The liver is an important immunological organ that remains sterile and tolerogenic in homeostasis, despite continual exposure to non-self food and microbial-derived products from the gut. However, where intestinal mucosal defenses are breached or in the presence of a systemic infection, the liver acts as a second 'firewall', because of its enrichment with innate effector cells able to rapidly respond to infections or tissue dysregulation. One of the largest populations of T cells within the human liver are mucosal-associated invariant T (MAIT) cells, a novel innate-like T-cell population that can recognize a highly conserved antigen derived from the microbial riboflavin synthesis pathway. MAIT cells are emerging as significant players in the human immune system, associated with an increasing number of clinical diseases of bacterial, viral, autoimmune and cancerous origin. As reviewed here, we are only beginning to investigate the potential role of this dominant T-cell subset in the liver, but the reactivity of MAIT cells to both inflammatory cytokines and riboflavin derivatives suggests that MAIT cells may have an important role in first line of defense as part of the liver firewall. As such, MAIT cells are promising targets for modulating the host defense and inflammation in both acute and chronic liver diseases.

Clinical & Translational Immunology (2016) 5, e98; doi:10.1038/cti.2016.51; published online 19 August 2016

INTRODUCTION

Enteric commensals and pathogens are usually confined to the gut by the intestinal epithelium and mesenteric lymph nodes, but in the presence of intestinal inflammation and increased permeability, the liver is the first organ to receive gut-derived bacteria and their products. Thus, the liver functions as a second 'firewall', clearing commensals from the portal circulation where intestinal defenses are overwhelmed,1 and is enriched with a number of innate immune cells, including Kupffer cells (liver-resident macrophages), natural killer (NK) cells and innate-like T cells. In the human liver, mucosal-associated invariant T cells (MAIT) cells are the most dominant population of innate-like T cells, comprising up to 50% of all T cells in the liver,2 which is in contrast to invariant NKT cells (iNKT; ~1%) and γδ T cells (~15%).3,4

The invariant T-cell receptor (TCR) rearrangement of MAIT cells, Vα7.2-Jα33, was first identified during an extensive analysis of the TCR repertoire of human CD4+CD8+ (double-negative; DN) T cells, Porcelli et al.5 and subsequently shown to be characteristic of a novel population restricted by the non-polymorphic and highly evolutionarily conserved major histocompatibility complex (MHC) class Ib molecule, MHC class I-related protein 1 (MR1).6,7 The relative abundance of Vα7.2-Jα33 transcripts in human gut biopsies, as well as the enrichment of homologous Vα19-Jα33 transcripts among murine lamina propria lymphocytes compared with intraepithelial lymphocytes or mesenteric lymph nodes,7 led to this population being called MAIT cells. Importantly, these cells were found to be broadly reactive to bacterial and yeast species,8,9 because of their ability to recognize metabolic intermediates of the microbial riboflavin synthesis pathway.10

Despite their name, in humans MAIT cells are most enriched in the liver, constituting 20–50% of intrahepatic T cells.2,11 The dominance of MAIT cells in the liver suggests that they have a major defensive role in maintaining the liver firewall and in driving liver inflammation in disease. In this article, we will discuss what is currently known about MAIT cell biology, and explore what role MAIT cells may have in maintaining liver homeostasis and in liver disease.

MAIT CELL BIOLOGY

MR1 and its ligand
MR1 is an antigen-presenting molecule first sequenced in 1995,12 and in contrast to the highly polymorphic MHC class I molecules, it is highly conserved among mammals,13,14 with the ε1-ε2 domains of human and mouse MR1 being 89–90% identical.13,15 MR1 expression is essential for the development of MAIT cells, which are absent in MR1−/− mice.7

Two seminal papers in 2010 showed that MR1-restricted MAIT cells could be activated by various species of bacteria and yeast, and were critical for early protection against bacterial infections.8,9 These reports, together with the observation that MAIT cells are absent in germ-free mice,7,8 suggested that MR1 presents a microbial
The nature of the MR1 ligand was subsequently discovered by Kjer-Nielsen et al. who showed that MR1 can present derivatives of the highly conserved riboflavin and folic acid synthesis pathways. MAIT cells are, therefore, activated by organisms possessing the riboflavin synthesis pathway, including *Mycobacteria, Enterobacter, Pseudomonas, Salmonella* and *Candida* species, but not those lacking it (e.g. *Streptococcus pyogenes* and *Enterococcus faecalis*). The most potent MAIT cell activatory ligand found to date is 5-OP-RU (5-(2-oxopropylideneamino)-6-o-ribitylaminouracil), generated from the non-enzymic condensation of an early intermediate of the riboflavin synthesis pathway with glyoxal or methylglyoxal byproducts. Folate-based ligands such as 6-formylpterin and its synthetic analog, acetyl-6-formylpterin, have also been shown to inhibit conventional MAIT cell activity, but can activate non-conventional, folate-reactive MAIT cells. MR1-tetramers loaded with riboflavin and folate intermediates have subsequently allowed the specific detection and characterization of human and murine MAIT cells.

