(Dated: September 18, 2018)

We use a semiclassical approach to study out of equilibrium dynamics and transport in quantum systems with massive quasiparticle excitations having internal quantum numbers. In the universal limit of low energy quasiparticles, the system is described in terms of a classical gas of colored hard-core particles. Starting from an inhomogeneous initial state, in this limit we give analytic expressions for the space and time dependent spin density and spin current profiles. Depending on the initial state, the spin transport is found to be ballistic or diffusive. In the ballistic case we identify a “second front” that moves more slowly than the maximal quasiparticle velocity. Our analytic results also capture the diffusive broadening of this ballistically propagating front. To go beyond the universal limit, we study the effect of non-trivial scattering processes in the $O(3)$ non-linear sigma model by performing Monte Carlo simulations, and observe local equilibration around the second front in terms of the densities of the particle species.

I. INTRODUCTION

Out of equilibrium dynamics of quantum many-body systems have been in the focus of research in the last decade [1–5]. Despite the great deal of progress and effort devoted to the subject, the mechanisms underlying transport phenomena in integrable and non-integrable systems are still not well understood.

A striking instance is provided by the presence of anomalous transport in integrable systems. For example, both diffusive and sub-diffusive spin transport have been observed numerically in the XXZ spin chain [6–12]. The appearance of diffusion in integrable systems is rather enigmatic as one would expect ballistic transport due to the ballistically propagating stable quasiparticles. Over the last year, a generalized hydrodynamical (GHD) approach has been developed that captures ballistic transport phenomena in integrable and non-integrable systems are still not well understood.

Here we intend to pursue another, semiclassical route to understand non-equilibrium steady state physics, an approach that has been successfully applied to compute dynamical correlation functions both at finite temperature [33–37] and out of equilibrium after a quantum quench [38–41]. This approach is applicable to gapped one dimensional systems with quasiparticles possessing some topological or symmetry-protected internal quantum numbers $\mu$ which we shall refer to in what follows as ‘spin’. The meaning and possible values of $\mu$ differ from model to model: in quantum rotor models, for example, $\mu$ corresponds to the angular momentum $I_{\mu} = -l, \ldots, l$ of the quasiparticles [42], in the sine–Gordon model it refers to the topological charge $\tau = \pm$ [35, 40], in the quantum Potts model it labels domain walls or residual permutation symmetry [36], while in the spin-1 Heisenberg model or other similar spin models [43] and non-linear sigma models [34, 39] it describes the spin of the quasiparticles.

In this work we apply semiclassical and hybrid semiclassical approaches to investigate equilibration and the formation of non-equilibrium steady states (NESS). The physical setup we study is the so-called partitioning protocol or tensor product initial state displayed in Fig. 1, where two-semi infinite systems with different quasiparticle velocity and ‘spin’ distributions are suddenly joined. This setup has been used to study energy and spin transport in various systems [6, 11, 13, 14, 18, 19, 21, 26, 29, 31, 32, 44–65].

In the semiclassical approach stable quasiparticles follow classical trajectories, while collisions are governed by quantum mechanics. In the so-called universal (low momentum) limit the scattering matrix of these quasiparticles becomes fully reflective. In this peculiar limit quasiparticles behave in many ways as hard-core billiard balls, and their various correlation functions can be computed analytically even under non-equilibrium circumstances [38–40]. We first focus on this universal limit and report analytic closed form expressions for the spin density and spin current profiles valid for arbitrary times in the thermodynamic limit. We verify these analytical results by detailed Monte Carlo simulations.

Naively one would expect the semiclassical approach to be able to describe only ballistic behavior. However, this is not the case if one is interested in the transport of internal degrees of freedom. Indeed, we identify both diffusive and ballistic spin transport in our simple model. In particular, we show that particle and ‘spin’ densities display generically ballistic ‘shock wave’ propagation, but the front itself shows diffusive behavior. These results parallel the very recent results of Ref. [66], where the authors demonstrated ballistic as well as diffusive behav-
ior in a classical cellular automaton toy model involving charged hard-core particles and neutral non-interacting particles. The behavior we observe is similar to that observed in classical hard-core models [67–69].

Unfortunately, the analytical approach described in the previous paragraphs has its limitations, since for quasiparticles of finite kinetic energy the scattering matrix is not fully reflective. Nevertheless, as demonstrated recently [41], it is possible to go beyond this universal limit by means of a hybrid semi-semiclassical Monte Carlo approach, and thereby account for the generically weak transmissive scattering events and simulate the actual physical systems accurately at long times.

Our hybrid semiclassical simulations show that the generic features survive beyond the universal limit, i.e., if we allow transmissive and ‘spin’ changing scattering processes encoded by a non-trivial scattering matrix. As an example, we analyze the $O(3)$ non-linear sigma model, e.g., elementary excitations are triplet particles with spin components $S^z = \pm 1, 0$, and have relativistic dispersion relations $\epsilon(p) = \sqrt{p^2 + c^2}$. In this integrable model, the two-body S-matrix is exactly known (see Appendix A4), and in the universal limit of low momenta it becomes perfectly reflective. In this and the following section we focus entirely on this universal purely reflective limit, and derive general analytical semiclassical results for the time evolution of the steady state. (Effects emerging beyond this universal limit shall be discussed in Sec. IV).

The initial distribution of quasiparticles is characterized by the distribution functions $f_{L/R}(\mu, p)$, where $p$ is the momentum and the superscripts $L$ or $R$ refer to the left and right systems, respectively. Our only assumption is that the distribution function factorizes, $f_{L/R}(\mu, p) = g_L(\mu) f_{L/R}(p)$ with $\sum_{\mu} g_L(\mu) = 1$. This condition can be released in numerical simulations, however, it is important for the analytical solution presented in this section. An example for such a factorization is given by thermal equilibrium in the presence of some external field $\hbar$, when $f_\alpha(\mu, p) \sim e^{\beta_\alpha \hbar \mu - \beta_\alpha \epsilon(\mu)}$, with $\alpha = L, R$.

A semiclassical configuration is thus given by the initial locations, momenta, and spins of all quasiparticles. We assume that particles are initially evenly distributed in space on each side and their momenta and spins are drawn from the distribution $f_{L/R}(\mu, p)$. We are interested in averages over these configurations, i.e., over the $\{x, p, \mu\}$ initial coordinates of all particles. Pictorially, such a configuration is represented by a set of semi-infinite straight lines in the $(x, t)$ plane (see Fig. 1), and by energy and momentum conservation, particles must move along segments of these lines. Each line starts at a
random point of the $t = 0$ horizontal line with a slope

$$v_p = \frac{d\varepsilon(p)}{dp}$$

(1)
corresponding to the initial velocity of the particle and each segment carries a label $\mu$ according to the spin of the particle. We connect the two half systems at $t = 0$ and $x = 0$, and to generate transport, the momenta and the spins are drawn at $t = 0$ from different distributions for $x > 0$ and $x < 0$. The initial particle number and magnetization densities on the two sides are given by

$$n_{L/R} = \sum_\mu \int \frac{dp}{2\pi} f_{L/R}(\mu, p) = \int \frac{dp}{2\pi} f_{L/R}(p),$$

(2)

$$m_{L/R} = \sum_\mu \int \frac{dp}{2\pi} \mu f_{L/R}(\mu, p) = n_{L/R} \sum_\mu \mu g_{L/R}(\mu),$$

(3)

and the initial polarization, i.e. the average magnetization of a single particle is expressed as

$$\hat{\mu}_{L/R} \equiv \langle \mu \rangle_{L/R} = m_{L/R} / n_{L/R} = \sum_\mu \mu g_{L/R}(\mu).$$

