INTRODUCTION

Several recent studies have reported a 40–50% lower risk of colorectal cancer in people who are continuously taking aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) (Thun et al., 1991; 1993; Marnett, 1992; 1995; Giovannucci et al., 1994; 1995). The mechanism by which NSAIDs prevent colorectal carcinogenesis is not clear, but one possibility involves inhibition of cyclooxygenase (COX).

COX is a key enzyme in the conversion of arachidonic acid to prostaglandins, and two isoforms of COX, COX-1 and COX-2, have been identified. Recently COX-2 has been reported to frequently overexpress in colorectal neoplasms and to play a role in colorectal tumorigenesis and tumour progression. In this study, using immunohistochemistry, we examined COX-2 expression in advanced human colorectal cancer and its correlation with clinicopathological features. COX-2 expression was observed mainly in the cytoplasm of cancer cells in all the specimens examined, but some stromal cells and endothelial cells were also stained. According to the grade of COX-2 expression of the cancer cells, patients were divided into high- and low-COX-2 expression groups. High-COX-2 expression significantly correlated with tumour recurrence, especially haematogenous metastasis. These results suggest that a selective COX-2 inhibitor can be a novel class of therapeutic agents not only for tumorigenesis but also for haematogenous metastasis of colorectal cancer. To our knowledge, this is the first report on the correlation between COX-2 overexpression and recurrence of colorectal cancer. © 2000 Cancer Research Campaign

MATERIALS AND METHODS

Patient samples

Specimens from 63 patients with advanced colorectal cancer without haematogenous metastasis receiving radical surgical treatment at the Department of Surgical Oncology, the University of Tokyo, in the period 1990–1994, were evaluated. In all these patients, the depth of tumour invasion was proper muscle (mp) or subserosa (ss). The median follow-up period was 60 months (range 6–98).

Immunohistochemistry

Tissue samples were fixed with 10% formaldehyde in phosphate-buffered saline (PBS), embedded in paraffin, and cut into
with PBS, the specimens were incubated with biotinylated anti-rabbit immunoglobulin G (IgG) for 30 min at room temperature. After washing three times in PBS, they were incubated with avidin and biotinylated horseradish peroxidase complex, followed by three washes with PBS. Then, the immune complex was visualized by immersing the slides in 0.2 mg ml⁻¹ diaminobenzene and 0.03% H₂O₂ in PBS for 1.5 min. The sections were then counterstained with haematoxylin and mounted. Non-immunized rabbit serum was used as the negative control. As an alternative control, all the 63 specimens were simultaneously stained for COX-1 using a specific rabbit polyclonal antibody (IBL, Gunma, Japan), and exactly the same methodology applied for COX-2 immunostaining.

**Evaluation of COX-2 immunostaining**

The specimens immunostained for COX-2 were evaluated independently by two blinded investigators. According to the intensity and extent of positive reaction of tumour cells, the patients were divided into grades 1–4. Grades 1 and 2 were classified as low-COX-2 group, and grades 3 and 4 as high-COX-2 group. In brief, the reactions of normal colonic epithelium and stromal mononuclear cells in the colonic mucosa distant from cancer tissue were used as the internal built-in controls. Normal colonic epithelium showed a very weak but diffuse staining pattern, whereas mononuclear cells stained strongly. Immunostaining of cancer tissues was stronger than the normal epithelium in all cases. Therefore, the intensity of staining was graded on a scale of 1–4 using mononuclear cells as the reference. Grades 1 and 2 were cases with COX-2 expression weaker than, grade 3 similar to, and grade 4 stronger than, mononuclear cells. The extent of immunostaining was diffuse in all cases, and heterogeneity was observed in only a few cases.

**Statistical analysis**

The correlation between patient’s age or tumour size and COX-2 expression was studied using Student’s t-test. The other clinicopathological features were analysed in relation to COX-2 expression by chi-squared test. The Kaplan–Meier method was used to estimate the survival rates without tumour recurrence, and the log-rank test was used to compare survival rates in the two groups. To determine significant prognostic factors, multivariate analysis was performed using the Cox proportional hazards modelling of factors potentially related to disease-free survival. Differences were considered statistically significant at $P < 0.05$.