The MR1 transcript is ubiquitously expressed, but endogenous surface expression of MR1 has been difficult to detect. Recently, however, it was demonstrated that MR1 accumulates in the endoplasmic reticulum in an incompletely folded form, and in the absence of bound ligands only a few MR1 molecules traffic to the surface. Increased ligand availability leads to the association of MR1 with β2-microglobulin and egress of the MR1-β2-microglobulin-ligand complex, inducing rapid MR1 surface expression. MAIT surface expression also increases with the nuclear factor-κB-dependent activation of antigen-presenting cells. This contrasts with MHC class II and CD1, which capture their exogenous ligands in endosomal compartments and are highly expressed even in the absence of infection.

**MAIT cell TCR**

The MAIT cell TCR is semi-invariant and relatively evolutionarily conserved within mammals. The majority of human MAIT cells express the canonical TCRα chain, Vα7.2-Jα33, although Vα7.2-Jα12 or Vα7.2-Jα20 are also used by a minority of MAIT cells. These TCRα chains are preferentially paired with Vβ2 or Vβ13.2 in humans. In mice, MAIT cells express Vα19-Jα33 that is paired with Vβ6 or Vβ8, although Vβ usage can be variable. Recently, human nonclassical MR1-restricted T cells that have a diverse TCR repertoire and do not express the Vα7.2 TCR chain have also been identified, which are preferentially activated by folate-based ligands, analogous to type II NKT cells.

**MAIT cell tissue distribution**

MAIT cells are rare in lymphoid tissues because of their lack of CCR7 and CD62L expression, required for lymph node homing. Instead, MAIT cells preferentially home to peripheral tissues, mediated by expression of chemokine receptors CCR6 and CXCR6, gut-homing integrin-α4β7 and low levels of CCR9. Indeed, they are called 'mucosal-associated' because the Vα7.2-Jα33 transcript was enriched in the human gut compared with skin tissues when they were initially characterized. MAIT1-tetramer studies have since confirmed their enrichment in the gut with different MAIT cell frequencies reported at different anatomical locations within the gastrointestinal tract. A higher frequency of MAIT cells are present in the jejunum (60% of CD4+ T cells) compared with reported frequencies in healthy ileum (1.5% of T cells), colon (10% of T cells) and rectum (2% of T cells) (Figure 1). Importantly, MAIT cells are further enriched within the liver (20-50% of T cells), as will be discussed later. MAIT cells are also abundant in human peripheral blood (1-10% of T cells) and the lungs (2-4% of T cells). A lower frequency of MAIT cells is also present in the healthy ileum (1.5% of T cells), colon (10% of T cells) and rectum (2% of T cells). MAIT cell tissue distribution has been reported in tissues such as kidneys, prostate and ovaries.

In contrast to humans, MAIT cells are rare in commonly used laboratory strains of mice, with the exception of the CAST/EiJ strain, and, therefore, the majority of murine studies have used invariant Vα19-Jα33 TCR transgenic (Vα19i-transgenic) mice. MAIT1-tetramers have allowed characterization of wild-type murine MAIT cells, however, showing that in C57BL/6 mice, for example, there is an enrichment of MAIT cells in the lung (mean 3.3% of T cells), liver (0.6% of T cells) and lamina propria (0.7% of T cells).

**Figure 1** Distribution of human and murine MAIT cells in tissues. The frequency of MAIT cells (defined either by MR1 tetramers or as CD161++ Vα7.2+ T cells) within T cells, as has been described in the indicated tissues of mice and humans. MAIT cells are enriched within peripheral organs including the liver and gut, whereas they are less enriched within lymphoid organs. However, MAIT cells are much more abundant in humans compared with common laboratory strains of mice.
Interestingly, the frequency of MAIT cells in the tissues of wild-type mice has been shown to markedly increase upon infection with Francisella tularensis live-vaccine strain, Salmonella Typhimurium or intranasal administration of 5-OP-RU in the presence of a toll-like receptor (TLR) agonist.

