(Received on June 14, 2013; Revised on October 1, 2013; Accepted on October 13, 2013)

The bacterial strain T-9, which shows strong antifungal activity, is isolated from the soils of Samcheok, Gangwon-do and identified as *Paenibacillus kribbensis* according to morphological and taxonomic characteristics and 16S rRNA gene sequence analysis. The *P. kribbensis* strain T-9 strongly inhibits the growth of various phytopathogenic fungi including *Botrytis cinerea*, *Colletotrichum acutatum*, *Fusarium oxysporum* f. sp. *radicis-lycopersici*, *Magnaporthe oryzae*, *Phytophthora capsici*, *Rhizoctonia solani*, and *Sclerotium cepivorum* in vitro. Also, the *P. kribbensis* strain T-9 exhibited similar or better control effects to plant diseases than in fungicide treatment through in vivo assays. In the 2-year greenhouse experiments, *P. kribbensis* strain T-9 was highly effective against clubroot. In the 2-year field trials, the *P. kribbensis* strain T-9 was less effective than the fungicide, but reduced clubroot on Chinese cabbage when compared to the control. The above-described results indicate that the strain T-9 may have the potential as an antagonist to control various phytopathogenic fungi.

**Keywords**: antifungal ability, in vivo assay, *Paenibacillus kribbensis*, plant pathogenic fungi, 16S rRNA gene

Recently, the use of synthetic fertilizers and pesticides have resulted in deterioration of soil structure and increase in soil-borne phytopathogens (Bailey and Lazarovits, 2003). As a result, along with many phytopathogenic fungi such as *B. cinerea*, *F. oxysporum*, *P. capsici*, *R. solani*, and *S. cepivorum* etc. having a wide range of host plants, it has been very difficult to control the spread of the plant disease. Although applying fungicide has been one of the conventional methods for controlling fungal diseases, there is increasing international concern over the use of fungicides on crops because of their harmful effects on human health and the emergence of pathogen resistance to fungicides. To cope with this problem, various disease managements including biological control, have been applied.

Biological control by microorganisms (Huang et al., 2012; Kim et al., 2012; Li et al., 2012) has received considerable attention as a reliable substitute for the use of various hazardous chemical fungicides, which have raised serious concerns of food and environmental contamination (Fernando et al., 2005). Microorganisms also play an essential role in several life support functions as they enable soil to recycle nutrients, suppress plant pathogens (Mendes et al., 2011), and serve as a suitable substrate for plant growth (Kim et al., 2011). Among the myriads of bacteria in the plant rhizosphere, a few spore-forming plant growth promoting rhizobacteria (PGPR) attract special attention due to their stable habitancy in soil (Emmert and Handelsman, 1999; Jin et al., 2006).

Soil samples were collected from the Chinese cabbage, garlic, and paddy fields in 30 regions of Samcheok, Gangwon province, South Korea during November 2011. Each sample was air-dried at ambient temperature and then passed through an 850 μm mesh sieve to remove plant debris. Soil samples were preserved in polyethylene bags at room temperature before use. Soil suspensions were prepared in sterile water and cultured on the surface of potato dextrose agar medium (PDA, Difco, USA) and tryptic soy agar medium (TSA, Difco, USA). The plates were incubated at 25°C for 10 days. Afterwards, colonies with different morphological appearances were chosen from the countable plates and streaked on fresh similar medium to obtain pure cultures.

*Bacterium* was identified by morphological and taxonomic characterization and 16S rRNA gene sequencing assay. Morphological characteristics were examined on
Antifungal Activity of Paenibacillus kribbensis against Several Plant Pathogenic Fungi

The predominant strain obtained from soil samples of Samcheok was named as T-9 and found to be a Gram-variable, rod-shaped, and facultative anaerobic bacterium. It produced flat colonies and unsmooth-surfaced spores (Fig. 1) and catalase (Table 1) although it did not produce H₂S. Methyl red reaction was positive while Voges-Proskauer reaction was negative. An array of carbon sources were utilized like glucose, lactose, sucrose, salicin, D-ribose, L-arabinose, raffinose, maltose, and cellobiose, but not dulcitol, D-adonitol, myo-inositol, and L-rhamnose. The 16S rRNA gene sequence analysis indicated that the closest relative (99%) of the strain T-9 (1465 bp) was P. kribbensis AM49 (AF391123) (Fig. 2). The 16S rRNA gene sequence of strain T-9 was deposited in the GenBank database with an accession number KF019740. From the results of morphologic and biological characteristics, and 16S rRNA gene sequence analysis, the predominant strain T-9 obtained from soil samples was identified as P. kribbensis and thus named P. kribbensis strain T-9.