**RESULTS**

**Immunostaining**

In all cases, COX-2 expression was predominantly localized in tumour cells, whereas some stromal cells, endothelial cells, and colonic normal mucosa adjacent to the cancer tissue stained weakly. In cancer cells, COX-2 expression was observed mainly in the cytoplasm and nuclear envelope. In general, normal colonic mucosa distant from the cancer tissue showed little or no COX-2 expression, whereas mononuclear cells are stained strongly.

3 μm-thick sections. The sections were deparaffinized, hydrated through xylene and alcohol, and microwaved in Target Retrieval Solution (DAKO Japan, Kyoto, Japan) for 15 min. After washing three times in PBS, endogenous peroxidase was blocked by immersion in 3% hydrogen peroxide for 30 min at room temperature. After washing three times in PBS, non-specific binding was blocked by incubation with 10% normal goat serum for 30 min. Then, rabbit polyclonal antibody specific for human COX-2 (IBL, Gunma, Japan) diluted 40-fold with PBS was applied and sections were incubated at 4°C overnight. After washing again three times
observed in 13 (21%) cases (grade 3 in 11 (18%) and grade 4 in 2 (3%)). Low COX-2 expression was observed in 50 (79%) cases (grade 1 in 20 (32%) and grade 2 in 30 (47%)).

In all cases COX-1 expression was restricted to some stromal cells and its expression was observed in neither the cancer nor the normal epithelium (Figure 1).

**Relation between COX-2 expression and clinicopathological features**

In Table 1, the association between COX-2 expression and the clinicopathological features is shown. There was no significant correlation between COX-2 expression and age, sex, tumour size, tumour location, histological type, depth of invasion, lymphatic or venous invasion, lymph-node metastasis and Dukes’ classification. However, high COX-2 expression was strongly correlated with tumour recurrence, especially haematogenous metastasis ($P = 0.005$).

**Table 2** Results of multivariate analysis of possible prognostic factors related to disease-free survival by Cox proportional hazards model

| Variable                | Hazard ratio (95% CI) | Unfavourable/favourable | $P$ value |
|-------------------------|-----------------------|-------------------------|-----------|
| Age (yrs)               | 0.940 (0.863–1.023)   | 0.940                   | 0.1538    |
| Sex                     | 0.382 (0.084–1.746)   | Male/Female             | 0.2148    |
| Histological type       | 1.118 (0.813–1.539)   | Poorly or moderately/Well| 0.4197    |
| Tumour size (mm)        | 1.020 (0.991–1.050)   | 0.1795                  |           |
| Tumour location         | 2.215 (0.542–8.054)   | Positive/Negative       | 0.2681    |
| Histological type       | 2.134 (0.633–7.189)   | Positive/Negative       | 0.2213    |
| Dukes’ stage            | 4.222 (0.999–17.835)  | C/A and B               | 0.0501    |
| COX-2 expression        | 10.086 (1.971–51.612) | High/Low                | 0.0055    |

---

Figure 2 Kaplan–Meier disease-free survival curves of patients in high-COX-2 (●) and low-COX-2 (○) groups. A statistically significant difference was observed between the two groups ($P = 0.0051$).
Correlation of COX-2 expression with disease-free survival

The survival rate without tumour recurrence for high- and low-COX-2 groups was assessed by the Kaplan–Meier method and compared by log-rank test (Figure 2). The disease-free survival rate was significantly different between the two groups (P = 0.0051). Table 2 shows the results of multivariate analysis for the 63 patients. Among the 8 potentially prognostic factors (age, sex, histological type, tumour size, lymphatic invasion, venous invasion, Dukes’ stage, and COX-2 expression), COX-2 expression was recognized as the only independent significant factor related to disease-free survival (P = 0.0055).

DISCUSSION

So far COX-2 has been thought to play a causal role in colorectal tumorigenesis. A null mutation of COX-2 caused a marked reduction in the number and size of intestinal polyps in a murine model of FAP (familial adenomatous polyposis) APC716 knockout mice (Oshima et al, 1996). In a separate study, SC-58635, a selective inhibitor of COX-2, reduced the formation of aberrant crypt foci and inhibited both the incidence and multiplicity of colon tumours in the intestines of azoxymethanetreated rats (Reddy et al, 1996; Kawamori et al, 1998). Recently, it has been reported that in nude mice, selective inhibition of COX-2 by SC-58125 reduced growth of a human colon cancer cell line, HCA-7, which expresses a high level of COX-2, but it did not reduce the growth of HCT-116 cells, which lack COX-2 protein (Sheng et al, 1997). In addition, it has been shown that COX-2 level was significantly higher in colorectal tumours with larger size and in those with deeper invasion (Fujita et al, 1998). These results suggest an important role of COX-2 in colorectal tumourigenesis and growth.