(4)

Notice that straight lines in Fig. 1 are not the actual physical trajectories of the hard-core particles because their spin degree of freedom gets reflected and follows complicated zig-zag trajectories (see Fig. 1). It is this non-trivial movement of the particles that renders the calculation of the spin current non-trivial. Indeed, in contrast to the spin, expectation values of fully transmitted quantities such as energy or particle density are easy to compute, because they propagate along the straight trajectories. Therefore, near position $x$ and at time $t$ only those particles contribute to the current that come from the left and are faster than $x/t$, and those that come from the right and are slower than $x/t$. In Fig. 1 each line carries momentum $p$, energy $\varepsilon(p)$, and unit particle number. For example, the mean particle density and current are given by

$$n(x, t) = \int \frac{dp}{2\pi} \left[ \Theta(x/t - v_p) f_R(p) + \Theta(v_p - x/t) f_L(p) \right],$$

(5)

$$j(x, t) = \int \frac{dp}{2\pi} v_p \Theta(x/t - v_p) f_R(p)$$

$$+ \int \frac{dp}{2\pi} v_p \Theta(v_p - x/t) f_L(p) v_p.$$  

(6)

The energy density and energy current are given by analogous expressions, only the integrands contain an extra factor of $\varepsilon(p)$. Note that these expressions depend solely on the scaling variable

$$\xi = x/t,$$

(7)
i.e. on the “ray” in the $(x, t)$ plane. If there is a maximal quasiparticle velocity $c$, then particle and energy currents are zero outside of the light cone, i.e. for $|\xi| > c$. Keeping $x$ finite while sending $t \to \infty$ corresponds to the $\xi = 0$ ray, identified as the non-equilibrium steady state (NESS) developing at the center.

**B. Analytic space-time profiles**

We shall now derive closed, analytical expressions for the complete spatial and time dependence of the magnetization profile, $m(x, t)$ in the limit of fully reflective collisions. To do that, we shall first compute the average magnetization $M(x, t)$ transferred through point $x$ until time $t$. Differentiation then yields immediately the magnetization current, $J(x, t) = \partial_t M$, and the change in the magnetization density $m(x, t) - m(x, 0) = -\partial_x M$.

For a given configuration $C$ and time $t$, the magnetization $M(C)$ transported across point $x$ is the sum of the spins of the particles crossing the segment $[(x, 0), (x, t)]$, each weighted by $|\pm 1$ depending on whether it crosses from the left or from the right. To compute $M(x, t)$ we must average this quantity over all possible initial quasiparticle configurations, $M(x, t) = \langle M(C) \rangle_C$.

Consider now the triangle on the $(x, t)$ plane with vertices $(0, 0)$, $(x, 0)$, and $(x, t)$, shown in Fig. 1. As magnetization is conserved by the dynamics, the total magnetization flowing into this triangle, including the inflow along the edge $B = [(0, 0), (x, 0)]$, must be zero. This implies that $M(C)$ can also be calculated as the sum of the spins (again with signs) encountered when moving along the $A = [(0, 0), (x, t)]$ segment, $M_A(C)$, plus the sum of the spins along the $B$ interval, $M_B(C)$. The second quantity is related to the initial magnetization, but $M_A$ is, in principle, complicated: although the spins of particles at $t = 0$ are uncorrelated, they travel along zig-zag trajectories as a result of multiple collisions, and they can cross segment $A$ multiple times.

However, due to the perfectly reflective elastic collisions, the spatial sequence of the spins at any fixed time is unchanged under the time evolution. As a consequence, if the number of net crossings along $A$ is $s$, $M_A$ is equal to the negative sum of the first $|s|$ spins to the right (if $s < 0$) or to the sum of the first $s$ spins to the left (if $s > 0$) of the origin at $t = 0$.

To obtain the expectation value of the transported magnetization, we have to average over all semiclassical configurations. As the spin and orbital degrees of freedom follow independent distributions, we can first average over the spins. This implies that the average left and

\[^1\text{Or, thinking in terms of spatial domains, the initial magnetization of the interval B must flow out at the left and the right boundaries while we shrink the interval to zero by moving the left boundary to the right one.}\]
right magnetizations can be used, yielding
\begin{align}
\langle M_A \rangle_C &= \langle \Theta(s) \rangle \hat{\mu}_L + \langle \Theta(-s) \rangle (-\hat{\mu}_R), \quad (8a) \\
\langle M_B \rangle_C &= \langle \Theta(x) \rangle \hat{\mu}_R n_R + \Theta(-x) \hat{\mu}_L n_L x, \quad (8b)
\end{align}

where \( \langle \ldots \rangle \) denotes averaging over the remaining orbital degrees of freedom:
\begin{equation}
\langle O \rangle = \frac{1}{(n_R L)^N} \prod_{i=1}^{N_R} \int_0^L dy_i \int \frac{dp_i}{2\pi} f_R(p_i) \frac{1}{(n_L L)^N} \prod_{j=1}^{N_L} \int_{-L}^0 d\bar{y}_j \int \frac{d\bar{p}_j}{2\pi} f_L(\bar{p}_j) O, \quad (9)
\end{equation}

where the physical quantity \( O \) depends implicitly on the initial positions and momenta of the particles, \( \{ y_i, p_i \} \) and \( \{ \bar{y}_j, \bar{p}_j \} \), with the bar referring to particles on the left. Then the average transported magnetization is
\begin{equation}
M(x,t) = \langle M_A \rangle_C + \langle M_B \rangle_C. \quad (10)
\end{equation}

To evaluate \( \langle \Theta(s) \rangle \) and \( \langle \Theta(-s) \rangle \) we notice that \( s \) is just a crossing number, and is simply given by the number of straight lines from the right ending up left of the point \( x \) at time \( t \) minus the number of lines from the left ending up right of \( x, t \),
\begin{equation}
s = \sum_{j=1}^{N_L} \Theta(y_j + v(p_j)t - x) - \sum_{j=1}^{N_R} \Theta(x - y_j - v(p_j)t), \quad (11)
\end{equation}

where it is understood that \( y_j > 0 \) and \( \bar{y}_j < 0 \).

To evaluate \( \langle \Theta(s) \rangle \) we rewrite the Heaviside theta function as \( \Theta(s) = \int \frac{dp e^{ip}}{2\pi} \). Now the average \( \langle e^{ip} s \rangle \) is a product of averages over independent variables, which we can evaluate analytically and reexponentiate the result in a few steps to yield (see Appendix A1)
\begin{equation}
\langle \Theta(s) \rangle = 2\sqrt{Q_R Q_L} e^{-Q_R - Q_L} x \int \frac{du}{2\pi} \sin(u - i\gamma) e^{2\sqrt{Q_R Q_L} \cos(u - i\gamma)} , \quad (12)
\end{equation}

where \( \tanh \gamma = (Q_L - Q_R)/(Q_L + Q_R) \) and
\begin{align}
Q_R(x,t) &= \int \frac{dp}{2\pi} \Theta(x/t - v_p) f_R(p)(x - v_p t) , \quad (13a) \\
Q_L(x,t) &= \int \frac{dp}{2\pi} \Theta(v_p - x/t) f_L(p)(v_p t - x) \quad (13b)
\end{align}

are the expectation numbers of right/left particles crossing the segment \( A \) connecting the origin with the point \((x, t)\). Repeating the derivation for \( \langle \Theta(-s) \rangle \) and using Eq. (8a), we finally obtain for \( \langle M_A \rangle \)
\begin{equation}
\langle M_A \rangle = 2\sqrt{Q_R Q_L} e^{-Q_R - Q_L} \int \frac{du}{2\pi} \sin(u - i\gamma) e^{2\sqrt{Q_R Q_L} \cos(u - i\gamma)} \left( \frac{\hat{\mu}_L}{u - i\varepsilon} - \frac{\hat{\mu}_R}{u + i\varepsilon} \right). \quad (14)
\end{equation}

An alternative but maybe less transparent derivation presented in Appendix A2 yields an equivalent but possibly more convenient, alternative expression,
\begin{equation}
\langle M_A \rangle = (Q_L - Q_R) \langle \Theta | Q_R - Q_L | \hat{\mu}_R + \Theta | Q_L - Q_R | \hat{\mu}_L \rangle + (\hat{\mu}_L - \hat{\mu}_R) \sqrt{Q_R Q_L} \int_1^\infty \frac{dz}{z} e^{-(Q_R + Q_L)z} I_1 \left( 2\sqrt{Q_R Q_L} z \right), \quad (15)
\end{equation}

where \( I_1(x) \) is the modified Bessel function of the first kind.

