Background. Migratory animals comprise a significant portion of biodiversity worldwide with annual investment for their conservation exceeding several billion dollars. Designing effective conservation plans presents enormous challenges. Migratory species are influenced by multiple events across land and sea—regions that are often separated by thousands of kilometres and span international borders. To date, conservation strategies for migratory species fail to take into account how migratory animals are spatially connected between different periods of the annual cycle (i.e., migratory connectivity) bringing into question the utility and efficiency of current conservation efforts. Methodology/Principal Findings. Here, we report the first framework for determining an optimal conservation strategy for a migratory species. Employing a decision theoretic approach using dynamic optimization, we address the problem of how to allocate resources for habitat conservation for a Neotropical–Nearctic migratory bird, the American redstart Setophaga ruticilla, whose winter habitat is under threat. Our first conservation strategy used the acquisition of winter habitat based on land cost, relative bird density, and the rate of habitat loss to maximize the abundance of birds on the wintering grounds. Our second strategy maximized bird abundance across the entire range of the species by adding the constraint of maintaining a minimum percentage of birds within each breeding region in North America using information on migratory connectivity as estimated from stable-hydrogen isotopes in feathers. We show that failure to take into account migratory connectivity may doom some regional populations to extinction, whereas including information on migratory connectivity results in the protection of the species across its entire range. Conclusions/Significance. We demonstrate that conservation strategies for migratory animals depend critically upon two factors: knowledge of migratory connectivity and the correct statement of the conservation problem. Our framework can be used to identify efficient conservation strategies for migratory taxa worldwide, including insects, birds, mammals, and marine organisms.

INTRODUCTION

Migratory birds comprise more than 80% of avian diversity in temperate regions of the world [1]. Protecting these species presents a unique conservation challenge because population abundance is influenced by geographically separated events that occur during different periods of the year [2]. If maximizing population persistence is a central goal of species conservation [3], then the optimal allocation of resources for conserving migratory species should consider population dynamics throughout the annual cycle, not just during a single period of the year. However, the lack of information on how populations are geographically linked between periods of the annual cycle (i.e., migratory connectivity) has made it virtually impossible to develop conservation strategies that incorporate year-round dynamics [4].

Investment in migratory bird conservation is substantial with over US$650 million allocated to wetland lease and acquisition in North America for migratory birds in 2005 alone [5]. Global estimates for this same fiscal year are likely to be several billion if all migratory species are considered [6]. Current strategies used to allocate funds are ad-hoc or based on ranking methods [7] and fail to incorporate both migratory connectivity and the cost of implementing the conservation action.

Several recent studies addressing cost-effectiveness in conservation planning provide guidance on how to estimate where, when and how much to invest for the conservation of non-migratory species [7–10]. We build upon these approaches using a unique dataset from a long-distance migratory songbird, the American redstart (Setophaga ruticilla), to examine whether incorporating migratory connectivity into habitat protection schemes influences decisions designed to maximize the persistence of populations. We demonstrate for migratory species how failure to include estimates of migratory connectivity leads to the improper formulation of the problem and could doom regional populations to near extinction.

RESULTS

Following a decision theoretic framework [7,11,12], we employed an optimal search algorithm Dijkstra [13] to find optimal resource allocation strategies for two problems; first, to maximize the number of birds protected across the wintering range, and second, to maximize the number of birds protected across the entire range of the species by adding the constraint of maintaining a minimum population size within each of five temperate breeding regions (see Materials and Methods).

To solve the first problem, we developed an optimization model where sequential decisions to acquire parcels of wintering habitat, within a fixed budget and time period, were based on rates of winter habitat loss, land value, and the relative density of birds in each wintering region (Table 1; see Supporting Information, Text S1 i, ii). To solve the second problem, we developed an optimization model that incorporated information on migratory connectivity, using stable-hydrogen isotopes (δD) to estimate the breeding origin of individuals sampled on the tropical wintering grounds [14] (Figure 1; Supporting Information, Table S1). This information allowed us to estimate the relative change in abundance of breeding populations as a result of habitat conservation on the wintering grounds. Although we used land acquisition as our mechanism to preserve populations, our models can readily incorporate ongoing management costs [15] and other conservation strategies such as easements or active management [10].