**MAIT cell phenotype and effector functions**

In addition to their distinct chemokine receptor profile, human MAIT cells have a characteristic phenotype that has been described in detail (Figure 2). In adults, MAIT cells express a uniform effector phenotype during development. In humans the majority of MAIT cells are CD8+ T cells, although a very minor population that express the CD4 coreceptor. As conventional T cells require TCR signaling before the expression of cytokines from human MAIT cells ranges from none to low. The effector functions of MAIT cells also includes their ability to be activated by cytokines alone is shared with other innate T cells, and constitute the main conventional T cells require TCR signaling before the expression of cytokines from human MAIT cells ranges from none to low.28,53 Interestingly, however, IL-10 expression from MAIT cells is constitutively high expression of RAR-related orphan receptor γ (RORγt) in IL-17-producing T-cell population within the human liver. Although rapid IL-4, IL-5 and IL-10 expression has been described in MAIT cells from Vαt9β-transgenic mice, the expression of these cytokines from human MAIT cells ranges from none to low.28,53 Interestingly, however, IL-10 expression from MAIT cells is particularly high in adipose tissue, suggesting an immunosuppressive function for MAIT cells in certain tissues.

The effector functions of MAIT cells also includes their ability to degranulate and kill bacterially infected or sensitized cells, lysing cells infected with BCG28 and Shigella.55 Ex vivo resting MAIT cells are not efficient killers because of their lack of granzyme B (GrB) and low levels of perforin expression compared with conventional CD8+ T cells. Upon activation, either in an MR1-dependent manner or longer cultures with inflammatory cytokines, however, they upregulate GrB and perforin, greatly enhancing killing of target cells. GrB may therefore be a useful activation marker of MAIT cells.

Finally, despite expansion of MAIT cells after birth, adult MAIT cells lack expression of Ki67 in the periphery and were initially thought to be poorly proliferative. However, recent studies have confirmed the ability of murine and human MAIT cells to proliferate.

**Figure 2** The phenotype of human MAIT cells and their mechanisms of activation. Mature MAIT cells in peripheral blood express the chemokine receptors CCR2, CCR5, CCR6, CXCR6, the C-type lectin-like receptor CD161, the dipeptidase CD26 and a CD45RO-CR7+ effector memory phenotype, with the majority of human MAIT cells expressing the CD8 co-receptor. MAIT cells also express the transcription factors RAR-related orphan receptor γ (RORγt), T-bet and promyelocytic leukemia zinc-finger (PLZF) at rest. During bacterial infection, derivatives of the riboflavin biosynthesis pathway are captured by MR1 and presented on the surface of antigen-presenting cells (APCs). Alternatively, viruses can also rapidly activate MAIT cells in an MR1-independent manner owing to the induction of IL-18, IL-12 and IFNγ. Activated MAIT cells express IFNγ, TNFα, granzyme B, perforin and IL-17.

In line with this, control of intracellular M. bovis bacillus Calmette-Guérin (BCG) growth in vitro by murine MAIT cells required IL-12, but was independent of MR1 signaling. This ability to be activated by cytokines alone is shared with other innate T cells, as conventional T cells require TCR signaling before the expression of cytokines such as IL-18R, and is attributable to the expression of promyelocytic leukemia zinc-finger by these cells.21,51

In addition to IFNγ and TNFα, which can be induced both in a TCR-dependent and -independent manner,2,9,47 MAIT cells have a constitutively high expression of RAR-related orphan receptor γt and the associated ability to express IL-17A, and constitute the main IL-17-producing T-cell population within the human liver. Although rapid IL-4, IL-5 and IL-10 expression has been described in MAIT cells from Vαt9β-transgenic mice, the expression of these cytokines from human MAIT cells ranges from none to low.28,53 Interestingly, however, IL-10 expression from MAIT cells is particularly high in adipose tissue, suggesting an immunosuppressive function for MAIT cells in certain tissues.
in both an MR1-dependent manner and in response to cytokines in vitro^{21,56,59} and in vivo^{42}. As MAIT cells are highly sensitive to activation-induced cell death,^{60} one possible explanation for the discrepancy between studies may be that overstimulation of MAIT cells in some studies led to the loss of MAIT cells before they were able to proliferate.

