with Planck and a ground-based experiment with significant instrumental noise. In the top panel of Fig. 2 we show the projected ISW contribution to the temperature quadrupole as a function of redshift, and expected errors for a ground-based survey targeting clusters down to a mass limit of $10^{14} M_{\odot}$ in a total area of $10^4$ deg$^2$ with an instrumental noise for polarization observations of 0.1 $\mu$K. As in 17, we assume four channels for these observations so that the ISW quadrupole can be separated from the contribution of the kinematic quadrupole. The latter has a distinct spectrum and the separation based on frequency information leads to an overall increase in noise by a factor of 2 to 3 depending on the exact frequencies of channels selected. Note that we have assumed an instrumental noise of 0.1 $\mu$K for these observations. While a polarization sensitive detector array on the SPT can be expected to reach noise levels of $\sim 1$ $\mu$K or less per pixel, we have assumed an order of magnitude reduction in noise, as expected from the planned CMBPol satellite mission. Since the expected noise level for arcminute scale polarization observations from such a mission is not currently defined, and to consider ground-based efforts such as the SPT, we have considered the range of values between 0.1 and 1 $\mu$K so as to obtain some guidance on how well cluster polarization measurements with noise in this range can be used to probe dark
energy.

In addition to instrumental noise, the polarization measurements are subject to cosmic variance. This variance is determined by the number of independent volumes that last scattering spheres of individual clusters, in some redshift bin, occupy \( \Omega_M \). Dotted lines in the top panel of Fig. 2 show the cosmic variance contribution for an all-sky experiment. As one moves to higher redshift, the number of independent samplings of the local quadrupole increases, leading to a reduction in cosmic variance. The expected redshift distribution of clusters peaks at redshifts around 1–1.5 where it provides the best estimate of the local quadrupole, while errors increase at very low and high redshift due to the smaller number of clusters.

To consider how well these observations can be used to understand dark energy parameters, we again perform a Fisher matrix calculation. The bottom panels of Fig. 2 show how well \( \Omega_M \) and \( w \) (assuming a flat universe and constant \( w \)), and \( w_0 \) and \( w_a \) (assuming a two-parameter description of \( w(z) \) as before and a prior on \( \Omega_M \) of 0.01) can be measured. While the errors are fairly large with a 1 \( \mu K \) noise level per pixel, improving this noise threshold to 0.1 \( \mu K \) leads to significant gains in the determination of \( \Omega_M \) and \( w \). Note also that these errors roughly scale as the inverse square root of the area of sky covered, and with all-sky coverage the errors are expected to decrease by a factor of two. With an order of magnitude improvement in noise, the redshift evolution of the ISW effect extracted from polarization measurements becomes a powerful probe of dark energy providing significant estimates of parameters, comparable and complementary to type Ia supernovae.

To conclude, we have argued that the rate of evolution of the growth suppression factor, \( dg/dz \), is a very powerful probe of dark energy. We have shown that the polarization signal from a large number of galaxy clusters is directly related to this quantity, and can be used to constrain dark energy parameters. In the next decade, the planned mission CMBPol is expected to reach a sensitivity of order 0.1 \( \mu K \) at arcminute resolution and have all-sky coverage, providing polarization measurements of a significant number (~ 10^4) of clusters, from which the quadrupole can be reconstructed as a function of redshift. Although our study is preliminary, we have shown that this method can provide constraints on the dark energy equation of state and its time variation comparable and complementary to those from type Ia supernovae and other well-studied probes of dark energy. More importantly, this method is entirely different from most of the others both in its theoretical underpinnings and in the systematic errors expected. Combining this method with others opens the exciting possibility of significantly improving the constraints on \( w \) and helps usher a new era in our exploration of dark energy.
