ABSTRACT

Long-period brown dwarf companions detected in radial velocity surveys are important targets for direct imaging and astrometry to calibrate the mass–luminosity relation of substellar objects. Through a 20-yr radial velocity monitoring of solar-type stars that began with ELODIE and was extended with SOPHIE spectrographs, giant exoplanets and brown dwarfs with orbital periods longer than ten years are discovered. We report the detection of five new potential brown dwarfs with minimum masses between 32 and 83 M_Jup orbiting solar-type stars with periods longer than ten years. An upper mass limit of these companions is provided using astrometric HIPPARCOS data, high-angular resolution imaging made with PUEO, and a deep analysis of the cross-correlation function of the main stellar spectra to search for blend effects or faint secondary components. These objects double the number of known brown dwarf companions with orbital periods longer than ten years and reinforce the conclusion that the occurrence of such objects increases with orbital separation. With a projected separation larger than 100 mas, all these brown dwarf candidates are appropriate targets for high-contrast and high angular resolution imaging.

Key words. techniques: radial velocities – binaries: spectroscopic – stars: low-mass – brown dwarfs – stars: general

1. Introduction

Brown dwarfs (BD) are substellar objects in the mass range of approximately 13–80 Jupiter masses; they have enough mass to burn deuterium, but are too light to permit hydrogen burning in their inner cores (Burrows et al. 1997; Chabrier & Baraffe 2000; Spiegel et al. 2011). BDs constitute intermediate objects between giant planets and low-mass stars, but there is not a complete consensus about their formation mechanisms. The separation between planet and brown dwarf population may not only be related to the mass, but also to the formation scenario. Core–accretion models predict the formation of objects as heavy as 25 M_Jup (Mordasini et al. 2009). BD companions orbiting solar-type stars with periods of up to about ten years clearly occur less frequently (≤1%) than planetary systems and stellar binaries

* Based on observations made with ELODIE and SOPHIE spectrographs on the 1.93-m telescope at Observatoire de Haute-Provence (CNRS/AMU), France.

long-term surveys. These objects are important targets for direct imaging and astrometry with the aim to calibrate the mass–luminosity relation of substellar objects. Since the end of 2006, the SOPHIE consortium conducts a large program to search for exoplanets (Boisse et al. 2009). One of the different subprograms focuses on following-up the drifts and long-period signals detected within the ELODIE historical program initiated on the 1.93 m telescope at the Observatoire de Haute-Provence (OHP) by M. Mayor and D. Queloz in 1994. This program has monitored about 400 solar-type stars (from F5 to K0 dwarfs) in 12 yr and led to the detection of 24 exoplanets (e.g., Mayor & Queloz 1995; Perrier et al. 2003; Naef et al. 2004). In the past years, this program was focused on monitoring RV drifts that were identified as incomplete orbits of gravitationally bound companions. Since 2007, we have continued this program with the SOPHIE spectrograph with the objective to characterize orbital parameters of exoplanets similar to Jupiter and Saturn in our solar system and brown dwarfs with orbital periods longer than 8 to 10 yr. About 50 targets with a slow RV drift were selected from the original ELODIE sample and are followed-up with SOPHIE. This unique sample allows extending the time base to more than 20 yr to find substellar companions beyond 5 AU. As part of this subprogram, we reported the detection of two Jupiter-analogs around HD 150706 and HD 222155, we refined the parameters of the long-period planets HD 154345b and HD 89307b, and we determined the first reliable orbit for HD 24040b (Boisse et al. 2012).

In this paper, we report the detection of five new brown dwarf candidates with minimum masses of between 32 and 78 M_Jup orbiting solar-type stars with periods longer than 10 yr. We attempt to derive an upper limit on the true mass of these companions to determine their nature using astrometric HIPPARCOS data, high-angular resolution imaging made with PUEO for two of our targets, and deep analysis of the cross-correlation function (CCF) of our spectra to search for a blend effect or a faint secondary component. Such a CCF analysis was performed on HD 16702 and allowed identifying the secondary component. Such a CCF analysis was performed on HD 16702 and allowed identifying the secondary component. Such a CCF analysis was performed on HD 16702 and allowed identifying the secondary component.