**MAIT CELLS AND DISEASE**

**MAIT cells in bacterial infections**

High evolutionary conservation of MR1 and its recognition of intermediates of the riboflavin pathway, conserved in various species of bacteria and yeast, suggests that MAIT cells have a critical and non-redundant role in microbial protection. Indeed, a number of papers have suggested that MAIT cells have a protective role in bacterial infections. MR1⁻/⁻ mice lacking MAIT cells had a higher bacterial burden in the first few days following intraperitoneal injection of *Escherichia coli* or intravenous injection of *Mycobacterium abscessus*,^{8} and were overwhelmed by a fatal burden of intraperitoneally injected *Klebsiella pneumoniae*.^{61} Aerosol infection models have demonstrated MAIT cells to be essential for early control of bacterial burden in the lung.^{42,48} Interestingly, mice were protected from *F. tularensis* live-vaccine strain even in the absence of conventional αβ T cells, but were overcome in MR1⁻/⁻ mice,^{42} suggesting that MAIT cells may be important for microbial control in immunocompromised patients.

Various studies of MAIT cell frequencies in patients indicate involvement in bacterial infections. For example, there is a higher frequency of MAIT cells in the lung of patients with *Mycobacterium tuberculosis* infection, with lower frequencies of MAIT cells in the blood.^{8,9} Reduced MAIT cell frequencies are, however, only observed in patients with active *M. tuberculosis* infection, but not latent infection,^{9} suggesting MAIT cells are recruited to the lung in active disease. Peripheral MAIT cells in these patients also have increased expression of the exhaustion marker, programmed cell death protein 1,^{1,62,63} and their responsiveness to *M. bovis* BCG is increased upon programmed cell death protein 1 blockade (Table 1).

In addition to pulmonary infections, there is evidence of MAIT cell involvement in enteric infections, as MAIT cells are reduced early in the blood of patients that received an attenuated strain of *Shigella dysenteriae* 1,^{55} as well as in *Vibrio cholera* O1-infected children.^{64} Interestingly, the presence of activated MAIT cells in the peripheral repertoire was specific to vaccine responders that developed an infection.^{55} and correlated with protective *Vibrio cholera* O1-lipopolysaccharide-specific immunoglobulin (Ig) A response,^{55} and correlated with protective *Vibrio cholera* O1 lipopolysaccharide-specific immunoglobulin A and immunoglobulin G antibody responses.^{64} These two studies suggest that MAIT cells have a role in the development of protective antibody responses against polysaccharide antigens.

Last, reduced MAIT cell frequencies have been associated with increased severity of cystic fibrosis, and is particularly enhanced in patients with chronic *Pseudomonas aeruginosa* infections,^{65} as well as being a risk factor in critically ill patients with sepsis for subsequent nosocomial infections.^{66}

**MAIT cells in viral infections**

Although early studies showed MR1⁻/⁻ mice were not susceptible to influenza compared with control mice,^{6} MAIT cell frequencies are markedly affected during human viral infections. For example, MAIT cells have been consistently and repeatedly reported to be severely depleted from the periphery of patients infected with human immunodeficiency virus (HIV),^{33,35,56,67,68} as well as HIV/M. tuberculosis-co-infected patients.^{70} MAIT cell loss occurs as early as 2–3 weeks after HIV infection,^{70} and does not recover with successful antiretroviral therapy.^{33,35} CD8⁺ MAIT cells in the rectal mucosa^{33} and colon^{53} were better preserved, although CD4⁺ MAIT cells were specifically lost from the rectal mucosa, in line with the significant loss of all CD4⁺ T cells in the rectal mucosa in HIV-infected patients.^{33} As peripheral CD8⁺ MAIT cells were not specifically infected by HIV,^{33} depletion of MAIT cells from the blood of HIV-infected patients is suggested to be due to either the activation-induced cell death of MAIT cells from HIV-induced microbial translocation into the periphery^{33} or exhaustion and downregulation of the MAIT cell marker CD161.^{33} Although a recent tetramer study confirmed the loss of MAIT cells from the peripheral blood of HIV-infected patients, with no detectable loss of CD161 expression on MAIT cells,^{67} the mechanism behind the severe depletion of MAIT cells in these patients remains to be explained. Nevertheless, the loss of MAIT cells may potentially have a profound effect on microbial protection in HIV-infected patients, as exemplified by the loss of mucosal T-helper type 17 cells in simian immunodeficiency virus-infected rhesus macaques.^{71}

In addition to HIV, a loss of MAIT cells from the periphery has also been observed in patients with dengue and severe influenza infection,^{72} as well as in chronic hepatitis C virus (HCV) patients,^{72,73} as discussed in detail later. *In vivo* MAIT cell activation was demonstrated in these patients, and correlated with disease severity in acute dengue. Activation of MAIT cells by the different viruses was dependent on IL-18 in synergy with IL-12, IL-15 and/or IFN-α/β, in line with previous studies showing that IL-12 in combination with IL-18, secreted by monocytes through TLR stimulation, can activate MAIT cells *in vitro*.^{11,47} These studies suggest that MAIT cells may have a larger role in the immune system that is not limited to protection against bacterial infection.