The spin current is given by the time derivative of the total transported magnetization at position \( x \),
\begin{equation}
J(t) = \partial_t M(x,t) = \partial_t \langle M_A \rangle, \quad (16)
\end{equation}

since \( \langle M_B \rangle \) is independent of time. The magnetization (spin) density \( m(x,t) \) can then be obtained by integrating the continuity equation
\begin{equation}
\partial_t m(x,t) + \partial_x J(x,t) = 0 \quad (17)
\end{equation}

with the initial condition given by the initial state. This yields
\begin{equation}
m(x,t) = -\partial_x M(x,t) + \Theta(x) n_R \hat{\mu}_R + \Theta(-x) n_L \hat{\mu}_L \\
= -\partial_x \langle M_A \rangle. \quad (18)
\end{equation}

where we noticed that the initial condition exactly cancels the spatial derivative of \( \langle M_B \rangle \). The function \( \langle M_A \rangle \) depends on \( x \) and \( t \) through \( Q_L \) and \( Q_R \) only, which implies that apart from an overall sign, the expression for \( m(x,t) \) and \( J(x,t) \) will have the same structure. When differentiating Eq. (15), it is useful to change the integration variable \( z \) to \( u = 2\sqrt{Q_R Q_L} z \) and change it back after differentiation. We thus find
\[
\left( \frac{J(x,t)}{m(x,t)} \right) = (\nabla Q_L - \nabla Q_R) (\Theta[Q_R - Q_L] \mu_R + \Theta[Q_L - Q_R] \mu_L)
\]
\[
+ (\mu_L - \mu_R) \nabla Q_R Q_L + Q_R \nabla Q_L \left( \int_1^\infty \frac{e^{-(Q_R + Q_L)z}}{z} I_1 \left( 2\sqrt{Q_R Q_L} z \right) - e^{-(Q_R + Q_L)} I_1 \left( 2\sqrt{Q_R Q_L} \right) \right)
\]
\[
- (\mu_L - \mu_R) \nabla Q_R Q_L - Q_R \nabla Q_L (Q_R - Q_L) \int_1^\infty dz e^{-(Q_R + Q_L)z} I_1 \left( 2\sqrt{Q_R Q_L} z \right),
\]

where
\[
\nabla Q_{R/L}(x,t) \equiv \left( \frac{\partial_x Q_{R/L}}{-\partial_z Q_{R/L}} \right).
\]

Expression (19) is one of the main results of the paper that gives the space-time profile of the magnetization current and density in the thermodynamic limit for arbitrary \(x\) and \(t\).

### III. LARGE TIME ASYMPTOTIC RESULTS

Although Eq. (19) has an analytical beauty, it is not very transparent. To gain some physical insight, let us now analyze its physical content by extracting its behavior at large times.

For later purposes, let us introduce the \textit{rates} at which particles from the right/left cross segment \(A\)
\[
\Gamma_{R/L}(x,t) \equiv \frac{Q_{R/L}(x,t)}{t}.
\]

Interestingly, these rates depend on \(x\) and \(t\) only through the ratio \(\xi \equiv x/t\), with the velocity variable \(\xi\) specifying “rays” in the \((x,t)\) plane. Similarly, the derivatives \(\partial_x Q_{R/L}(x,t)\) and \(\partial_z Q_{R/L}(x,t)\) also depend on \(\xi\) only,
\[
\partial_x Q_R (\xi) = \pm \int \frac{dp}{2\pi} \Theta[\pm(\xi - v_p)] f^{R/L}(p),
\]
\[
\partial_z Q_{R/L}(x,t) = \pm \int \frac{dp}{2\pi} \Theta[\pm(\xi - v_p)] v_p f^{R/L}(p).
\]

Notice that \(\partial_x Q_R - \partial_x Q_L\) is nothing but the particle density \(n(x,t) = n(\xi)\) in Eq. (5) and \(\partial_z Q_L - \partial_z Q_R\) is the particle current \(j(x,t) = j(\xi)\) in Eq. (6).

Since we are mainly interested in the large time behavior of the magnetization density and the current profiles, and since \(Q_{R/L}\) are both proportional to \(t\) for any fixed \(\xi\), for large times we can use the asymptotic behavior of the Bessel function and obtain an analytical estimate of

![Figure 2](image_url)

**FIG. 2.** Evolution of the magnetization profile for particles with dispersion relation \(\varepsilon(p) = \sqrt{\Delta^2 + p^2 c^2}\). The coordinate \(x\) is measured in units of the Compton length \(\hbar c/\Delta\) while time \(t\) is measured in units of \(\hbar/\Delta\), and we set \(\hbar = 1\) and \(c = 1\). The left/right momentum distributions are \(f_{R/L}(p) \sim e^{-\beta_{R/L} \varepsilon(p)}\) with inverse temperatures \(\Delta \beta_L = 1\), \(\Delta \beta_R = 2\) and average magnetizations per particle \(\mu_L = 0.8\), \(\mu_R = -1\). (a) Magnetization profiles for different times as indicated in the legend. The analytic result (19) is plotted in solid lines while symbols represent Monte Carlo simulations. (b) Same data as functions of \(x/t\), demonstrating ballistic transport. Eq. (27a) is shown as a dashed line. Inset: Magnetization profiles around the second front as a function of \([x-x^*(t)]/\sqrt{t}\), demonstrating the diffusive broadening of the front.
the integrals in Eq. (19) (see Appendix A3)

\[
\begin{align*}
J(x,t) \\ m(x,t)
\end{align*}
\approx (\nabla Q_L - \nabla Q_R) (\Theta[Q_R - Q_L] \hat{\mu}_R + \Theta[Q_L - Q_R] \hat{\mu}_L)
+ \Delta \hat{\mu} \frac{\nabla Q_R Q_L + Q_R \nabla Q_L}{2(Q_R Q_L)^{3/4}} \left( e^{-R^2}/(2\sqrt{\pi}) - |R| \text{erfc}|R| \right)
- \Delta \hat{\mu} \frac{\nabla Q_R Q_L - Q_R \nabla Q_L}{4(Q_R Q_L)^{3/4}} \left( \sqrt{Q_R} + \sqrt{Q_L} \right) \text{sgn}(R) \text{erfc}|R|,
\]

where \(R(x,t) \equiv \sqrt{Q_R} - \sqrt{Q_L}\) and \(\Delta \hat{\mu} = \hat{\mu}_L - \hat{\mu}_R\).