Bird density, cost, threat, available habitat, parcel size and number of parcels available for acquisition for 5 regions in the wintering range of the American redstart. Numbers in brackets represent a rank of parameters based on their relative priority from 1 (high priority) to 5 (low priority). Based on these ranks it is impossible to design an optimal investment strategy.

doi:10.1371/journal.pone.0000751.t001

Our first objective was to maximize the number of birds throughout the wintering range. The optimal resource allocation strategy for this objective was to invest solely in Central America and the Eastern Greater Antilles for the first 30 years (Figure 2a), then include a single investment in the Western Greater Antilles at year 35, and a heavy investment in the Lesser Antilles/South America through to year 45. This optimal strategy did not recommend an investment in Mexico.

In contrast, by adopting an objective that included the protection of at least 30% of the redstarts in each of the five breeding regions through incorporating information on migratory connect-

![Figure 1. Patterns of connectivity in American redstarts.](image1)

![Figure 2. The total number of parcels purchased in each region over a 45-year time-horizon.](image2)
tivity, we obtained an entirely different conservation strategy (Figure 2b). In the first five years, investments were targeted in Western Greater Antilles, the Lesser Antilles/South America, and heavily in Central America. In years 5–20, investments were made solely in Mexico with one land parcel purchased every 5 years. In years 20–45, investments were made in Central America and the Eastern Greater Antilles, and heavily in the Lesser Antilles/South America after year 35.

The conservation strategies to achieve each objective resulted in large differences in the proportion of birds protected on the breeding grounds (Figure 3). When migratory connectivity was ignored, the Northwest region shrank to less than 2% of its original population size because 82% of birds breeding in this region wintered in Mexico [14], which did not receive any protection under objective 1. In contrast, incorporating the conservation of regional breeding populations into the decision analysis (objective 2) resulted in the purchase of habitat in Mexico despite its cost.

**DISCUSSION**

We have discovered that key decisions aimed at conserving migratory populations may depend critically on considering the link between different periods of the annual cycle. Focusing solely on maximizing winter population size without considering their connection to breeding areas has the potential to reduce dramatically the regional distribution of redstart populations in North America. In contrast, using information on migratory connectivity allowed us to set targets for maintaining minimum population sizes within each breeding region, thereby dramatically changing the decision pathways and improving the regional stability thousands of kilometers away on breeding areas.

Our results have immediate implications for the allocation of funds aimed at conserving migratory species. We demonstrate that using a decision theoretic approach integrated with information on migratory connectivity will improve the efficiency of resource allocation. This approach is applicable to migratory species around the globe and offers an effective means of identifying and prioritizing conservation investment strategies.

Due to the number and complexity of parameters involved, it is unlikely that the strategies we found to be optimal would arise from a ranking-based method (see Table 1) or expert opinion. We also suggest that the cost of protecting the wrong or insufficient winter habitat, which may result in the loss of regional breeding populations, is very likely to exceed the cost of collecting information on migratory connectivity and running analyses like those described here. A decision theoretic approach incorporating species density, level of threat and cost of collecting migratory connectivity per species, could be used to develop a species prioritization list for the collection of data on migratory connectivity. The range of many migratory species also spans multiple countries or even continents. The probability of compliance with conservation strategies will likely vary by country or region and should be considered as another potential factor in the decision analysis. For migratory birds in particular, the inclusion of key information about stopover regions including level of threat, the number of individuals that use each area, their origin and destination will also be extremely valuable input for this type of decision analysis.

Because our aim was to find an optimal solution, the sheer size of the solution search space (see Supporting Information, Text S1) forced us to assume that the system dynamics were deterministic. In doing so, we made several simplifying assumptions. In the absence of quantitative data, we assumed that American redstart density was directly proportional to habitat loss, whereby a loss in a habitat parcel resulted in the loss of birds occupying that parcel. The budget per time-step was based on the cost of a parcel in the most expensive region. The number of parcels that could be purchased for the equivalent cost in each other region determined the number of parcels available for purchase. This alleviated the need for a stochastic process to determine how to allocate leftover funds at each time-step (See Supporting Information, Text S1). We acknowledge that species density, rate of habitat loss, and cost are subject to unknown stochastic processes. However, it is not clear whether a suboptimal stochastic solution [7] would be more effective than our optimal deterministic solution. We also note that the optimal strategy presented here is only for one species, whereas managers must often make decisions that are designed to benefit multiple species [16]. Our study introduces a framework for achieving this goal while emphasizing the importance of considering multiple periods of the annual cycle. We also show that the optimal decision schedule depends on the time-horizon for planning such strategies (Supporting Information: Text S1 iv, Figure S1). Recognizing this dependency will be critical when making decisions with fixed, short-term budgets subject to long-term uncertainty.