**MAIT cells and autoimmunity**

There is increasing interest in the involvement of MAIT cells in autoimmune conditions, which has been reviewed in detail elsewhere.^{74} In particular relevance to the liver, however, a number of studies have linked MAIT cells with intestinal inflammation. For instance, reduced frequencies of MAIT cells have been consistently demonstrated in the blood of patients with inflammatory bowel disease (both Crohn’s disease and ulcerative colitis),^{32,75–77} although there are conflicting findings between studies in the frequency of MAIT cells within the inflamed tissues.^{32,75,76} MAIT cell frequencies are also altered in coeliac disease, where MAIT cells are depleted from the blood and gut.^{78} Although the fate of MAIT cells in the tissue during intestinal inflammation requires further investigation, it is possible that chronic inflammation of the gut leads to both the recruitment and accumulation of MAIT cells, followed by their activation-induced cell death because of bacterial translocation and dysbiosis. In addition to intestinal inflammatory conditions, MAIT cells may also have a role in arthritic diseases, as they have been shown to exacerbate collagen-induced arthritis,^{79} whereas depletion of blood MAIT cells has also been reported in patients with systemic lupus erythematosus and rheumatoid arthritis.^{31,53} Various reports have also associated MAIT cells with multiple sclerosis, with the presence of MAIT cells in multiple sclerosis lesions confirmed by immunohistochemistry,^{77,80,81} although both regulatory and pathogenic roles have been implicated.^{80,82}

**MAIT cells and cancer**

Little is known about the role of MAIT cells in cancer. An early study reported the increased detection of Vα7.2-Jα33 transcripts in kidney cancer tissue and brain tumors compared with control tissue.
| Disease/infection | Frequency of MAIT cells | Effect on MAIT cell phenotype | Effect on MAIT cell function | References |
|-------------------|-------------------------|-----------------------------|-----------------------------|------------|
| TB                | Loss during active, but not latent, infection | Higher in lung lesions from patients with active infection; loss from tuberculous pleural effusions; no loss in ascitic fluids from patients with tuberculous peritonitis | Increase in PD-1 in active TB | 8, 9, 62 |
| Cholera           | Loss (only in children) | Increase in CD38 expression | 64 |
| Cystic fibrosis   | Loss (associated with *P. aeruginosa* infection) | | 65 |
| Sepsis            | Loss (associated with riboflavin-synthesizing bacterial infections) | | 66 |
| HIV               | Loss (occurs early, no recovery with ART) | MAIT cells better preserved or unaffected in rectal mucosa and colon; lost from lymph nodes | Increase in CD57, CD38, TIM-3, HLA-DR, PD-1; lower in CD27, IL-7R, CCR6, T-bet, Eomes | 33, 35, 57, 63–69 |
| HIV+TB            | Loss (similar to HIV mono-infection, no recovery with ART) | Higher PD-1 and lower CCR6 in HIV/TB treatment-naive patients | 63, 70 |
| HCV               | Loss (no recovery with treatment) | Increased GrB with prolonged but not in resolved infection | 72, 73 |
| Dengue            | Loss between acute and convalescent phase of infection | Increased CD38 and GrB, resolved in convalescent samples | 72 |
| Influenza         | Loss | No difference | 66 |
| No change         | Present in active white matter lesions but not present in non-pathological brain | Increased in Ki67, NKG2D, BTLA | 77, 107 |
| Higher            | CD161+CD8+IFNγ+ T cells present in MS brain | Reduced IFNγ, higher IL-17, higher IL-22 (only in CD) to PMA/IONO | 80 |
| Loss              | Present in MS brain lesions and CSF | | |
| IBD               | Loss | Higher in injured ileum in CD | Increased Ki67, NKG2D, BTLA | 81, 52 |
| Loss              | Higher in colon in UC | Increase in CD69 | 75 |
| Loss              | Loss in colon in UC and small intestine in CD | Lower integrin-α4β7 in CD | 76 |
| Loss              | | Increased IL-17 to PMA/IONO | |
| Loss              | | Increased IL-22 (only in UC); increased activated caspase | |
| Loss              | | Increased expression of Annexin V (only in inflamed CD mucosa) | |
| Disease/infection | Frequency of MAIT cells | Effect on MAIT cell phenotype | Effect on MAIT cell function | References |

| Colorectal cancer | No difference | Higher in tumor compared with healthy colon lamina propria | Increased CD8α in tumors compared with unaffected colon lamina propria; increased CD69 and PD-1 compared with blood | Lower IFNγ to PMA/iono | 84-86 |
| Kidney and brain cancer | Present in tumor tissues; MAIT clonotypes more dominant than blood | | | | 83 |