2. Spectroscopic observations

The targets reported in this paper and their basic stellar characteristics are listed in Table 1. The parallaxes are derived from the HIPPARCOS reduction (van Leeuwen 2007). The stellar rotation parameter v sin i is derived from the calibration of the SOPHIE cross-correlation function by Boisse et al. (2010) with an uncertainty of ~1 km s⁻¹. The time span of the observations and the numbers of the ELODIE and SOPHIE measurements are listed in Table 1.

Spectroscopic observations of our targets were first conducted with the ELODIE spectrograph (Baranne et al. 1996) mounted on the 1.93 m telescope at OHP between late 1993 and mid-2006. The stars were then monitored by the SOPHIE spectrograph (Perruchot et al. 2008) from early 2007 to late 2014. The spectrograph configuration, the observing mode, and the data reduction were the same as those described in Boisse et al. (2012).

One of the main SOPHIE systematic effects was caused by the insufficient scrambling of the fiber link and the high sensitivity of the spectrograph to illumination variation. Seeing change at the fiber input introduced radial velocity changes. This so-called seeing effect on SOPHIE has been described by Boisse et al. (2010, 2011), Díaz et al. (2012), and Bouchy et al. (2013). Considering that variations in the pupil illumination produce a differential RV effect along spectral orders, the difference between RVs measured in each half of the spectral orders can be used to partially correct the main RV. We systematically applied the correction of the seeing effect by computing the RV difference between the left part (or blue side) and right part (or red side) of the spectral orders and using the average correlation coefficient of ~1.04 estimated on standard stars (Bouchy et al. 2013). We added quadratically a systematic RV error of 6 m s⁻¹ on the SOPHIE measurements corresponding to the average RV RMS measured on these stars.

In June 2011 (BJD = 2455730), a piece of octagonal-section fiber was implemented in the SOPHIE fiber link and significantly improved the radial velocity precision by eliminating the seeing effect, see Bouchy et al. (2013). We checked on standard stars that the RV offset introduced by the instrumental upgrade is smaller than the systematic errors of SOPHIE. Since this change and despite a clear improvement in RV precision on times scales of a few tens of days, some intervention within the instrument and strong variations of the outside temperature propagated to the tripod of the spectrograph introduced zero-point offsets. The systematic drift was corrected using a set of RV constant star and following the approach described by Courcol et al. (2015).

3. Data analysis

3.1. Stellar characteristics

Spectra obtained without simultaneous thorium-argon calibration and with signal-to-noise ratios in the range of 150–200 were used to accurately derive the stellar effective temperature T_eff, surface gravity log g, and metallicity [Fe/H]. The spectroscopic analysis method is described in Santos et al. (2004) and Sousa et al. (2008). In brief, the procedure is based on the equivalent widths of the FeI and FeII lines and the iron excitation and ionization equilibrium, which is assumed to be in local thermodynamic equilibrium. Using the derived spectroscopic parameters as input, stellar masses M_* were derived from the calibration of Torres et al. (2010) with a correction following Santos et al. (2013). Errors were computed from 10 000 random values of the stellar parameters within their error bars and assuming a
Gaussian distribution. Ages were estimated using the method described by da Silva et al. (2006) using PARSEC stellar tracks and isochrones from Bressan et al. (2012). The stellar activity level was estimated from the emission in the core of the Ca II H and K-bands measured on each SOPHIE spectra with the calibration described in Boisse et al. (2010). The average values derived from this analysis are reported in Table 2 with an estimated uncertainty of 0.05.