Despite these caveats, we demonstrate the over-riding importance of considering year-round dynamics for allocating conservation funds to habitat acquisition for migratory species. Understanding how different periods of the year are influenced by conservation strategies can only be achieved through information on migratory connectivity. Our modeling framework incorporates this factor and can be applied to all migratory taxa. With this knowledge, adopting a decision theoretic approach to the optimal allocation of conservation resources should provide an effective and timely method for securing the persistence and future of migratory species around the world.

**MATERIALS AND METHODS**

**Study Species**

American redstarts are small (8 g) migratory songbirds that breed in deciduous and mixed deciduous-coniferous forest across North America and winter in Central America, the Caribbean, and the north coast of South America [17]. Evidence suggests that the quality of habitat used by redstarts on the tropical wintering
grounds influences individual success. Redstarts occupying high-
quality mesic habitats, such as coastal mangroves and lowland
forests, are in better condition over the winter, have higher annual
survival rates, depart earlier for spring migration, and have higher
reproductive success the following season on the temperate
breeding grounds compared to individuals occupying lower-quality
habitats, such as tropical dry forests [18–21]. These findings
suggest that the availability of high quality winter habitat is a key
limiting factor to the abundance of redstarts. In this study, we
consider coastal mangroves only as they are considered to be most
limiting non-breeding habitat for this species [18–21].

Problem definition and approach
In the first problem our goal was to maximize the number of birds
protected across the winter range. In doing so, we took into
account the amount of winter habitat available for conservation,
its rate of loss, the cost of land acquisition, and estimates of redstart
density across the winter range (Table 1). In the second problem
our goal was to maximize the number of birds protected across its
entire range by adding the constraint of maintaining a minimum
proportion (≥30%) of each regional breeding population (Sup-
porting Information, Text S1 i). To do this, we incorporated
information on migratory connectivity to estimate the proportion
of birds at a given wintering site that bred in one of five breeding
regions in North America [14] (Figure 1; Supporting Information,
Table S1). The winter regions are defined as the Western Greater
Antilles (Dominican Republic, Haiti, Puerto Rico), Eastern
Greater Antilles (Florida, Bahamas, Jamaica), Lesser Antilles/ South
America (Trinidad, Tobago, Venezuela), Mexico, and Central
America (Belize, Panama) (Figure 1).

Algorithm
We implemented an optimal search algorithm, ‘Dijkstra’ [22], to
find the shortest path from our starting state (the current situation)
to our goal state. Dijkstra’s algorithm does not traverse the entire
solution space but rather only pursues paths that are likely to lead
to the optimal path and is therefore an efficient and computa-
tionally fast method of finding an optimal solution for problems of
this size (Supporting Information, Text S1 iii).

The efficacy of our optimal search algorithm was evaluated
through a comparison of results with a second algorithm ‘myopic’
[7] (see Supporting Information, Text S1 iv). This heuristic
algorithm makes the optimal choice one step at a time with the
goal of finding a global optimum. In other words, at each time
step, the site with the most birds per unit cost is chosen. However,
because this algorithm moves in a single forward direction, it is
‘short-sighted’ leading to solutions that are likely to be suboptimal
(cf. the maximize ‘short-term gain’ and ‘minimize short-term loss’
heuristics [7]). We found that ‘Dijkstra’ outperformed the ‘myopic’
algorithm returning between 4 to 28 percent more birds protected
per dollar spent depending on the time-horizon. Our findings are
presented for Dijkstra’s algorithm using a 45-year time-horizon.

Simulations and Sensitivity
We ran scenarios with each algorithm for each objective function,
with various finite time-horizons (5 to 60 years). We determined
the sensitivity of changes in cost and migratory connectivity by
comparing our results to simulations run with an equal cost
function for each region. This comparison revealed that including
information on migratory connectivity resulted in greater
differences in the prioritization of winter parcels than regional
variation in cost of winter habitat. All models and simulations were
run using MATLAB version 7.0 [23].