The genus Paenibacillus, originally included within the Bacillus and reclassified as a separate genus (Ash et al., 1993), is prevalently distributed in different soils and plant rhizospheres (Berge et al., 2002; von der Weid et al., 2002; Garbeva et al., 2003; Yoon et al., 2003). Different species of Paenibacillus have been demonstrated as having potential antifungal activities (Fortes et al., 2008; He et al., 2007; Liu et al., 2008; Raza et al. 2008; von der Weid et al., 2003; von der Weid et al., 2005). The P. kribbensis is recently described as a new Paenibacillus species isolated from soil (Yoon et al., 2003). Some strains produced antimicrobial substances, suggesting an important role in the soil. However, no biological role of this species in the rhizosphere have been reported.

The antifungal activity of P. kribbensis strain T-9 against the phytopathogenic fungi was performed by dual culture. Briefly, a mycelial column (6.5 mm in diameter) was cut off from the white perimeter portion of the colony, which had been cultured on PDA plates at 25°C for 7 days, and placed at a distance 1.5 cm away from the rim of a fresh PDA plate. Afterwards, the P. kribbensis strain T-9 growing in PDA was sowed in a hole with a sterilized toothpick on the PDA plate (1.5 cm away from the other rim). Simultaneously, control plates inoculated in different mycelial columns were prepared without P. kribbensis strain T-9. The antagonistic effect of the control plates was evaluated by measuring the size of the inhibition zone on the PDA plates following culturing at 25°C for 14 days.

The P. kribbensis strain T-9 showed strong antagonistic activity against the phytopathogenic fungi.
Table 1. Differential characteristics of antagonistic strain T-9 and Paenibacillus kribbensis

| Characteristic          | Strain T-9 | P. kribbensis\textsuperscript{a} |

\textsuperscript{a}Data for P. kribbensis are from Yoon et al. (2003).

\textsuperscript{b+}, Positive; –, Negative; +/-, Gram-variable.

activity against a wide range of phytopathogenic fungi that cause disease on different crops (Table 2). It produced the highest antifungal activity against *P. capsici*, which was cosmopolitan in distribution. Furthermore, there was a moderate antifungal activity against *B. cinerea, C. acutatum* and *M. oryzae*. Other test phytopathogenic fungi were also inhibited, but the antifungal activity was relatively less.

The *in vivo* efficiency of *P. kribbensis* strain T-9 for control of anthracnose in pepper fruits, Phytophthora blight in pepper plant, blast, sheath blight in rice plant and gray mold in tomato plant, was evaluated in plastic sieve systems or under greenhouse conditions (Table 3). Pepper (*Capsicum annuum*) cv. Super manitta and Hongjinjoo, rice (*Oryza sativa*) cv. Nakdongbyeo and tomato (*Solanum lycopersicum*) cv. Super dotaerang were sown in horticultural soil in seedling plate. The plants were kept in the greenhouse for one month. To obtain culture broth, *P. kribbensis* strain T-9 was cultured in potato dextrose broth medium (PDB, Difco, USA) for three days, which included incubation in a rotary shaker at 200 rpm and 25°C. After incubation, *P. kribbensis* strain T-9 suspension was diluted in distilled water to 10^8 cfu/ml (OD\textsubscript{580}=0.1).

Each seedling and fruit was treated with growth broth one day before inoculation with *B. cinerea, C. acutatum, M. oryzae, P. capsici*, and *R. solani*. For pepper anthracnose, each fruit was soaked in culture broth, water, or propineb for 30 min. For pepper Phytophthora blight, each seedling was dip-treated with culture broth, water, or dimethomorph for 10 min. Also culture broth, water, or fungicides were sprayed on each seedling for other plant diseases. Chemical fungicides were used as the positive control and water was used as the negative control. The inoculated plants were placed in a moist chamber to maintain approximately 90% humidity at 25°C for 24 h, and then transferred to the growth room for further incubation. There were three replicates for each treatment.