### 3.2. Radial velocity analysis and orbital solutions

ELODIE and SOPHIE radial velocities were fit using the Bayesian genetic software Yorbit, which is briefly described in Ségransan et al. (2011). The main advantage of a genetic algorithm compared to other advanced methods such as a Markov chain Monte Carlo method (hereafter MCMC) with parallel tempering is that it allows probing the full model parameter space in an extremely efficient way. The first step of the radial velocity data analysis consists of identifying significant periodic signals in the data. This is done using the General Lomb-Scargle periodogram algorithm (Zechmeister & Kürster 2009), which is applied to the radial velocity measurements. False-alarm probabilities are estimated through a bootstrap approach by permuting the data. When a significant peak is located at a given period, the corresponding Keplerian is adjusted. For multiple Keplerians, the adjusted component is removed, the process is repeated several times until no significant peak remains, and all parameters are readjusted at each step of the analysis. However, the population at the end of the evolution is not statistically reliable owing to the quite large uncertainty of the RV offset relation (23 m s$^{-1}$ rms), we decided to let this parameter free to vary for the Keplerian fit. For all the candidates we also tested a model including a long-term drift in addition to the Keplerian, but no significant drift was found, or it was strongly correlated to the ELODIE-SOPHIE offset. No significant additional signals were found on the RV residuals for the five targets. The orbital solutions are listed in Table 4, and each candidate is discussed in Sect. 4.

### 3.3. Diagnostic for resolving the nature of the companions

The RV analysis provides a minimum mass for the companion within the range of brown dwarf masses. We used other diagnostics to attempt to derive an upper limit on the mass. More specifically, we used HIPPARCOS astrometry, high angular resolution imaging, and bisector span and CCF diagnostics.

#### 3.3.1. HIPPARCOS astrometry

For the five BD candidates, we used the new HIPPARCOS reduction (van Leeuwen 2007) to search for signatures of orbital motion in the Intermediate Astrometric Data (IAD). The analysis was performed as described in Sahlmann et al. (2011) using the orbital elements given by the RV analysis and reported in Table 4. The basic parameters of the HIPPARCOS observations relevant for the astrometric analysis are listed in Table 3.

#### 3.3.2. Bisector span analysis

Following the approach described by Díaz et al. (2012), we examined the bisector span of the SOPHIE CCF of our BD candidates to check whether significant variation and a correlation with RV measurements can reveal a relatively luminous

companion polluting the peak of the primary star. The detection of a correlation indicates that the velocity signal is the result – at least in part – of a deformation of the stellar CCF. For the five targets the bisector span varies only negligibly and does not exhibit any significant correlation with radial velocity measurements; this excludes massive $M$ dwarfs. The correlation slopes were systematically smaller than 8 $m\,s^{-1}$ per km s$^{-1}$ within the uncertainties. However, such a non-detection does not definitively exclude low-mass stellar companions. Simulations indicate that only massive $M$ dwarfs heavier than 0.5 $M_\odot$ can be firmly excluded.

### 3.3.3. Search for a second component in the CCF

If the companion is relatively bright, we expect that it is blended within the main spectrum and then pollutes the CCF of the primary star. To search for a secondary peak in our SOPHIE CCFs, we proceeded in the following way: first we built the CCFs using an $M$ mask to maximize the contribution of a suspected low-mass star companion. Then we shifted all the CCFs to the systemic velocity $V_0$ and averaged them, after normalization of the minimum and maximum of the CCF, to build a master CCF. We then subtracted this master CCF from all the individual CCFs shifted to the systemic velocity. The velocity of the second component $V_c$ is expected to be at $-V_1/q$ with respect to the systemic velocity $V_0$, with $V_1$ the velocity of the main component and $q$ the mass ratio $M_C/M_\star$. Considering that all individual CCFs are shifted to the systemic velocity, this second component is expected to be at $(V_0 - V_1) \times (1 + 1/q)$. To increase the detection capability, we combined all the CCF residuals after shifting them to this last quantity with $q$ varying from 0.1 to 0.6. For each value of $q$ we computed the dispersion of the average of CCF residuals and searched for a significant peak centered at the systemic velocity.

We tested our approach on HD 16702, which was first identified by Díaz et al. (2012) to have a companion with a minimum mass of 48.7 $M_{\text{Jup}}$. These authors showed that HIPPARCOS astrometric analysis and CCF simulations lead to a companion mass of 0.55 $\pm 0.14$ $M_\odot$ and 0.40 $\pm 0.05$ $M_\odot$, respectively. In the average CCF residuals, shown in Fig. 1, we find a deepest secondary peak of 1.3 $\pm$ 0.1% when a shift of $(3.5 \pm 0.4)\times(V_0 - V_1)$ is imposed, hence for a mass ratio $q = 0.4 \pm 0.06$. The uncertainty on the shift applied to have the deepest second peak was estimated considering the noise level within the continuum (0.1%) and determining the shift limit, which produced a peak depth of 1.2%.