All tissue entries show comparison with healthy/non-diseased tissues unless indicated as 'compared with blood'. Alternatively, 'present' means there was no comparison. Empty boxes mean there is no information in the clinical setting. Abbreviations: ALD, alcoholic liver disease; ART, antiretroviral therapy; BCG, Bacillus Calmette-Guerin; CD, Crohn's disease; COPD, chronic obstructive pulmonary disease; CSF, cerebrospinal fluid; GrB, granzyme B; HCV, hepatitis C virus infection; HIV, human immunodeficiency virus infection; IBD, inflammatory bowel disease; JT1D, juvenile type 1 diabetes; MS, multiple sclerosis; PBC, primary biliary cirrhosis; PMA/iono, phorbol 12-myristate 13-acetate+ionomycin stimulation; PSC, primary sclerosing cholangitis; NANB, non-A, non-B hepatitis; NASH, non-alcoholic steatohepatitis; PD-1, programmed cell death protein 1; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TB, Mycobacterium tuberculosis infection; T2D, type 2 diabetes; UC, ulcerative colitis.
and peripheral blood samples. Recent studies in colonic adenocarcinoma and colorectal cancer patients have supported these findings, demonstrating highly activated MAIT cell accumulation in tumor tissue, with the degree of MAIT cell infiltration into colorectal tumors negatively correlating with life expectancy. As MAIT cells can secrete both IFNγ—which can promote tumor-specific T-cell responses, as well as IL-17—which leads to the expansion and accumulation of immunosuppressive neutrophils and myeloid-derived suppressor cells, the role of MAIT cells in tumor development may depend on the tumor microenvironment and the ratio between

Figure 3 Proposed role of MAIT cells in the liver. (a) In the steady-state liver, MAIT cells home to the bile ducts within the portal tract through their expression of the chemokine receptors CXCR6 and CCR6 where they are located both adjacent to the biliary epithelium and within hepatic sinusoids. This allows them to protect against infection via the biliary tree and from the portal and systemic circulation via the portal vein and hepatic artery. (b) In the event of ascending biliary infection and following bacterial breach of the biliary epithelium, liver MAIT cells are recruited through their upregulation of CXCR3 and increased expression of chemokines (CCL20) and adhesion molecules (intercellular adhesion molecule 1 and vascular cell adhesion molecule 1) in the liver. MAIT cells are activated by riboflavin metabolites presented by MR1 expressed on both professional (Kupffer cells) and non-professional (BECs) antigen-presenting cells. MR1-activated MAIT cells release CD40L, which induces the expression of Fas, as well as cytotoxic molecules Granzyme B and perforin, leading to apoptosis of BECs. MAIT cells also express the proinflammatory cytokines IFNγ and TNFα, which activates Kupffer cells, BECs, liver sinusoidal endothelial cells (LSECs) and dendritic cells (DCs), whereas IL-7 produced by inflamed hepatocytes also promote IL-17 production from MAIT cells, leading to further inflammation and activation of Kupffer cells, BECs and hepatic stellate cells (HSCs). MAIT cells also produce IFNγ in response to IL-12 and IL-18, secreted by sinusoidal Kupffer cells activated by TLR4 (bacterial LPS) and TLR8 (viral ssRNA) agonists, leading to viral and bacterial control DCs.
IFNγ- and IL-17-secreting cells. Further studies into the role of MAIT cells in cancer and their immunomodulatory potential, as has been demonstrated with iNKT cells,90 could have important implications for cancer immunotherapy.

Last, it is important to note that the precise physiological role of MAIT cells in most of these conditions (bacterial, viral, autoimmune or cancerous) remains to be defined, with the majority of studies focusing on their frequency within the peripheral circulation and tissue, whether they contribute to disease or have a protective role in humans remains unclear.