At generic values of \(\xi\), the difference \(R\) is proportional to \(\sqrt{Q_R} - \sqrt{Q_L} \sim \sqrt{t}\) implying that the last two lines of Eq. (24) are exponentially suppressed for large \(t\), and only the first line survives. This gives a \textit{ballistic} result: both the magnetization density and the current profiles are scaling functions of the variable \(\xi = x/t\), and display a jump-like structure at a critical ray \(\xi = \nu^*\), where \(Q_L = Q_R\), i.e., the left and right crossing rates equal

\[\Gamma_R(\nu^*) = \Gamma_L(\nu^*).\] (25)

Using the explicit expressions (13) this equality can be rewritten in a more illuminating form,

\[j(\nu^*) = \nu^* n(\nu^*),\] (26)

where \(n(\xi)\) and \(j(\xi)\) are given in Eqs. (5) and (6). This equation always has a unique solution, which allows us to rewrite the ballistic component as

\[
\begin{align*}
\text{m}_{\text{bal}}(\xi) &= n(\xi)(\Theta[\xi - \nu^*] \hat{\mu}_R + \Theta[\nu^* - \xi] \hat{\mu}_L), \quad (27a) \\
\text{J}_{\text{bal}}(\xi) &= j(\xi)(\Theta[\xi - \nu^*] \hat{\mu}_R + \Theta[\nu^* - \xi] \hat{\mu}_L). \quad (27b)
\end{align*}
\]

These results have a clear physical meaning. Recalling the interpretation of \(Q_{R/L}\), Eq. (25) means that along the ray \(\nu^*\) the fluxes of particles coming from the left and the right are balanced. Equivalently, Eq. (26) implies that the fluid velocity defined as \(j(x,t)/n(x,t)\) along the ray \(x/t = \nu^*\) is equal to \(\nu^*\), so in the reference frame traveling at velocity \(\nu^*\) the particle flow is zero. Thus \(\nu^*\) is the velocity of the boundary between left and right particles. We shall refer to this front of left particles penetrating the gas of right particles or the other way around as the "second front". The "first front" is given by the light cone but yet to the right of the second front so \(\nu^*\) is the velocity of the second front. This shows that the first jump discontinuity in the ballistic result corresponds to a physical shock? To answer this, we have to take a closer look at the profiles around the second front at \(\nu^*.\) It is easy to see that around this point it is not justified to drop the terms we neglected in the derivation of Eqs. (27): for all \(t\) there is a region in \(\xi\) around \(\nu^*\) where \(R = \sqrt{Q_R} - \sqrt{Q_L}\) is small and the terms we dropped are non-negligible. Expanding around \(\xi = \nu^*\) we find that

\[R(x,t) = \sqrt{Q_R} - \sqrt{Q_L} \approx \frac{1}{2\sqrt{D^*}} (\xi - \nu^*) \sqrt{t},\] (28)

with the diffusion constant defined as

\[D^* = \frac{\Gamma(\nu^*)}{n(\nu^*)^2}.\] (29)

We thus conclude that the size of the region of \(\xi\) where the non-ballistic terms neglected in (27) are important shrinks as \(\sim t^{-1/2}\). In terms of the original space-time variables, however, this corresponds to a region \((x - x^*(t))^{2} \sim t D^*\) with \(x^*(t) = \nu^* t\) denoting the instantaneous position of the second front. This shows that the
spatial region around the ballistic second front actually grows diffusively as \( \sim \sqrt{t} \) and there is no real shock wave.

Let us now focus to the region close to the ballistic second front by taking the limits \( t \to \infty \) and \( R = \sqrt{QR - \sqrt{QL}} \) fixed. Then the last two lines of Eq. (24) can be simplified further,

\[
\left( \frac{J(x, t)}{m(x, t)} \right) \approx \left( \frac{j(n)}{n(n)} \right) \left( \Theta[x - v^*] + \Theta[v^* - x]\mu_L \right) + \left( \frac{j(v^*)}{n(v^*)} \right) \mu_L - \mu_R \frac{2}{\sqrt{4D^*t}} \text{erfc} \left( \frac{|x - v^*|}{\sqrt{4D't}} \right).
\]

This equation provides a surprisingly accurate approximation for the exact magnetization profiles, Eq. (19) at large times. In Figs. 2 and 3 we plot the magnetization and the spin current using thermal momentum distributions and relativistic dispersion relation (see caption of Fig. 2 for details). Fig. 3.a demonstrates that the asymptotic expression (30) plotted in dashed line approaches the full result (19) shown as a solid line. A similar behavior is observed for the magnetization profiles (not plotted in Fig. 2.a). The ballistic solutions (27) with the jump discontinuity are plotted in Figs. 2.b and 3.b in dashed line. Results of the Monte Carlo simulations discussed in Section IV are shown as symbols.

Both the \( \sqrt{t} \) dependence and the appearance of the error function hints at the diffusive nature of the correction. Indeed, around the second front \( \xi \approx v^* \), the magnetization is

\[
m(x, t) \approx n^* \frac{\mu_L + \mu_R}{2} - n^* \frac{\mu_L - \mu_R}{2} \text{erf} \left( \frac{x - x^*(t)}{\sqrt{4D't}} \right).
\]

In the reference frame of the front, this is just the solution of the diffusion equation with diffusion constant \( D^* \) with step-like initial condition. Our formula thus describes the diffusive broadening of the ballistically moving front.

The NESS is obtained by setting \( \xi = 0 \), \( t \to \infty \), yielding (for \( v^* \neq 0 \))

\[
\left( \frac{J_{\text{NESS}}}{m_{\text{NESS}}} \right) = \left( \frac{j(0)}{n(0)} \right) \left( \Theta[-v^*] + \Theta[v^*] \mu_L \right).
\]

Thus for right moving (left moving) fronts the magnetization and its current in the NESS are determined by the polarization on the left (right) and the average densities and particle currents of particles passing through the origin (see Eqs. (5) and (6)).

Interestingly, we can also compute the magnetization density and current analytically right at the front using that the last term in Eq. (19) vanishes and

\[
J_{\text{NESS}} \left[ \sqrt{\frac{t}{z}} \right] = J_1(2Q^* z) = e^{-2Q^*} [I_0(2Q^*) + I_1(2Q^*)]
\]

with the result

\[
\begin{align*}
m_{\text{NESS}} &= \frac{1}{2} \left( \frac{\mu_L + \mu_R}{2} \right) n(v^*) - \frac{\mu_L - \mu_R}{2} (\partial_z Q_R + \partial_z Q_L) e^{-2Q^*} I_0(2Q^*), \\
J_{\text{NESS}} &= \frac{1}{2} \left( \frac{\mu_L + \mu_R}{2} \right) j(v^*) + \frac{\mu_L - \mu_R}{2} (\partial_z Q_L - \partial_z Q_R) e^{-2Q^*} I_0(2Q^*),
\end{align*}
\]

where we used the notation \( Q^*(t) = \Gamma(v^*) \). The time dependence comes from the factors \( e^{-2P^* t} I_0(2P^* t) \) that give a \( \sim 1/\sqrt{t} \) approach towards the large time asymptotic values \( m(v^*)(\mu_L + \mu_R)/2 \) and \( j(v^*)(\mu_L + \mu_R)/2 \).