Given a primary mass of 0.98 $M_\odot$, the companion is then an M2-type star of 0.39 $\pm$ 0.06 $M_\odot$ in agreement with Diaz et al. (2012). This value also agrees with the identification of a second component in the spectra by Kolbl et al. (2015) with an estimated $T_{\text{eff}}$ of 3500 $\pm$ 250 K and contributing to 1.06% of the total flux. More recently, Santerne et al. (2015) performed blend models with PASTIS (Díaz et al. 2014) and derived a companion mass of 0.35 $\pm$ 0.03 $M_\odot$.

We estimated that for HD 16702 the detection limit is close to 0.3%. However, this approach requires several observations well spread across the orbit, and the systemic velocity should be known to correctly stack and average the CCFs. Furthermore, the effectiveness of the approach strongly depends on the orbital parameters, the number of measurements, and the phase coverage.

We applied this search for a second component on our candidates, but without any significant detection. To estimate the effectiveness of the approach and derive an upper limit, we injected an artificial second component into the CCFs that corresponds to a companion with a velocity at $V_c + (Vc - V_1)/q$, a CCF contrast from 0.2 to 2% of the primary, and the same CCF.

### Table 4. Median and 1-$\sigma$ limit of posterior parameters derived from our MCMC analysis.

| Parameters | HD 10844 | HD 14348 | HD 18757 | HD 72946 | HD 209262 |

**Fig. 1.** Averaged CCF residuals of HD 16702 for different radial velocity shifts. The deepest peak (red curve) occurs for a shift corresponding to a mass ratio of 0.4.
FWHM as the primary. We note that a larger CCF FWHM of
the secondary, although not expected for low-mass stars of sev-
eral billion years, reduces the detection sensitivity. The detection
limit obtained a range from 0.5% up to 2% for the worst cases
like HD 10844 and HD 209262, for which the SOPHIE velocities
only cover one side with respect to the systemic velocity. In this
case the second component is not well averaged and not enough
diluted when computing the master CCF. It was therefore par-
tially removed in all the individual CCFs when we subtracted
the master CCF. Assuming that the CCF contrast ratio could be
used as a rough estimate of the flux ratio between primary and
secondary, we derive an upper mass limit using the evolution-
ary models for the main sequence of low-mass stars by Baraffe et al.
(2015) taking into account the mass and age of the primary. The
derived upper limits are in the range of 0.18–0.4 \( M_\odot \) and are re-
ported in Table 4. The lowest upper limit of 0.18 \( M_\odot \) is found for
HD 18757.

3.3.4. High-resolution imaging with PUEO
HD 14348 and HD 18757 were observed as filter targets during a
program dedicated to mass measurements for \( M \) dwarfs at the 3.6 m
Canada-France-Hawaii Telescope (CFHT) using PUEO, the
CFHT Adaptive Optics Bonnette (Rigaut et al. 1998), and the
KIR infrared camera (Doyon et al. 1998). The observing
procedure is described by Delfosse et al. (1999). High angular
resolution imaging for these two stars was analyzed to derive a
detection limit for the companion. The flux detection limit was
converted into an upper mass limit considering the age of the
primary and using the models NEXTGEN for low-mass stars
(Baraffe et al. 1998) and DUSTY for brown dwarfs (Allard et al.
2001). The RV orbital parameters and the mass of the primary
were used to compute the sky-projected orbital separation of the
companion relative to the host star at the date of PUEO observa-
tions assuming different orbital inclinations.

Figure 2 shows the mass detection limit as function of the
angular separation for HD 18757. The green line represents the
projected separation varying the orbital inclination. Companions
along the green line and above black line (NEXTGEN) or red
line (DUSTY) are excluded. This gives an upper limit of 0.13 \( M_\odot \)
for HD 18757b, which is lower than the upper limit derived from
the CCF analysis.