MAIT CELLS IN THE LIVER
Role of MAIT cells in the liver
Mouse models have demonstrated that in the presence of healthy intestinal mucosa, the liver remains a sterile organ,1 with the mesenteric lymphoid system containing the immune response to commensal gut organisms.91 Yet, the liver provides an important second ‘firewall’ where intestinal mucosal defenses are breached or in the presence of systemic infection.3 The liver hosts not only the large phagocytic Kupffer cell population, dendritic cells, liver sinusoidal epithelial cells and hepatic stellate cells but also rapidly activated innate cells such as NK, iNKT and MAIT populations.92 The innate reactivity of MAIT cells to both MR1-presented bacterially derived metabolites of riboflavin and proinflammatory cytokines including IL-12, IL-18 and type I IFN indicates that MAIT cells are well placed to have an important role in first line of defense as part of the liver firewall. With little data published to date, we are only just beginning to understand their function within this complex immunological organ.

MAIT cells are highly enriched in the human liver, representing 20–50% of intrahepatic T cells, compared with the gut.2,36 This is in keeping with their homing receptor expression profile, and although MAIT cells express the gut-homing integrin-α4β7,7 they express lower levels of the gut-homing chemokine receptor CCR9 compared with other T cells.2,37 Instead, MAIT cells express receptors that allow them to home to the liver, such as CXCR6 and CCR6, which binds CXCL16 and CCL20, respectively—chemokines constitutively expressed in the liver.93,94 This liver-homing phenotype is conserved in mice, as murine MAIT cells also express CXCR6,21 similar to the murine hepatic iNKT cell population.95 CCL20 is also upregulated in the inflamed liver and drives CXCR6+ T-cell localization to the biliary epithelium.96 Indeed, recent work by Jeffery et al.37 has described Vα7.2+ and Vα7.2+CD161+ cells to predominantly reside around bile ducts within the portal tracts in both healthy and diseased livers. Importantly, bacterially loaded biliary epithelial cells (BECs) were able to activate MAIT cells in an MR1-dependent manner, and suggests a mechanism by which MAIT cells may defend the biliary mucosa against ascending infection from the gut. In the inflamed liver, MAIT cells may be further recruited to the sinusoids through their expression of CXCR3, LFA-1 and VLA-4,17 as IFNγ-inducible CXCR3 ligands, intercellular adhesion molecule-1 and vascular cell adhesion molecule-1, have all been shown to mediate recruitment of lymphocytes during inflammation.37 The distribution of intrahepatic MAIT cells is likely critical to understanding their function within the liver.

Three features of MAIT cells in the context of liver immunosurveillance are important to note. First, although at a transcriptional level, intrahepatic MAIT cells are very similar to their blood counterparts, liver MAIT cells are highly activated and almost all express the activation marker CD69, as well as HLA-DR and CD38.36,37 This suggests that liver MAIT cells are in a highly activated state, poised to respond to incoming antigen from the gut. Second, intrahepatic MAIT cells, along with CD56bright NK cells, are the main source of IFNγ after TLR8 stimulation of liver-derived mononuclear cells, mediated by their ability to respond to IL-12 and IL-18 from monocytes.11 The striking sensitivity of intrasinusoidal cells in this study to the TLR8 agonist ssRNA40, compared with other TLR agonists, suggests that intrahepatic cells are highly reactive to viral and phagocytosed bacterial RNA,98 and that MAIT cells are an important effector population in the liver. Third, MAIT cells are the predominant IL-17 producers among intrahepatic T cells (~65% of IL-17+ T cells) following phorbol 12-myristate 13-acetate/ionomycin stimulation.36 As IL-17 targets multiple cell types in the liver, including Kupffer cells and BECs, to produce proinflammatory cytokines and chemokines,99 MAIT cells may be important regulators of hepatic inflammation and fibrosis.

Interestingly, however, liver MAIT cells in the steady state are unable to produce IL-17 upon TCR stimulation.36 Indeed, MAIT cells from the liver appear less skewed towards type 17 functions (IL-17 and IL-22 production) compared with those of the mucosa. For example, MAIT cells of the fetal liver failed to produce IL-22 on MR1-dependent stimulation, in contrast to those of the small intestine.50 Similarly, MAIT cells derived from the female genital tract were able to produce IL-17 and IL-22 on bacterial stimulation.39 The presence of commensal bacteria at mucosal surfaces may drive type 17 skewing of mucosal MAIT cells through IL-1p production by resident macrophages.100 In the steady state, MAIT cells seem to require IL-7 licensing before acquiring the ability to secrete IL-17 in response to TCR stimulation, potentially by increasing their sensitivity to TCR-mediated signals,36,57 but liver MAIT cells may become similarly skewed to mucosal MAIT cells during episodes of infection.

Taken together these studies suggest hepatic MAIT cells are highly activated within the liver and likely have a defensive role against a range of extra- and intracellular bacteria, fungi and viruses through their abundant and rapid production of IFNγ and IL-17 (Figure 3).