### A. Balanced case: diffusive spin transport

The asymptotic result in Eq. (30) is not correct for the special, balanced case, when the streams of particles coming from the left and right balance each other such that the front does not move, \( v^* = 0 \). In this case we have \( \Gamma_L(v^*) = \Gamma_R(v^*) \), which, through the general relation \( \partial_t Q(v^*) = \Gamma(v^*) - v^* \partial_z \Gamma(v^*) \) immediately yields that \( \partial_t Q_R(v^*) = \partial_t Q_L(v^*) \), i.e. that the particle current at the front vanishes \( j(v^*) = 0 \). Apart from fine tuned cases, this can happen most naturally in a balanced situation when \( f_L(p) = f_R(p) = f(p) = -f(p) \), i.e. when the even momentum distributions and the average densities on the two sides are equal, only the spin distributions are different. Then the particle current and the associated ballistic component of the magnetization current is identically zero, \( \partial_z Q_R - \partial_z Q_L = 0 \), and \( \partial_z Q_R - \partial_z Q_L = n \) so the orbital degrees of freedom are homogeneous throughout the system. For thermal initial states this is the case when \( T_L = T_R \) and \( h_L = -h_R \) implying opposite magnetizations \( \mu_R = -\mu_L \).

In this balanced case the magnetization dynamics is entirely described by the diffusive component. At the origin we find, in particular

\[
Q_R(0) = Q_L(0) = t \int \frac{dp}{2\pi} \Theta(v^*) f(p) v_p = t/(2\tau),
\]

\[
\partial_t Q_R(0) = \partial_t Q_L(0) = \int \frac{dp}{2\pi} \Theta(v^*) f(p) v_p = 1/(2\tau),
\]

\[
\partial_z Q_R/L(0) = \pm \int \frac{dp}{2\pi} \Theta(\mp v^*) f(p) = \pm n/2,
\]

where we introduced the collision time \( \tau \) defined as the ratio of the average separation and the average velocity modulus,

\[
\tau^{-1} = n(|v|) = \int \frac{dp}{2\pi} f(p)|v_p|.
\]
Using Eqs. (33) we find that at the origin
\[ m(0, t) = n \frac{\hat{\mu}_L + \hat{\mu}_R}{2}, \]
\[ J(0, t) = \frac{\Delta \hat{\mu} e^{-t/\tau}}{2} I_0(t/\tau). \]

After a sudden jump, the magnetization current decreases linearly for short times, \( J(0, t) \approx \Delta \hat{\mu} / (2\tau) (1 - t/\tau) \), while for large times it decays to zero,
\[ J(0, t) \approx \frac{\Delta \hat{\mu}}{\sqrt{2\pi t} \tau}. \]

Both the short and the long time behavior are governed by the collision time \( \tau \).

Expanding around the origin then gives \( \sqrt{Q_R} - \sqrt{Q_L} \approx x / (2\sqrt{Dt}) \), where the diffusion constant \( D = \frac{1}{2n^2 \tau} \) is proportional to the collision rate, Eq. (37).

The magnetization density is given by Eq. (30), while the current can be obtained from Eq. (24). Now due to \( \partial_t Q_R = \partial_t Q_L \), an extra factor of \( Q_L - Q_R \) appears in the numerator of the last term rendering the last two lines of the same order. Luckily, a cancellation takes place and we find
\[ m(x, t) \approx n \frac{\hat{\mu}_L + \hat{\mu}_R}{2} - n \frac{\hat{\mu}_L - \hat{\mu}_R}{2} \text{erf} \left( \frac{x}{\sqrt{4Dt}} \right), \]
\[ J(x, t) \approx n \frac{\Delta \hat{\mu}}{2} \sqrt{\frac{D}{\pi t}} e^{-x^2/(4Dt)}. \]

The magnetization profile for large times is the solution of the diffusion equation
\[ \partial_t m(x, t) = D \partial_x^2 m(x, t), \]
with the step-like initial condition \( m(x, 0) = \Theta(-x) n \hat{\mu}_L + \Theta(x) n \hat{\mu}_R \).

IV. BEYOND THE UNIVERSAL LIMIT

The analytic treatment discussed in the previous sections relied on the assumption of purely reflective scattering, valid in the limit of vanishing quasiparticle momenta. For faster quasiparticles, however, transmissive processes are also allowed, moreover, the set of outgoing spins need not coincide with the incoming set. In this section, we shall investigate the effect of these non-transmissive processes through Monte Carlo simulations [41]. For simplicity, we focus on the O(3) \( \sigma \)-model, where the magnetization is locally conserved, so the S-matrix has non-zero matrix elements between states of the same total spin component in the \( z \) direction. In a collision of a + and a − particle there are three possible out states, \((+, -), (-, +), (0, 0)\), corresponding to reflection, transmission, and transmutation into \( \theta \) particles.

In the simulations we average over semiclassical configurations numerically. While generating the initial quasiparticle configurations and finding the coordinates of the collisions is simple, following the trajectories of the spins is more complicated. In the universal limit, spins get reflected at each collision, and follow zig-zag paths. Averaging the snapshots of the spin positions at given times over the semiclassical configurations yields the density profiles for each particle species, and determines the magnetization profile. This is how the numerical data shown in Figs. 2, 3 was obtained using two particle species, i.e. when \( \mu \) can take two values \( \mu = \pm 1 \).

In the non-universal case, different spin configurations are superposed with the respective probability amplitudes of the 2-particle S-matrix. The issuing coherent time evolution of the quasiparticle spins can be described by a hybrid semiclassical matrix product state approach [41], whereby the spatial sequence of the particle spins is treated as an effective spin chain. Here, however, we focus on magnetization densities, and we do not expect spin coherence to play a major role \(^2\). Therefore we use a simpler, classical version of the hybrid method where we disregard the quantum coherence of spins and assign specific outcomes of each collision with probabilities derived from the respective S-matrix amplitudes, \(|S_{\mu_1, \mu_2}^{\nu_1, \nu_2}|^2 \).

\(^2\) Indeed, the two versions of the hybrid method was found to give identical results even for equal time correlation functions after a quantum quench.
A. Relaxation of particle densities in a homogeneous system

Let us study first the relaxation of the number (density) of particles with a given spin in a spatially homogeneous setup. Though the total quasiparticle number $N$ and the spin $N_+ - N_-$ are both conserved, $(0, 0) \leftrightarrow (+, -)$ scattering leads to a relaxation of the particle numbers $N_\mu$ and the corresponding densities $n_\mu$ and probabilities $p_\mu = N_\mu/N$.

The time evolution of the occurrences $p_\mu(t)$ is shown in Fig. 5 for an initial state of thermalized quasiparticles with no $\emptyset$ particles and $80\%$ ($20\%$) of type $+$ ($-$) particles. By parity and time reversal, however, the equilibrium densities must satisfy detailed balance,

$$p_+ p_- = \frac{1}{2} P_0^2,$$  \hspace{1cm} (43)

where the factor $1/2$ takes into account that colliding $0$ particles are identical. Noticing that only collisions of type $(0, 0) \leftrightarrow (+, -)$ generate particle number relaxation, we can parameterize the occurrences of the particle species as $p_+ = p_0^0 - x$ and $p_0 = p_0^0 + 2x$. Substitution to Eq. (43) then determines the stationary values of the probabilities $p_\mu$. Indeed, the $p_\mu(t)$ curves in Fig. 4 approach these values, clearly demonstrating that the hybrid semiclassical method is able to capture equilibration of particle species.