For HD 14348, the upper limit is 0.6 \( M_\odot \), which is well above
the upper limit derived from the CCF analysis because the angu-
lar separation is close to 0.1 arcsec, just below the diffraction
limit of the CFHT in \( K \)-band (0.12 arcsec).

4. Long-period brown dwarf companions

4.1. HD 10844
HD 10844 is a \( V = 8.13 \) mag F8V star with a mass \( M_* \) of
0.98 \( M_\odot \) located at 52.3 parsec from the Sun. The Keplerian
fit to the RV measurements, listed in Table 5, indicates a
companion of minimum mass \( M_c \sin i = 83.4 \, M_{\text{Jup}} \) on a 30-yr
orbit, with an eccentricity \( e = 0.57 \). With such a minimum mass,
HD 10844b is fairly likely to be stellar, since the incli-
nation only needs to be slightly less than edge-on. Although the
measurement time-span covers less than half of the orbital pe-
riod of HD 10844, the Keplerian fit is quite well constrained
because the orbit is eccentric and has a large semi-amplitude.
The instrumental offset between ELODIE and SOPHIE is ad-
justed to \(-98^{+304}_{-70} \, \text{m} \, \text{s}^{-1} \) in agreement with the expected one at
\(-66 \pm 23 \, \text{m} \, \text{s}^{-1} \). Using the expected instrumental offset as prior
does not significantly change the result, but it reduces the uncer-
tainties with \( P = 32.3^{+0.5}_{-0.2} \) yr and \( K = 885^{+12}_{-13} \, \text{m} \, \text{s}^{-1} \). Systematic
errors of 17.8 \( \text{m} \, \text{s}^{-1} \) and 1.2 \( \text{m} \, \text{s}^{-1} \) were quadratically added to
ELODIE and SOPHIE, respectively, to obtain the reduced
\( \chi^2 = 1 \).

4.2. HD 14348
HD 14348 is a F5V star with \( V = 7.2 \) mag located at 56.6 parsec
from the Sun, with a mass of 1.2 \( M_\odot \). The RV measurements
listed in Table 6 show a peak-to-peak variation of 1150 \( \text{m} \, \text{s}^{-1} \)
that reveal the presence of an \( M_c \sin i = 48.9 \, M_{\text{Jup}} \) com-
panion on a 13-yr orbit, with an eccentricity of 0.45. The
instrumental offset between ELODIE and SOPHIE is adjusted
to \(-57 \pm 3.7 \, \text{m} \, \text{s}^{-1} \), which agrees with the expected offset at
\(-53 \pm 23 \, \text{m} \, \text{s}^{-1} \). Systematic errors of 14.8 \( \text{m} \, \text{s}^{-1} \) and 5.3 \( \text{m} \, \text{s}^{-1} \)
were quadratically added to ELODIE and SOPHIE, respectively.

Fig. 2. Mass detection limit as function of angular separation for
HD 18757 observed with PUEO. The black and red curves cor-
respond to NEXTGEN and DUSTY models, respectively. The green line repre-
sents the projected separation varying the orbital inclination and shows
that no companion with a mass higher than 0.13 \( M_\odot \) was detected.

Fig. 3. Radial velocity curve of HD 10844 obtained with
ELODIE (blue) and SOPHIE (red).
4.3. HD 18757

HD 18757 is a bright V = 6.64 mag G4V star with low metallicity located at only 24.2 parsec from the Sun. HD 18757 is part of a multiple system with an M-dwarf component of V = 12.5 located at 12.7 arcsec (307 AU; Dommanget & Nys 2002) and a physically associated common proper motion companion with a separation of 262 arcsec (6340 AU) and a spectral type of M2V (Raghavan et al. 2010). The RV measurements listed in Table 7 are fitted by a 109-yr Keplerian orbit with a semi-amplitude \( K = 666 \) m s\(^{-1}\) and a high eccentricity \( e = 0.94 \). The spectral analysis together with the comparison with evolutionary models yields a stellar mass of \( M_\star = 0.88 M_\odot \) and a companion minimum mass of 35.2 \( M_{\text{Jup}} \). Although a small fraction (17%) of the orbital period is covered, the Keplerian fit is sufficiently well constrained because the orbit is highly eccentric and the RV extrema are covered. The instrumental offset between ELODIE and SOPHIE is adjusted to \( -120^{+9.5}_{-8.0} \) m s\(^{-1}\), which is marginally higher than the expected offset at \( -66 \pm 23 \) m s\(^{-1}\). Systematic errors of 1.4 m s\(^{-1}\) and 2.7 m s\(^{-1}\) were quadratically added to ELODIE and SOPHIE, respectively. The large distance of the companion and the vicinity of the target allows placing a quite strong constraint on the mass upper limit derived from PUEO observations with \( M_c \leq 0.13 M_\odot \).