Another recent report demonstrated that human colon cancer (Caco-2) cells permanently transfected with a COX-2 expression vector acquired increased invasiveness, with increased activation of matrix metalloproteinase-2 (MMP-2) and increased RNA level of membrane-type matrix metalloproteinase-1 (MT-MMP-1) (Tsujii et al, 1997). In a previous study we have also demonstrated that a selective COX-2 inhibitor, JTE-522, prevented haematogenous metastasis of colon cancer in mice (Tomozawa et al, 1999). These results suggest that COX-2 increases the metastatic potential of colorectal cancer cells.

In the present study, using immunohistochemistry, we examined COX-2 expression in advanced human colorectal carcinomas and demonstrated that COX-2 overexpression, although not correlated with the other clinicopathological features, was significantly associated with tumour recurrence, especially haematogenous metastasis.

Contrary to our results, in a recent study (Fujita et al, 1998), elevated COX-2 levels were not correlated with metastasis. In that study, however, only patients with a very short follow-up period were included, and consequently only synchronous metastasis could be evaluated. In the present study, we used samples from patients who received curative resection and had a longer follow-up (median 60 months), and consequently more reliable data on the correlation of COX-2 expression and the development of haematogenous metastasis could be obtained. Moreover, different from the previous report, in which COX-2 expression was investigated at the mRNA level and expressed as the COX-2 & COX-1 ratio, we investigated it at the protein level. These facts may explain the discrepancy between the two studies.

Haematogenous metastasis of colorectal cancer develops through a complicated process: cancer cells detach from the primary site and reach the vasculature by proteolytic cleavage of the surrounding interstitial tissues. Then the cells reach the secondary sites by adhesion to and transmigration through the endothelial cell layer and invasion of the secondary organ, and they proliferate at secondary sites by induction of angiogenesis (Liotta et al, 1986). From our data, COX-2 overexpression in colorectal cancer did not correlate with venous permeation, but with increased haematogenous metastasis formation. COX-2 expression was recognized as the only independent significant factor related to disease-free survival. Therefore, COX-2 may affect not only the proliferative and invasive properties but also the adhesion of colorectal cancer cells to extracellular matrix (ECM) protein or endothelial cells. It has been reported that rat intestinal epithelial (RIE) cells permanently transfected with a COX-2 expression vector oriented in the sense (RIE-S) demonstrated increased adhesion to ECM and expressed undetectable E-cadherin, which is involved in cell–cell adhesion (Tsujii et al, 1995). However, more studies are necessary to elucidate the effect of COX-2 on adhesion of cancer cells to ECM or endothelium, and such studies are ongoing in our laboratory.

Another possible role of COX-2 in the development of haematogenous metastasis is promotion of angiogenesis. Tumour growth and metastasis require the development of new vessels, i.e. angiogenesis (Folkman, 1990; Mahadevan and Hart, 1990; Horak et al, 1992). In a recent report, COX-2 was reported to modulate the production of angiogenic factors by colon cancer cells, while COX-1 was associated with angiogenesis regulation in endothelial cells (Tsujii et al, 1998).

Furthermore, COX-2 expression has recently been reported to be up-regulated not only in colorectal neoplasms but also in gastric, breast, oesophageal, pancreatic and lung carcinoma (Ristimaki et al, 1997; Hida et al, 1998; Hwang et al, 1998; Zimmermann et al, 1999; Tucker et al, 1999), and COX-2 overexpression enhanced lymphatic invasion and metastasis of human gastric carcinoma (Murata et al, 1999). And another recent report has shown that elevated COX-2 expression has a poorer prognostic significance in early-stage primary resected lung adenocarcinoma (Achiwa et al, 1999). These findings suggest that COX-2 may provide a new therapeutic target for several kinds of neoplasms.

To our knowledge, this is the first report on the correlation between COX-2 overexpression and recurrence of colorectal cancer, especially haematogenous metastasis, and this fact suggest that selective COX-2 inhibitors can be useful chemopreventive agents not only for tumorigenesis but also for haematogenous metastasis of colorectal cancer.