The *P. kribbensis* strain T-9 for control of Phytophthora blight in pepper plant, blast, sheath blight in rice plant and gray mold in tomato plant, was highly effective, reducing disease severity by 92.9%, 78.5%, 100%, and 89.8% relative to the inoculated control, respectively. The chemical fungicides were used as reference, which reduced disease severity by 99.3%, 74.3%, 100% and 93.2%, respectively. The *in vivo* efficacy of *P. kribbensis* strain T-9 against anthracnose in pepper fruits was evaluated in plastic sieve systems. The *P. kribbensis* strain T-9 was highly effective, which showed a control efficiency of 96.7%. The synthetic fungicide was used as reference, which showed a 92.3% control value.

The suppressive effects of *P. kribbensis* strain T-9 against *Plasmodiophora brassicae* in the greenhouse and the field were assessed in 2011 and 2012, respectively (Fig. 3). Chinese cabbage (*Brassica campestris*) cv. Gaeluma, a highly susceptible to clubroot, was sown in horticultural soil in seedling plate. The plants were kept in the greenhouse for one month. To obtain culture broth, the method was same in upper. Frozen galls were soaked in distilled water for a while to soften the tissue, and then they were macerated in a homogenizer with distilled water at high speed. For inoculation, inoculate suspension was mixed...
Antifungal Activity of Paenibacillus kribbensis against Several Plant Pathogenic Fungi

In 2011 and 2012, a study using Chinese cabbage was conducted to assess the efficacy of microbes in the field, based on the efficacy observed in a previous experiment. Inoculate suspension was mixed into field soil using a rotary cultivator. Each seedling was dipped in culture broth for 10 min. Seedlings were transplanted in the infected field and cyazofamid was used as the positive control and water as the negative control. The trials were arranged in a randomized complete block design with three replicates. The seedlings were watered regularly to keep constant soil moisture. After seventy days, each root was rinsed with tap water and assessed for clubroot severity based on the 0–4 scale mentioned above.

Fig. 2. Phylogenetic relationship between strain T-9 and representative species based on partial 16S rRNA gene sequence developed with the ClustalW program in MEGA 5.10 and constructed using the Neighbor-joining method with 1,000 bootstrap replicates. The values indicate the percentage of clustering matches. The scale bar indicates the number of differences in base composition among sequences.

Table 2. Antagonistic activity of strain T-9 against various phytopathogenic fungi in dual culture assay

into horticultural soil. In 2011 and 2012, Chinese cabbage was transplanted in a plastic pot containing the clubroot-infested horticultural soil. Each seedling was dipped into culture broth. Cyazofamid was used as the positive control and water as the negative control. The seedlings were watered regularly to keep constant soil moisture during cultivation in the greenhouse. After forty days, each root was rinsed with tap water and assessed for clubroot severity based on a 0–4 scale, where 0 indicated no infection; 1 indicated 1–25% of roots infected; 2 indicated 26–50% of roots infected; 3 indicated 51–75% of roots infected; and 4 indicated more than 75% of roots infected. Statistical analyses were conducted with the Statistical Analysis System for personal computers (Ver. 9.2, SAS Institute Inc.). Fisher’s protected least significant difference (LSD) at $P \leq 0.05$ was applied to determine whether or not differences between treatments were significant.

In 2011 and 2012, a study using Chinese cabbage was conducted to assess the efficacy of microbes in the field, based on the efficacy observed in a previous experiment. Inoculate suspension was mixed into field soil using a rotary cultivator. Each seedling was dipped in culture broth for 10 min. Seedlings were transplanted in the infected field and cyazofamid was used as the positive control and water as the negative control. The trials were arranged in a randomized complete block design with three replicates. The seedlings were watered regularly to keep constant soil moisture. After seventy days, each root was rinsed with tap water and assessed for clubroot severity based on the 0–4 scale mentioned above.
For greenhouse experiment, the \textit{P. kribbensis} strain T-9 was highly effective against clubroot, which showed a control efficiency of 89.3\% and 99.2\% in 2011 and 2012, respectively. Cyazofamid was used as a reference, which showed 86.3\% and 100\% control values. For field trials, \textit{P. kribbensis} strain T-9 had no substantial impact on clubroot severity, with 79.6\% and 82.2\% disease severity on the susceptible cultivar of Chinese cabbage, which reduced the disease severity by 11.7\% and 12.6\% in 2011 and 2012, respectively. The cyazofamid treatment reduced the disease severity by 24.9\% and 85.8\%.