MAIT CELLS AND LIVER DISEASE
Inflammatory liver diseases
In the most comprehensive study to date of MAIT cells in liver disease, Jeffery et al.37 describe the distribution, function and phenotype of hepatic MAIT cells from healthy controls and explants from patients with acute non-A, non-B hepatitis, as well as the end-stage chronic liver diseases such as autoimmune hepatitis, primary biliary cholangitis, primary sclerosing cholangitis, alcoholic liver disease and non-alcoholic steatohepatitis (NASH). Overall, a reduction in MAIT cells was seen in patient blood and livers compared with controls, in agreement with another study of end-stage liver disease.11 The similar distribution of Vα7.2+ cells and CD161+Vα7.2+ cells around the bile duct in both controls and the chronic diseases studied would suggest that the presence of these cells is likely more physiological than pathological in this location (or related to end-stage liver disease). Although the specificity of these cells needs to be confirmed, peribiliary MAIT cells may provide defense against ascending infection via the biliary system, as discussed above. However, as ligation of CD40 on BECs leads to their Fas-dependent apoptosis,101 upregulation of CD40L on MAIT cells in response to bacteria-derived MR1 ligands presented by BECs suggests that MAIT cells could potentially drive bile duct damage, contributing to pathogenesis in biliary disease.

Hepatitis C infection
Two recent papers have clearly demonstrated that circulating MAIT cells in chronic HCV patients are reduced in frequency.72,73 This supports previous observations that blood CD161+CD8 T cells, the majority of which are MAIT cells in adults,2 are significantly
reduced in patients with chronic HCV. Whether this represents blood-to-tissue translocation or activation-induced cell death, as has been suggested in HIV infection, has not been addressed. Ex vivo analysis of MAIT cells from patients with chronic HCV showed that activation markers such as GrB, CD38 and CD69 were upregulated, and MAIT cells could be activated upon in vitro coculture with HCV-exposed antigen-presenting cell. Additionally, type I IFNs, known to have an important role in viral control, were shown to induce MAIT cell production of IFNβ in combination with IL-12 or IL-18, and where antigen-presenting cells infected with HCV were cocultured with a vaccine virus-derived soluble type 1 IFN receptor (B18R), MAIT cell activation was inhibited. Interestingly, in an HCV Sofosbuvir treatment trial, those patients in the arm receiving pegylated-IFN, in addition to Sofosbuvir and ribavirin, had a higher sustained virologic response rate, as well as activated circulating MAIT cells compared with the other treatment arms. Whether this indicates a direct role for MAIT cells in HCV control and clearance or sustained virologic response rate, as well as activated circulating MAIT cells compared with the other treatment arms. Whether this indicates a direct role for MAIT cells in HCV control or not is ripe for exploitation in the future.

CONCLUSION

MAIT cells are emerging as significant players in the human immune system where they represent a major lymphocyte population—this is most obvious in the liver where their dominance, even their presence, has only been evident in the past few years. Our understanding of the distinct biology of MAIT cells is rapidly increasing as the field widens and appears to include not only responsiveness to bacteria but also to inflammatory and viral signals. Their enrichment within the liver is striking and there is much work to be carried out in understanding the physiologic role of MAIT cells, as guardians of the biliary mucosa, as monitors of sinusaloid hygiene and as part of the liver’s defensive firewall. Loss of MAIT cells in fibrotic liver disease, as has been indicated, may lead to weakening of this firewall and increased susceptibility to systemic infections—it may be possible to address this mechanistically in emerging mouse models. Their role in the pathogenesis of liver disease also needs to be defined—clearly they are present at the site of inflammation, but to what extent they are protagonists, protectors or just innocent bystanders again may only be solved by analysis using appropriate mechanistic models. Even with these, given the specific and chronic nature of some of the infectious/inflammatory processes, further clinical correlative and mechanistic studies are needed.

Overall, given their distinctive functions and surface phenotype, MAIT cells represent attractive therapeutic targets to modulate host defense and inflammation in the liver and other organs, and certainly excellent markers of responses to biologic therapies. Both avenues—therapeutic and diagnostic—are ripe for exploitation in the future.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

ACKNOWLEDGEMENTS

This work was sponsored by the Wellcome Trust, the Medical Research Council, the NIHR Biomedical Research Centre, Oxford, the Oxford Martin School and NIHR (U19A10828630) and an NIHR Senior Fellowship (PK). We also thank Dr Bonnie von Wilgenburg for comments and critical reading of this review.