B. Transport beyond the universal limit

Let us now turn to the setup studied in Sections II and III to see the effect of the non-universal S-matrix on the non-equilibrium dynamics and transport. We focus on the fully polarized initial state with only $+$ particles on the left, and only $-$ particles on the right. Fig. 5.a shows the density profiles of the three particle species separately. The second front moving with velocity $x/t = v^*$ is the location of the boundary between the $+$ and $-$ particles coming from the left and from the right, respectively. The magnetization profile given by $m(x, t) = n_+(x, t) - n_-(x, t)$ is shown in Fig. 5.b. The qualitative behavior of the magnetization and the spin current is the same as in the universal case. In particular, the picture of a ballistically propagating and diffusively spreading “second front” remains valid. However, due to the collisions of $+$ and $-$ particles, a bump of $\emptyset$ particles develops around the front (see Fig. 5.a).

As time evolves, local equilibration takes place around the front. In Fig. 5.c we show the populations of the particle species around the front at $x = v^* t$. The analytical result, Eq. (31) predicts that asymptotically a magnetization $m(x/t = v^*) = v^* (\mu_L + \mu_R)/2$ so $p_+ - p_- = (\mu_L + \mu_R)/2$ at the front. Assuming that this result carries over to non-reflective scattering, we can use again the detailed balance condition (43) to determine the proportion of charged particles at the front. In Fig. 5 we have $(\mu_L + \mu_R)/2 = 0$, yielding $p_\pm = 2-\sqrt{2}/2 \approx 0.293$ and $p_0 = 2\sqrt{2} - 1 \approx 0.414$. These are in very good agreement with the numerics, shown in Fig. 5.c, thus demonstrating local equilibration of particles with different spins at the
FIG. 6. The left and right hand side of the detailed balance condition (43) involving the relative populations of the three particle species as functions of the position for the setup initial to that in Fig. 5. The dynamics leads to local equilibration: at each point the local densities satisfy detailed balance. Units and conventions as in Fig. 5.

second front.

This local equilibration takes place not only at the second front but in a region around the second front and eventually in the whole system. In Fig. 6 we show the quantities at the two sides of the detailed balance condition (43) as functions of the position \( x \) for two different times. For the fully polarized initial state, the densities on the left and right hand side satisfy the detailed balance condition \(^3\). Near the second front where the left and right particles meet, detailed balance is not satisfied initially. However, local equilibration takes place with time, and detailed balance is restored.

V. CONCLUSIONS

In this work we used the semiclassical approach to study transport and front propagation in systems with massive “spinful” quasiparticles with an internal quantum number. We found that unlike the energy and density that propagate ballistically, the dynamics of internal degrees of freedom is generically not ballistic (unless the scattering of particles is completely transmissive), but rather ballistic front propagation and diffusive dynamics coexist.

In the universal low energy limit of fully reflective scattering, in particular, we derived analytical expressions for the evolution of the magnetization density and spin current profiles for the case of two semi-infinite systems joined at time \( t = 0 \). We find that spin transport can be diffusive or ballistic depending on the initial state. A purely diffusive behavior arises in the ‘balanced’ case, when the densities and momentum distributions are the same on the two sides, and only spin polarizations differ. This is reminiscent to the situation studied in Ref. [11] where diffusive behavior was observed numerically in the XXZ spin chain for equal temperatures and opposite magnetic fields on the two sides.

In the – more generic – imbalanced case, magnetization density and spin current profiles have a jump discontinuity as a function of \( \xi = x/t \) in the limit \( x, t \to \infty \) with \( \xi \) finite. This jump corresponds to the interface between left and right particles. This is somewhat similar to, but not the same as the jumps predicted by the GHD framework in the gapped phase of the different quasiparticle species [26]. Remarkably and in contrast to the GHD description [70], our analytic expressions capture also the sub-ballistic, diffusive broadening of this front.

To go beyond the universal low momentum regime, we also studied the effect of non-reflective scattering on transport and front propagation phenomena in the \( O(3) \) non-linear sigma model using a hybrid semiclassical Monte Carlo approach [41]. This approach accounts also for processes where individual spins are not conserved in the collisions, so that populations of the three possible spin states can change in time. Interestingly we find that spin populations reach local equilibrium rather quickly, and the propagating front obeys local detailed balance.

From the viewpoint of Bethe Ansatz, our model belongs to the class of systems having non-diagonal scattering. The first application of GHD in such a system was done in the recent contribution [27], but further implications of the non-diagonal nature of the scattering remain to be studied. We believe that our semiclassical calculations provide valuable benchmarks for the further development of hydrodynamic descriptions.

Our system can also be related to the so-called classical soliton gas that was proposed to provide a physical picture for the GHD equations [24]. It would be interesting to include velocity dependent time delays of colliding particles, classical counterparts of quantum scattering phase shifts, that are essential for reproducing the structure of the GHD equations [24].

The semiclassical approach applied here has many perspectives. It can and has been used to describe the time evolution of correlation functions [38–41], carrying valuable information in the current setup as well [71]. These calculations could possibly be extended to inhomogeneous non-equilibrium states, investigated here. It may

\(^3\) For initial states not obeying detailed balance there is a nontrivial evolution towards local equilibration even far from the second front.
also be possible to extend the semiclassical description to higher dimensions. Here collisions cannot be treated in terms of point-like particles but a finite cross section must be introduced. Moreover, different geometries may lead to different types of behavior as the particle density at the front can change in time. We leave these interesting questions and directions for future study.

APPENDIX

A1. DETAILS OF THE DERIVATION OF EQ. (14)

Let us first compute \( \Theta(s)s \) where \( s \) is given in Eq. (11), using formula (9). In order to decouple the coordinates of the different particles, we employ the integral representation for the Heaviside theta function,

\[
\Theta(x) = \int \frac{du}{2\pi i u + \varepsilon},
\]

and obtain

\[
(\Theta(s)s) = \frac{1}{N_R^N} \prod_{i=1}^{N_R} \int_0^L dy_i \int \frac{dp_i}{2\pi} f_R(p_i) \frac{1}{N_N^L} \prod_{j=1}^{N_N} \int_{-L}^0 d\tilde{y}_j \int \frac{d\tilde{p}_j}{2\pi} f_L(\tilde{p}_j) \int \frac{du}{2\pi i u + \varepsilon} e^{iu \sum_{j=1}^{N_N} \Theta(\tilde{y}_j + \tilde{v}_j t - x - iu) - \sum_{j=1}^{N_N} \Theta(\tilde{y}_j - \tilde{v}_j t - x) + \sum_{j=1}^{N_N} \Theta(x - y_j - v_j t)} \sum_{j=1}^{N_R} \Theta(x - y_j - v_j t) - \sum_{j=1}^{N_R} \Theta(x - y_j - v_j t) \right),
\]

where \( v_j = v_{i=1} \) and \( \tilde{v}_j = \tilde{v}_{i=1} \). Now the multiple integral over positions and velocities can be factorized, leading to double integrals like

\[
\int_0^L dy \int \frac{dp}{2\pi} f_R(p)e^{iu \Theta(x - y - v_p t)} \Theta(x - y - v_p t) = \frac{1}{N_R} \int \frac{dp}{2\pi} f_R(p)\Theta(x/t - v_p)(x - v_p t)e^{-iu} = \frac{Q_R}{N_R} e^{-iu},
\]

\[
\int_0^L dy \int \frac{dp}{2\pi} f_R(p)e^{iu \Theta(x - y - vt)} = \frac{1}{N_R} \int \frac{dp}{2\pi} f_R(p)\Theta(x/t - v_p)(x - v_p t)(e^{-iu} - 1) = \frac{Q_R}{N_R}(e^{-iu} - 1).
\]
where $Q_{L/R}$ are defined in Eq. (13). Evaluating the other integrals in a similar manner we obtain

$$
\langle \Theta(s) \rangle = \int \frac{du}{2\pi iu + \varepsilon} \left\{ N_L Q_L e^{iu} \left[ 1 + \frac{Q_L}{N_L} (e^{iu} - 1) \right]^{N_L - 1} \left[ 1 + \frac{Q_R}{N_R} (e^{-iu} - 1) \right]^{N_R} - N_R \frac{Q_R}{N_R} e^{-iu} \left[ 1 + \frac{Q_R}{N_R} (e^{-iu} - 1) \right]^{N_R - 1} \left[ 1 + \frac{Q_L}{N_L} (e^{iu} - 1) \right]^{N_L} \right\}. \tag{A4}
$$