The stratagem of controlling the biological properties of the \textit{P. brassicae} has become an important approach for creating a long-lasting effect on the facilitation of sustainable agriculture; however, only a few antagonistic microorganisms have been reported, including \textit{Micromonospora rosea} subsp. \textit{rosea} and \textit{Streptomyces} spp. (Kim et al., 2002), \textit{Cellulosimicrobium cellulans}, and \textit{Paenibacillus} spp. (Choi et al., 2007). The progress and applicable fields of biological control for clubroot are limited compared to other soil-borne plant diseases, and there are no commercial biological control products available. The continuous search for antagonistic agents against clubroot is necessary. In this study, the suppressive effects of \textit{P. kribbensis} strain T-9 against \textit{P. brassicae} were assessed in the greenhouse and the field in 2011 and 2012. We found the efficacy observed from the field trial to be lower than that of the greenhouse experiment. For the greenhouse experiment, \textit{P. kribbensis} strain T-9 showed a good control efficiency of 89.3\% and 99.2\% in 2011 and 2012, respectively. However, for field trials, there was no substantial impact, but the treatment reduced the clubroot on the susceptible cultivar of Chinese cabbage, with disease severity, by 79.6\% and 82.2\% in 2011 and 2012, respectively. Basic environmental conditions, such

*Fruits of pepper were inoculated by dropping 20 μl of \textit{C. acutatum} conidia suspension (more than 10^5 conidia/ml). Pepper seedlings were inoculated by drenching 20 ml of \textit{P. capsici} zoospores suspension (more than 10^5 sporangia/ml, chilling) near the seedling. Rice seedlings were inoculated by spraying \textit{M. oryzae} spores suspension (more than 10^5 spores/ml, 1\% Tween 20) on foliage. Rice seedlings were inoculated by sticking PDA disk with \textit{R. solani} on stem base. Tomato seedlings were inoculated by spraying \textit{B. cinerea} spores suspension (more than 10^5 spores/ml, PDB) on foliage.

*For pepper anthracnose, each fruit which surface was slightly scratched by a sandpaper was soaked in culture broth, water (control), or propineb for 30 min. For pepper phytophthora blight, each seedling was dip-treated with culture broth, water (control), or dimethomorph for 10 min. Culture broth, water (control), or fungicides were sprayed on each seedling for other plant diseases.

*Disease spot extended length was calculated for rice sheath blight. A disease severity was calculated over all of the plants for the treatment of other plant diseases.

*Means and standard error based on three replicates sharing a common capital letter (control value) or lower case letter (disease severity or disease spot extended length) were not significantly different based on the protected LSD test at \( P \leq 0.05 \).
Antifungal Activity of Paenibacillus kribbensis against Several Plant Pathogenic Fungi

as temperature, moisture, and soil physical and chemical characteristics, can greatly affect the interactions among plant, pathogen, and biocontrol agents in various ways, and all of these effects may influence the efficacy of biological control (Larkin and Fravel, 2002). On the other hand, enormous microorganisms exist in the rhizosphere of plants, which may influence the efficacy of biological control. Finally, endospore formation and longer generation times influence them to rapidly colonize roots, which they directly protect against soil-borne pathogens while they adapt their fitness to that of rhizosphere (Ryu et al., 2005).

In summary, this study is the first antagonistic activity assay of P. kribbensis strain T-9 against various soil-borne phytopathogenic fungi. It was found that the P. kribbensis strain T-9 has the potential to offer protection to plants against different soil-borne phytopathogenic fungi, in addition to its antagonistic activity, suggesting that further studies should be considered for using P. kribbensis strain T-9 as a biological control agent and enhancer of control efficiency in field trials.

Acknowledgements

This study was supported by a grant (Project No. 609002-5) from the Screening Center for Disease Resistant Vegetable Crops of TDPAF funded by the MIFAFF of the South Korean government.