4.4. HD 72946

HD 72946 is a V = 7.25 mag G5 star with a mass of 0.96 \( M_\odot \) located at 26.2 parsec from the Sun. HD 72946 (GJ310.1B) has a physically associated common proper motion companion HD 72945 (GJ310.1A) located at 10 arcsec (230 AU). This companion is a spectroscopic binary with a period of 14.3 days including an F8V primary of \( m_v = 5.99 \) (Duquennoy & Mayor 1991). We checked that this bright component located at 10 arcsec cannot introduce contaminating light within the 3-arcsec fiber acceptance of SOPHIE. Even with a seeing as high as 6 arcsec, the contamination remains lower than 0.3% and therefore is negligible. HD 72946 is also part of a multiple stellar system with a V = 10.7 star at 93 arcsec and a V = 12 star at 117 arcsec (Dommanget & Nys 2002). The Keplerian fit to the RV measurements listed in Table 8 indicates a companion of minimum mass \( M_c \sin i = 0.4 M_{\text{Jup}} \) in a 16-yr orbit, with an eccentricity \( e = 0.495 \). The instrumental offset between ELODIE and SOPHIE is adjusted to \( -113 \pm 14 \) m s\(^{-1}\), which fully agrees with the expected offset of \( -100 \pm 23 \) m s\(^{-1}\). Systematic errors of 22 m s\(^{-1}\) and 15 m s\(^{-1}\) were quadratically added to ELODIE and SOPHIE, respectively, which may be due to the fact that the star is slightly active (\( \log R'_{\text{HK}} = -4.74 \)). Although a non-significant drift was found from fixing the instrument offset, we note that the F8V companion at 230 AU may introduce a radial velocity change on HD 72946 of up to few m s\(^{-1}\) per year.

4.5. HD 209262

HD 209262 is a V = 8.0 G-type star located at 49.7 parsec from the Sun. HD 209262 is part of a double system (Dommanget & Nys 2002) with a component BD+044788B (V = 9.8) at 78.3 arcsec and possibly a third component (V = 12.4) at 22.4 arcsec. The RV measurements listed in Table 9 are fitted by a 15-yr Keplerian orbit with a semi-amplitude of 385 m s\(^{-1}\) and an eccentricity \( e = 0.35 \). The spectral analysis combined with the comparison with evolutionary models yields a stellar mass of \( M_\star = 1.02 M_\odot \) and a companion minimum mass of 32.3 \( M_{\text{Jup}} \). The instrumental offset between ELODIE and SOPHIE is adjusted to \( -165 \pm 24 \) m s\(^{-1}\), which is marginally
higher than the expected offset at \(-91 \pm 23 \, \text{m s}^{-1}\). Systematic errors of 1.43 \, \text{m s}^{-1} and 3.3 \, \text{m s}^{-1} were quadratically added to ELODIE and SOPHIE, respectively.