In the thermodynamic limit $N_R, N_L, L \to \infty$ with the densities $n_{R/L} = N_{R/L}/L$ fixed, so

$$
\langle \Theta(s) \rangle = \int \frac{dp}{2\pi iu + \varepsilon} \left( Q_L e^{iu} e^{-i\gamma} Q_R e^{i\gamma} - Q_R e^{iu} e^{i\gamma} Q_L e^{-i\gamma} \right) = 2\sqrt{Q_R Q_L} e^{-Q_R - Q_L} \int \frac{du}{2\pi iu - i\varepsilon} \sin(u - i\gamma)e^{2\sqrt{Q_R Q_L} \cos(u - i\gamma)}, \tag{A5}
$$

where $\tanh \gamma = (Q_L - Q_R)/(Q_L + Q_R)$. Repeating the derivation for $\langle \Theta(-s)(-s) \rangle$ and using Eqs. (8a), we arrive at Eq. (14) for $M(x, t)$.

### A2. ALTERNATIVE DERIVATION

In this appendix we provide an alternative derivation of $M(x, t)$ yielding the expression (15). The starting point is Eq. (8) but now we compute the expectation values based on the probability that the number of net crossings $s$ admits a given value in a configuration.

A straight line from the left of momentum $p$ can intersect the $A = [(0, 0), (x, t)]$ segment (see Fig. 1) only if its velocity is greater than $x/t$. The probability that it intersects $A$ is, due to the even spatial distribution of lines, given by the length of the interval where the line can come from divided by the length $L_L$ of the left system, $|x - v_t t|/L$. Similarly, a line from the right can cross $A$ if $v_p < x/t$ with probability $(x - v_t t)/L_R$. Then the probability that a randomly chosen straight line from the left or the right intersects the segment $A$ is

$$q_l = n_{L_1}^{-1} \int \frac{dp}{2\pi} \Theta(v_p - x/t) f_L(p) \frac{v_p - x}{L_L} = Q_L/N_L, \tag{A6}
$$

$$q_R = n_{R_1}^{-1} \int \frac{dp}{2\pi} \Theta(x/t - v_p) f_R(p) \frac{x - v_p t}{L_R} = Q_R/N_R, \tag{A7}
$$

where $N_{L/R}$ are the total initial particle numbers on the left and on the right, and $Q_{L/R}$ are defined in Eqs. (13).

The key quantity in the calculation is the net crossing number $s = k_L - k_R$, where $k_L$ and $k_R$ denote the number of left and right crossing lines in a configuration. The probability of such a configuration, thanks to the independence of the straight lines, is

$$P(k_L, k_R) = \binom{N_L}{k_L} \binom{N_R}{k_R} q_L^{k_L} (1 - q_L)^{N_L - k_L} q_R^{k_R} (1 - q_R)^{N_R - k_R}. \tag{A8}
$$

Then $M(x, t)$ in Eq. (8a) can be computed as

$$M(x, t) = \sum_{k_L=0}^{N_L} \sum_{k_R=0}^{N_R} P(k_L, k_R) (k_L - k_R) [\Theta(k_L - k_R)\mu_L + \Theta(k_R - k_L)\mu_R]. \tag{A9}
$$

Now we use the identity

$$x[\Theta(x)\mu_R + \Theta(-x)\mu_L] = \frac{1}{2} (\mu_R + \mu_L)x + \frac{1}{2} (\mu_R - \mu_L)|x|, \tag{A10}
$$

and we rewrite $M(x, t)$ as

$$M(x, t) = \frac{1}{2} (\mu_R + \mu_L)(N_L q_L - N_R q_R) + \frac{1}{2} (\mu_R - \mu_L) \sum_{k_L=0}^{N_L} \sum_{k_R=0}^{N_R} \binom{N_L}{k_L} \binom{N_R}{k_R} q_L^{k_L} (1 - q_L)^{N_L - k_L} q_R^{k_R} (1 - q_R)^{N_R - k_R} |k_L - k_R|. \tag{A11}
$$
Without the loss of generality we can assume that $N_L = N_R = N$ since this can be achieved by setting the ratio of the lengths of the two segments which however should not matter in the thermodynamic limit. It turns out that the double sum can be rewritten as

$$ S = N(q_L + q_R) - N \sum_{l=0}^{N-1} \sum_{k=0}^{N-1-l} \left( \frac{k + 2l}{2l} \right) \frac{2}{l+1} \left( \frac{k + 2l}{2l} \right) (q_L q_R)^{l+1}(1 - q_L - q_R)^k, \quad (A12) $$

which has the advantage that it depends on two combinations, $q_L q_R$ and $1 - q_L - q_R$, moreover, one of the sums can be computed analytically:

$$ \sum_{k=0}^{N-l-1} \left( \frac{k + 2l}{2l} \right) (1 - q_L - q_R)^k = \frac{1}{(q_L + q_R)^{2l+1}} \left[ 1 - (N - l) \left( \frac{N + l}{2l} \right) B_{1-q_L-q_R}(N-l, 2l + 1) \right], \quad (A13) $$

where $B_z(a, b)$ is the incomplete Euler beta function.

In the thermodynamic limit,

$$ \lim_{N \to \infty} \sum_{k=0}^{N-l-1} \left( \frac{k + 2l}{2l} \right) (1 - q_L/N - Q_R/N)^k = \left[ 1 - \frac{\Gamma(2l + 1, Q_L + Q_R)}{(2l)!} \right] \left( \frac{Q_L}{Q_L + Q_R} \right)^{2l+1}, \quad (A14) $$

where $\Gamma(a, y) = \int_y^\infty dz z^{a-1} e^{-z}$ is the incomplete gamma function, so we obtain

$$ \lim_{N \to \infty} S = (Q_R + Q_L) - (Q_R + Q_L) \sum_{l=0}^{\infty} \left( \frac{2l}{l+1} \right) \frac{2}{l+1} \left( \frac{Q_L Q_R}{(Q_L + Q_R)^2} \right)^{l+1} \left[ 1 - \frac{\Gamma(2l + 1, Q_L + Q_R)}{(2l)!} \right], \quad (A15) $$

where we took $N$ to infinity in the upper limit of the sum as all the explicit dependence of the summand on $N$ has disappeared. It is convenient to introduce the notations

$$ r = Q_R + Q_L, \quad p = \sqrt{Q_L Q_R}, \quad R = \sqrt{Q_R - Q_L} \quad (A16) $$

where $R^2 = r - 2p$. The first term in the bracket gives in the sum

$$ \sum_{l=0}^{\infty} \left( \frac{2l}{l+1} \right) \frac{2}{l+1} \left( \frac{p}{r} \right)^{2l+2} = 1 - \sqrt{1 - 4(p/r)^2}, \quad (A17) $$

while the for the second one we obtain by switching the sum and the integral in the definition of the Gamma function

$$ \sum_{l=0}^{\infty} \left( \frac{2l}{l+1} \right) \frac{2}{l+1} \frac{1}{(2l)!} \Gamma[2l + 1, r] = \left( \frac{p}{r} \right)^2 \int_R^\infty dz e^{-z} \sum_{l=0}^{\infty} \frac{1}{(2l)!} \frac{2}{l+1} \left( \frac{p}{r} \right)^{2l} = 2p \int_R^\infty dz e^{-z} I_1(2p/r \cdot z), \quad (A18) $$

where $I_1(x)$ is the modified Bessel function of the first kind. So we arrive at

$$ \lim_{N \to \infty} S = s \sqrt{1 - 4(p/r)^2} + 2p \int_R^\infty dz \frac{e^{-z}}{z} I_1(2p/r \cdot z) = |Q_R - Q_L| + 2p \int_1^\infty dz \frac{e^{-r z}}{z} I_1(2p z). \quad (A19) $$

