Vulvovaginal-gingival syndrome and esophageal involvement in lichen planus

Sir,

Lichen planus is a common dermatological disorder that usually manifests as violaceous, pruritic papules on the skin. It has many clinical variants which also involve the mucosa; oral mucosa is frequently affected, but vulvovaginal involvement is rather rare. The association of lichen planus of the vulva and vagina with desquamative gingivitis is described as the vulvovaginal-gingival syndrome.\(^1\) We found only a few previous reports of this syndrome and even fewer with esophageal involvement.\(^2\)

A 50-year-old woman presented with complaints of burning in the mouth and soreness of the genitalia for
4 years. She had multiple episodes of oral ulceration and increased redness of the gums for the past few months. Other mucosal symptoms including dysuria, dyspareunia, occasional ulceration and dysphagia were present for 1 year. She had only partially responded to the multiple topical and oral medications she had received.

General physical and systemic examination revealed no abnormalities. Dermatological examination revealed extensive erythema and desquamation over the gingiva [Figure 1a]. The labial and vaginal mucosa had an erythematous, glazed appearance with excessive vaginal discharge [Figure 1b]. Associated white lacy plaques were present on the buccal mucosa.

On laboratory evaluation, she was detected to have microcytic hypochromic anemia (hemoglobin, 9.6 g%). Other hematological, biochemical and urinary parameters were normal. Antinuclear antibodies, ELISA for human immunodeficiency virus (HIV) infection, hepatitis B surface antigen and anti-hepatitis C antibodies were negative or non-reactive. Pelvic ultrasonogram was normal. Upper gastrointestinal endoscopy revealed multiple ulcers in the esophageal mucosa. A stricture was present, 26 cm from the proximal end beyond which the endoscope was not negotiable [Figure 2]. Biopsies from the vulval and vaginal mucosa showed ulcerated epidermis, granulation tissue and an extensive inflammatory infiltrate [Figure 3a]. There was saw-toothing of the rete ridges, basal cell vacuolation and an extensive band-like infiltrate in the upper dermis along the dermo-epidermal junction [Figure 3b]. The infiltrate was predominantly lymphocytic in nature. Melanin incontinence was also noted. No atypical cells or other evidence of malignancy were present.

Biopsy from the buccal mucosa revealed similar features [Figure 4a]. Biopsy from the esophagus revealed ulceration with extensive inflammatory infiltrate replacing the entire section [Figure 4b]. Direct immunofluorescence in all sections revealed fibrinogen, immunoglobulin G, immunoglobulin M and C3 deposition at the dermo-epidermal junction.
Thus, a diagnosis of vulvovaginal-gingival syndrome with esophageal involvement due to lichen planus was confirmed.

She was initially managed with tapering doses of oral corticosteroids over 8 weeks besides topical treatment with 0.1% tacrolimus ointment on the oral and vaginal mucosae. Oral methotrexate was also added in a dose of 7.5 mg/week after 4 weeks, as a steroid-sparing agent for long-term therapy. She underwent serial esophageal balloon dilatation fortnightly on 6 occasions to achieve a final controlled radial expansion of 12 mm. There was significant improvement in oral and vulval symptoms and she is presently able to swallow both solids and liquids comfortably.

Vulvovaginal-gingival syndrome or Hewitt–Pelisse syndrome, is a rare, severe variant of lichen planus which is characterized by erosions and desquamation of the vulval, vaginal and gingival mucosae and can result in scarring and the formation of strictures.[3] Rarely, conjunctivae, lacrimal glands, auditory canal and esophagus can also be involved.[4] Other findings include scarring alopecia and nail changes.[5] Strictures and stenosis have been reported in the vulval and vaginal mucosae.[6] Cutaneous lesions are also associated in a few cases but our patient had mucosal lesions alone. The probability of malignant conversion is 0.5–5%.[7,8]

Unlike cutaneous lichen planus where the histopathological findings are characteristic, histopathological diagnosis is difficult in vulvovaginal-gingival syndrome as the epidermis is often ulcerated and this obscures the changes of lichen planus. For this reason, biopsy from the mucosa adjoining the ulcer is recommended. In case the biopsy findings are not specific, direct immunofluorescence examination to exclude vesiculobulouls disorders such as pemphigus vulgaris and mucous membrane pemphigoid may be helpful. Other differential diagnoses include lichen sclerosus, leukoplakia, chronic candidiasis, Behcet’s disease and mucosal discoid lupus erythematosus. However, in our patient, all three mucosal sites revealed the classical features of lichen planus helping us to confirm the diagnosis.