5. Discussion and conclusion

We have reported the detection of five new potential brown dwarf companions with minimum masses of between 32 and 83 \(M_{\text{Jup}}\) orbiting solar-type stars with periods longer than ten years. These detection were made thanks to ELODIE and SOPHIE radial velocity measurements that cover a time span of up to 16 yr. Our different diagnostics allowed excluding companions heavier than 0.4 \(M_{\odot}\) and for HD 18757 heavier than 0.13 \(M_{\odot}\). These candidates double the number of known BD companions with orbital periods longer than ten years, which include HD 4747, HD 74014, HD 211847, and HD 167665 (Sahlmann et al. 2011). These BDs have orbital periods longer than ten years, which include HD 4747, HD 74014, HD 211847, and HD 167665 (Sahlmann et al. 2011). This increasing number of long-period BD companions reinforces the observation that the number of BDs increases with orbital period, as pointed out by Ma & Ge (2014). All our BD candidates have an eccentricity higher than 0.45 except for the lightest one, HD 209262b, with 0.35. Three of our five targets are part of a multiple stellar system. All our targets, with a projected separation larger than 100 mas, and especially HD 18757 with 917 mas, will be good targets for high-contrast and high angular resolution imaging, interferometry, or speckle observations. Such targets are important to constrain the mass–luminosity relation of brown dwarfs for different ages and metallicities. Microarcsecond astrometry with the Gaia satellite (Mignard 2011) will permit deriving constraints on the orbital inclination and the true mass of these companions.

Acknowledgements. We gratefully acknowledge the Programme National de Planétologie (telescope time attribution and financial support) of CNRS/INSU, the Swiss National Science Foundation, and the Agence Nationale de la Recherche (grant ANR-08-JCC-0102-01) for their support. We warmly thank the OHP staff for their support on the 1.93 m telescope. J.S. is supported by an ESA Research Fellowship in Space Science. Fig. 7. Radial velocity curve of HD 209262.
Appendix A: HD 29461

HD 29461 is a $V = 7.96$ mag G5-type star located at 46.5 parsec from our Sun. It was first identified as a spectroscopic binary in the Hyades field by Griffin et al. (1988) with a period of about ten years. Mason et al. (1993) and Patience et al. (1998) failed to resolve the system by speckle interferometry, indicating that the companion is very faint with a mass upper limit of $0.22 M_\odot$. Patel et al. (2007) gave a preliminary orbit for HD 29461 from Keck observations that did not cover a complete cycle. The period they selected was 18 yr. More recently, Griffin (2012) published the orbital elements derived from 78 radial velocity measurements spanning 38 yr, from 1972 to 2009. The Keplerian fit yields a period $P = 3760 \pm 8$ days, a semi-amplitude $K = 1.36 \pm 0.04$ km s$^{-1}$, and an eccentricity $e = 0.594 \pm 0.019$.

For this target we obtained 20 ELODIE and 20 SOPHIE measurements in a time span of 13 yr. Our measurements, displayed in Fig. A.1, confirm and agree with the orbital parameters derived by Griffin (2012), except for our semi-amplitude ($K = 1.483 \pm 0.015$ km s$^{-1}$), which is $3\sigma$ higher. The instrumental offset between ELODIE and SOPHIE is fitted to $-167 \pm 16$ m s$^{-1}$, which is marginally higher than the expected offset at $-78 \pm 23$ m s$^{-1}$. This slightly higher offset can explain the larger semi-amplitude found. Systematic errors of 15 m s$^{-1}$ and 8 m s$^{-1}$ were quadratically added to ELODIE and SOPHIE, respectively. The star is slightly active with $\log R'_{\text{HK}} = -4.73$, which may explain the RV jitter observed in SOPHIE measurements. We derive a period $P = 3776 \pm 12$ days and an eccentric $e = 0.613 \pm 0.004$. The spectral analysis and the comparison with evolutionary models yields a stellar mass of $M_\star = 1.06 \pm 0.07 M_\odot$ and a companion minimum mass of $93.4 M_{\text{Jup}}$, which firmly excludes a brown-dwarf companion.

Appendix B: HD 175225

HD 175225 is a $V = 5.5$ mag G9 subgiant located at 26.1 parsec from our Sun. Turner et al. (2001) made a direct detection of a companion at 1.1 arcsec (28.7 AU) using the adaptive optics system at Mount Wilson Observatory. They estimated from the $V - I$ color that the companion corresponds to an M2 dwarf. Considering the separation, the orbital period is expected to be about 150 yr. For this target we obtained 38 CORAVEL, 38 ELODIE, and 16 SOPHIE measurements in a time span of 31.7 yr. Radial velocities, displayed in Fig. B.1, show a long-term trend with curvature. The Keplerian fit is no constraint, but indicates an orbital period longer than 45 yr and a companion heavier than 0.2 $M_\odot$, which is fully compatible with the direct imaging.