Collecting the terms, we finally obtain in the thermodynamic limit

$$ M(x, t) = \frac{1}{2}(\mu_R + \mu_L)(Q_L - Q_R) + \frac{1}{2}(\mu_R - \mu_L) \left[ |Q_R - Q_L| + 2p \int_1^\infty dz \frac{e^{-r z}}{z} I_1(2p z) \right] $$

$$ = (Q_R - Q_L) [\Theta(Q_R - Q_L) \mu_R + \Theta(Q_L - Q_R) \mu_L] + (\mu_R - \mu_L) \sqrt{Q_L Q_R} \int_1^\infty dz \frac{e^{-(Q_R + Q_L) z}}{z} I_1 \left( 2\sqrt{Q_L Q_R} z \right). \quad (A20) $$
A3. SOME ASYMPTOTIC EXPRESSIONS

In this appendix we list approximating expressions valid for large times and used to derive Eq. (24) of the main text. Using \( Q_R/L \approx t \) we find

\[
e^{-Q_R + Q_L} I_1 (2\sqrt{Q_R Q_L}) \approx e^{-\sqrt{Q_R Q_L}} \frac{1}{(Q_R Q_L)^{1/4/4\pi}},
\]

(A21a)

\[
\int_1^\infty dz \frac{e^{-Q_R + Q_L} z}{z} I_1 (2\sqrt{Q_R Q_L} z) \approx e^{-\sqrt{Q_R Q_L} z} \sqrt{Q_R - \sqrt{Q_L}} \text{erfc} \left( \frac{\sqrt{Q_R} - \sqrt{Q_L}}{Q_R Q_L}^{1/4/4\pi} \right),
\]

(A21b)

\[
\int_1^\infty dz e^{-Q_R + Q_L} z I_1 (2\sqrt{Q_R Q_L} z) \approx \text{erfc} \left( \frac{\sqrt{Q_R} - \sqrt{Q_L}}{2\sqrt{Q_R - \sqrt{Q_L}}} \right)/(Q_R Q_L)^{1/4/4\pi}.
\]

(A21c)

A4. S-MATRIX OF THE \( O(3) \) NON-LINEAR SIGMA MODEL

The S-matrix in the \( x, y, z \) spin component basis is given by [72]

\[
S_{\alpha\beta}^{\gamma\delta} = \sigma_1(\theta) \delta_{\alpha\beta} \delta^{\gamma\delta} + \sigma_2(\theta) \delta_{\alpha\gamma} \delta^{\beta\delta} + \sigma_3(\theta) \delta_{\alpha\delta} \delta^{\beta\gamma},
\]

(A22)

where

\[
\sigma_1(\theta) = \frac{2i\pi\theta}{(\theta + i\pi)(\theta - 2i\pi)},
\]

(A23)

\[
\sigma_2(\theta) = \frac{\theta(\theta - 2i\pi)}{(\theta + i\pi)(\theta - 2i\pi)},
\]

(A24)

\[
\sigma_3(\theta) = \frac{-2i\pi(\theta - i\pi)}{(\theta + i\pi)(\theta - 2i\pi)}.
\]

(A25)

This is the basis where the \( SU(2) \) generators have the form

\[
J_1 = i \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad J_2 = i \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \quad J_3 = i \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.
\]

(A26)

A unitary transformation \( I_j = U J_j U^{-1} \) with

\[
U = i \begin{pmatrix} -1/\sqrt{2} & i/\sqrt{2} & 0 \\ 0 & 0 & 1 \\ 1/\sqrt{2} & i/\sqrt{2} & 0 \end{pmatrix}
\]

(A27)

brings these to the form in the "m-basis":

\[
I_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad I_2 = -i \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 0 \end{pmatrix}, \quad I_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}.
\]

(A28)

This means that the relation between the two bases

\[
\{|\alpha\rangle_{xyz} \rangle = \{|1\rangle_{xyz}, |2\rangle_{xyz}, |3\rangle_{xyz} \rangle = \{|x\rangle, |y\rangle, |z\rangle \rangle
\]

(A29)

\[
\{|j\rangle_m \rangle = \{|1\rangle_m, |2\rangle_m, |3\rangle_m \rangle = \{|+\rangle, |0\rangle, |-\rangle \rangle
\]

(A30)

is given by

\[
|\alpha\rangle_{xyz} = U_{j\alpha} |j\rangle_m, \quad |j\rangle_m = (U^{-1})_{\alpha j} |\alpha\rangle_{xyz}.
\]

(A31)

The S-matrix acts in the tensor product space so in the \( m \)-basis it is given by

\[
S_{ij}^{kl} = (U^{-1})_{\alpha i} (U^{-1})_{\beta j} U_{k\gamma} U_{l\delta} S_{\alpha\beta}^{\gamma\delta}.
\]

(A32)
This way we obtain

\[ S_{ij}^{kl} (\theta) = S_{ij}^{kl} (\theta) = S_{ik}^{li} (\theta), \]  

(A40)

the unitarity and crossing relations

\[ S_{JM}^{lm} (\theta) S_{MN}^{km} (\theta) = \delta_J^M \delta_K^N, \quad S_{ij}^{kl} (\theta) = S_{ij}^{kl} (i\pi - \theta) \]  

(A41)

as well as the Yang–Baxter equation (7)

\[ S_{ij}^{\alpha \gamma} (\theta_{12}) S_{jk}^{\alpha \gamma} (\theta_{13}) S_{ik}^{\alpha \gamma} (\theta_{23}) = S_{ij}^{\beta \gamma} (\theta_{23}) S_{ik}^{\beta \gamma} (\theta_{13}) S_{jk}^{\beta \gamma} (\theta_{12}). \]  

(A42)

In matrix notation,

\[
S = \begin{pmatrix}
\sigma_2 + \sigma_3 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \sigma_2 + \sigma_3 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & \sigma_3 + \sigma_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & \sigma_1 + \sigma_2 & \sigma_1 + \sigma_3 & \sigma_1 + \sigma_3 & 0 \\
0 & 0 & 0 & \sigma_1 + \sigma_2 & \sigma_1 + \sigma_3 & \sigma_1 + \sigma_3 & \sigma_1 + \sigma_3 \\
0 & 0 & 0 & 0 & \sigma_2 + \sigma_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & \sigma_3 + \sigma_2 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & \sigma_2 + \sigma_3
\end{pmatrix}
\]  

(A43)

where the 2-particle basis is

\[ |++\rangle, |+0\rangle, |0+\rangle, |+-\rangle, |00\rangle, |--\rangle, |-0\rangle, |0-\rangle, |--\rangle. \]

As \( \theta \to 0 \),

\[ \sigma_1 \to 0, \quad \sigma_2 \to 0, \quad \sigma_3 \to -1, \]  

(A44)

so all scatterings become purely reflective with transmissions and spin changing scatterings suppressed.
